The Ultimate High-ROI LeetCode Patterns Guide

Part 1: 41 patterns · 632 problems
Part 2: 50 extra topics · 210 more problems for practice
one problem per page · statements, examples, figures, Python solutions and follow-ups

Pattern list and problem order: Automedon / ultimate-leetcode-patterns (github.com/Automedon/ultimate-leetcode-patterns).
Problem statements, figures and solutions: doocs / leetcode (github.com/doocs/leetcode), CC BY-SA 4.0.
LeetCode is a trademark of LeetCode LLC; problems link back to leetcode.com.

How to use this guide

41 patterns, 20 problems each, all free — no Premium garbage. Sorted top to bottom by how often each pattern actually shows up in interviews. Hash Map and Sliding Window first because they're everywhere. Segment Tree and Fenwick Tree last because almost nobody asks them. Inside each pattern: Easy to Hard, so you're not getting wrecked by a Hard problem before you've even nailed the basic version of the trick.*

How to actually use this:

Don't grind all 820. That's a waste of your time and most of this list won't come up. Drill the first 10-15 patterns until you don't have to think — you see the problem, your hands already know the code. Everything below that is bonus coverage for if your interviewer likes to go off-script. Speed matters more than breadth here: 45 minutes isn't a lot of time, and if you're still figuring out syntax halfway through, you're not getting to the part where you actually look good.

Hard truths about the process:

Most loops are decided on the first problem.

Speed and clean code beat a late correct answer.

Follow-ups exist to catch memorized solutions.

You're graded against other candidates that week, not a fixed bar.

HOW THIS PDF IS ORGANISED

- Every pattern is a chapter. It opens with a one-page note (when to use it, how to spot it, a small reusable template) and the list of its 20 problems.
- Every problem starts on its own page: the full statement with examples, figures and constraints, then every solution as Python 3 with the reasoning and the complexity.
- Inside a pattern the problems go from Easy to Hard. Some problems belong to more than one pattern. Each problem is printed once, in the first pattern that lists it (its header says where else it appears); the other chapter lists it too, with a link to that page.
- A ★ marks the top 10 of every Part 1 chapter: seven Medium or Hard problems that cover the chapter's variations, plus up to three core Easy ones (a chapter with fewer than three Easy problems gets more Medium or Hard ones instead). If you can solve the starred problems cold, the other problems of the chapter are routine. Every Part 2 topic has at most 10 problems, so all of them are starred. Do the starred problems first, then the rest.
- Click anything in the contents, or use Prev / Contents / Next at the bottom of every page. The PDF outline (bookmarks panel) lists all patterns and problems.
- Solutions: the doocs/leetcode Python 3 solutions. Premium problems are included, with their statements and solutions.
- Part 1 is the 41 patterns. Part 2 is extra topics and more practice: the problems of AlgoMaster's 600 list that Part 1 does not have, in AlgoMaster's own groups (each group page also lists the group's problems that are already in Part 1).

Contents

PART 1

The 41 Patterns

The high-ROI patterns, with every problem worked in full

- 41 pattern chapters, 632 different problems (each printed once, in the first pattern that lists it; a problem that belongs to two patterns is a link in the second chapter).
- Each chapter starts with a one-page note: when to use the pattern, how to spot it, and a small template to keep in your hands.
- Every problem has its own page: full statement, examples and figures, the Python 3 solutions with the reasoning, and the follow-up code an interviewer may ask next.
- Problems go from Easy to Hard inside a chapter. Use Prev / Contents / Next at the bottom of every page.
- Want more practice after these? Part 2 covers the extra topics and the problems that are not in these 41 chapters.

PATTERN 1 OF 41

Hash Map / Hash Set

20 problems · 8 Easy · 10 Medium · 2 Hard

THE IDEA

You need to know whether you have seen something before, how many times, or where. Trade memory for time: one pass that stores what you saw turns an O(n^2) search into O(n).

Signals: pairs that add up to a target, duplicates, frequency counts, grouping by a key, first unique item, prefix totals stored in a dictionary.

A TEMPLATE TO KEEP IN YOUR HANDS (PYTHON)

```
seen = {}                       # value -> index (or count)
for i, x in enumerate(nums):
    need = target - x           # what would complete the answer?
    if need in seen:
        return [seen[need], i]
    seen[x] = i
```

PATTERN 1 · HASH MAP / HASH SET · PROBLEM 1 OF 20

1. Two Sum

Easy · Array, Hash Table

leetcode.com/problems/two-sum

★ **TOP 10 PROBLEM** in Hash Map / Hash Set: master this one first

PROBLEM

You are given an array of integers `nums` and an integer `target`, return *indices of the two numbers such that they add up to* `target`.

You may assume that each input would have ***exactly* one solution**, and you may not use the *same* element twice.

You can return the answer in any order.

Example 1:

```
Input: nums = [2,7,11,15], target = 9
Output: [0,1]
Explanation: Because nums[0] + nums[1] == 9, we return [0, 1].
```

Example 2:

```
Input: nums = [3,2,4], target = 6
Output: [1,2]
```

Example 3:

```
Input: nums = [3,3], target = 6
Output: [0,1]
```

Constraints:

- `2 <= nums.length <= 10^4`
- `-10^9 <= nums[i] <= 10^9`
- `-10^9 <= target <= 10^9`
- **Only one valid answer exists.**

Follow-up:

Can you come up with an algorithm that is less than

$O(n^2)$

time complexity?

SOLUTION (PYTHON 3)

Solution 1: Hash Table

How to think about it

The first idea is a nested loop: pick x, then scan for target-x. Correct, but $O(n^2)$. $n \le 10^4$ might pass, yet the follow-up asks for faster. The bottleneck is repeatedly searching for the complement among numbers already seen. A hash table makes that lookup expected O(1). Walk once, storing value → index: when we see x, ask whether target-x already appeared; if yes, return the two indices; if not, store x. Look up before inserting. Insert-then-lookup would reuse the same index on [3,3], target=6. Lookup-first guarantees the match is an earlier index.

We can use a hash table d to store each element and its corresponding index.

Traverse the array nums, for the current element nums[i], we first check if target - nums[i] is in the hash table d. If it is in d, it means the target value has been found, and we return the indices of target - nums[i] and i.

Time complexity is O(n), and space complexity is O(n), where n is the length of the array nums.

Python 3

```python
class Solution:
    def twoSum(self, nums: List[int], target: int) -> List[int]:
        d = {}
        for i, x in enumerate(nums):
            if (y := target - x) in d:
                return [d[y], i]
            d[x] = i
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

Built on the solutions above: helper functions, then the function for each follow-up. No tests and no restating of the question.

```python
# FOLLOW-UPS (answered below, in this order):
# 1. The array is already sorted
# 2. Return every pair of values that adds up to the
# target, without repeats
# 3. Numbers arrive one at a time and you must answer 'is
# there a pair that adds up to V?'

# ============================================================
# FOLLOW-UP 1: The array is already sorted
# ============================================================

# ---- follow-up 1: function ----
# Answer: Two pointers, one at each end, in O(n) time and
# O(1) space: a sum that is too small moves the left
# pointer up, a sum that is too big moves the right
# pointer down.
# Time: O(n).  Space: O(1).
def two_sum_sorted(numbers, target):
    left, right = 0, len(numbers) - 1
    while left < right:
        total = numbers[left] + numbers[right]
        if total == target:
            return [left, right]
        if total < target:
            left += 1
        else:
            right -= 1
    return []

# ============================================================
# FOLLOW-UP 2: Return every pair of values that adds up to
# the target, without repeats
# ============================================================

# ---- follow-up 2: function ----
# Answer: Count each value, then for every value x look
# for target - x. Take a pair only once (x < y), and a
# pair of equal values only when that value appears twice.
# Time: O(n).  Space: O(n).
def all_pairs(nums, target):
    count = {}
    for x in nums:
        count[x] = count.get(x, 0) + 1
    pairs = []
    for x in count:
        y = target - x
        if y in count and x < y:
            pairs.append((x, y))
        elif x == y and count[x] >= 2:
            pairs.append((x, x))
    return pairs
```

```
# ============================================================
# FOLLOW-UP 3: Numbers arrive one at a time and you must
# answer 'is there a pair that adds up to V?'
# ============================================================
```

```
# ---- follow-up 3: function ----
# Answer: Keep a dictionary of how many times each number
# was added. add() is O(1); find() looks at each stored
# number once, O(n).
# Time: add O(1), find O(n).  Space: O(n).
class TwoSumStream:
    def __init__(self):
        self.count = {}

    def add(self, number):
        self.count[number] = self.count.get(number, 0) + 1

    def find(self, value):
        for x in self.count:
            y = value - x
            if y != x and y in self.count:
                return True
            if y == x and self.count[x] > 1:
                return True
        return False
```

PATTERN 1 · HASH MAP / HASH SET · PROBLEM 2 OF 20

217. Contains Duplicate

Easy · Array, Hash Table, Sorting

leetcode.com/problems/contains-duplicate

★ **TOP 10 PROBLEM** in Hash Map / Hash Set: master this one first

PROBLEM

Given an integer array `nums`, return `true` if any value appears **at least twice** in the array, and return `false` if every element is distinct.

Example 1:

Input: nums = [1,2,3,1]

Output: true

Explanation:

The element 1 occurs at the indices 0 and 3.

Example 2:

Input: nums = [1,2,3,4]

Output: false

Explanation:

All elements are distinct.

Example 3:

Input: nums = [1,1,1,3,3,4,3,2,4,2]

Output: true

Constraints:

- `1 <= nums.length <= 10^5`
- `-10^9 <= nums[i] <= 10^9`

SOLUTIONS (PYTHON 3)

Solution 1: Sorting

How to think about it

Comparing every pair works but is slow for large n. Equal values become adjacent after sorting. Sort the array, then check whether any two neighbors are equal.

First, we sort the array `nums`.

Then, we traverse the array. If there are two adjacent elements that are the same, it means that there are duplicate elements in the array, and we directly return `true`.

Otherwise, when the traversal ends, we return `false`.

The time complexity is O(n × log n), where n is the length of the array `nums`.

Python 3

```
class Solution:
    def containsDuplicate(self, nums: List[int]) -> bool:
        return any(a == b for a, b in pairwise(sorted(nums)))
```

Solution 2: Hash Table

> **How to think about it**
>
> Sorting is O(nlog n) and reorders the array. Membership alone can be tracked with a hash set in one pass. A value that is already in the set is a duplicate.

We traverse the array and record the elements that have appeared in the hash table s. If an element appears for the second time, it means that there are duplicate elements in the array, and we directly return `true`.

The time complexity is O(n), and the space complexity is O(n), where n is the length of the array `nums`.

Python 3

```
class Solution:
    def containsDuplicate(self, nums: List[int]) -> bool:
        return len(set(nums)) < len(nums)
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

Built on the solutions above: helper functions, then the function for each follow-up. No tests and no restating of the question.

```
# FOLLOW-UPS (answered below, in this order):
# 1. The two equal numbers must be at most k positions
# apart
# 2. The numbers only have to be close (difference at most
# t) and at most k positions apart
# 3. Use O(1) extra space

# ============================================================
# FOLLOW-UP 1: The two equal numbers must be at most k
# positions apart
# ============================================================

# ---- follow-up 1: function ----
# Answer: Remember the last index of every value; a repeat
# only counts when the distance to its last index is at
# most k.
# Time: O(n).  Space: O(n).
def contains_nearby_duplicate(nums, k):
    last_seen = {}
    for i in range(len(nums)):
        x = nums[i]
        if x in last_seen and i - last_seen[x] <= k:
            return True
        last_seen[x] = i
    return False

# ============================================================
# FOLLOW-UP 2: The numbers only have to be close
# (difference at most t) and at most k positions apart
# ============================================================

# ---- follow-up 2: function ----
# Answer: Put every number into a bucket of width t + 1:
# two numbers in the same bucket are always close enough,
# and only the two neighbouring buckets can hold another
# close number. Keep only the last k numbers in the
# buckets.
# Time: O(n).  Space: O(min(n, k)).
def contains_nearby_almost_duplicate(nums, index_diff, value_diff):
    width = value_diff + 1
    buckets = {}                    # bucket number -> the one number in it
    for i in range(len(nums)):
        x = nums[i]
        b = x // width
        if b in buckets:
```

```
            return True
        if b - 1 in buckets and x - buckets[b - 1] <= value_diff:
            return True
        if b + 1 in buckets and buckets[b + 1] - x <= value_diff:
            return True
        buckets[b] = x
        if i >= index_diff:          # the oldest number leaves the window
            del buckets[nums[i - index_diff] // width]
    return False

# ============================================================
# FOLLOW-UP 3: Use O(1) extra space
```

```
# ============================================================

# ---- follow-up 3: function ----
# Answer: Sort the array in place; equal numbers become
# neighbours. O(n log n) time, and the input order is
# lost.
# Time: O(n log n).  Space: O(1) extra.
def contains_duplicate_no_extra_space(nums):
    nums.sort()
    for i in range(1, len(nums)):
        if nums[i] == nums[i - 1]:
            return True
    return False
```

PATTERN 1 · HASH MAP / HASH SET · PROBLEM 3 OF 20

242. Valid Anagram

Easy · Hash Table, String, Sorting

leetcode.com/problems/valid-anagram

★ **TOP 10 PROBLEM** in Hash Map / Hash Set, String Matching / Pattern Search: master this one first

Also appears in pattern 7 String Matching / Pattern Search

PROBLEM

Given two strings `s` and `t`, return `true` if `t` is an anagram of `s`, and `false` otherwise.

Example 1:

Input: s = "anagram", t = "nagaram"

Output: true

Example 2:

Input: s = "rat", t = "car"

Output: false

Constraints:

- `1 <= s.length, t.length <= 5 * 10^4`
- `s` and `t` consist of lowercase English letters.

Follow up: What if the inputs contain Unicode characters? How would you adapt your solution to such a case?

SOLUTIONS (PYTHON 3)

Solution 1: Counting

How to think about it

Anagrams have identical character counts. Unequal lengths fail immediately. Count s, then decrement while scanning t; a negative count means they differ.

We first determine whether the length of the two strings is equal. If they are not equal, the characters in the two strings must be different, so return `false`.

Otherwise, we use a hash table or an array of length 26 to record the number of times each character appears in the string s, and then traverse the other string t. Each time we traverse a character, we subtract the number of times the corresponding character appears in the hash table by one. If the number of times after subtraction is less than 0, the number of times the character appears in the two strings is different, return `false`. If after traversing the two strings, all the character counts in the hash table are 0, it means that the characters in the two strings appear the same number of times, return `true`.

The time complexity is O(n), the space complexity is O(C), where n is the length of the string; and C is the size of the character set, which is C=26 in this problem.

Python 3

```python
class Solution:
    def isAnagram(self, s: str, t: str) -> bool:
        if len(s) != len(t):
            return False
        cnt = Counter(s)
        for c in t:
            cnt[c] -= 1
            if cnt[c] < 0:
                return False
        return True
```

Solution 2

How to think about it

The first method maintains the table by hand. Comparing two counters is shorter and has the same complexity.

Python 3

```
class Solution:
    def isAnagram(self, s: str, t: str) -> bool:
        return Counter(s) == Counter(t)
```

Complexity. Time: O(n). Space: O(C), C = 26 letters.

205. Isomorphic Strings

Easy · Hash Table, String

leetcode.com/problems/isomorphic-strings

PROBLEM

Given two strings `s` and `t`, *determine if they are isomorphic*.

Two strings `s` and `t` are isomorphic if the characters in `s` can be replaced to get `t`.

All occurrences of a character must be replaced with another character while preserving the order of characters. No two characters may map to the same character, but a character may map to itself.

Example 1:

Input: s = "egg", t = "add"

Output: true

Explanation:

The strings `s` and `t` can be made identical by:

- Mapping `'e'` to `'a'`.
- Mapping `'g'` to `'d'`.

Example 2:

Input: s = "f11", t = "b23"

Output: false

Explanation:

The strings `s` and `t` can not be made identical as `'1'` needs to be mapped to both `'2'` and `'3'`.

Example 3:

Input: s = "paper", t = "title"

Output: true

Constraints:

- `1 <= s.length <= 5 * 10^4`
- `t.length == s.length`
- `s` and `t` consist of any valid ascii character.

SOLUTIONS (PYTHON 3)

Solution 1: Hash Table or Array

> **How to think about it**
>
> Isomorphism needs a bijection between characters of s and t; a one-way map misses many-to-one collisions. The strings have equal length and a finite alphabet, so one pass suffices. We keep d_1 and d_2 for s→ t and t→ s. A conflict with an existing mapping fails; otherwise we update and continue.

We can use two hash tables or arrays d_1 and d_2 to record the character mapping relationship between s and t.

Traverse s and t, if the corresponding character mapping relationships in d_1 and d_2 are different, return `false`, otherwise update the corresponding character mapping relationships in d_1 and d_2. After the traversal is complete, it means that s and t are isomorphic, and return `true`.

The time complexity is O(n) and the space complexity is O(C). Where n is the length of the string s; and C is the size of the character set, which is C = 256 in this problem.

Python 3

```python
class Solution:
    def isIsomorphic(self, s: str, t: str) -> bool:
        d1 = {}
        d2 = {}
        for a, b in zip(s, t):
            if (a in d1 and d1[a] != b) or (b in d2 and d2[b] != a):
                return False
            d1[a] = b
            d2[b] = a
        return True
```

Solution 2

> **How to think about it**
>
> Two hash maps are correct but pay hashing overhead. The alphabet has size 256, so arrays suffice. Store the last index of each character as a shared timestamp: if the recorded indices differ, the mapping is inconsistent.

Python 3

```python
class Solution:
    def isIsomorphic(self, s: str, t: str) -> bool:
        d1, d2 = [0] * 256, [0] * 256
        for i, (a, b) in enumerate(zip(s, t), 1):
            a, b = ord(a), ord(b)
            if d1[a] != d2[b]:
                return False
            d1[a] = d2[b] = i
        return True
```

Complexity. Time: O(n). Space: O(C), C = 256 characters.

PATTERN 1 · HASH MAP / HASH SET · PROBLEM 5 OF 20

290. Word Pattern

Easy · Hash Table, String

leetcode.com/problems/word-pattern

PROBLEM

Given a `pattern` and a string `s`, find if `s` follows the same pattern.

Here **follow** means a full match, such that there is a bijection between a letter in `pattern` and a **non-empty** word in `s`. Specifically:

- Each letter in `pattern` maps to **exactly** one unique word in `s`.
- Each unique word in `s` maps to **exactly** one letter in `pattern`.
- No two letters map to the same word, and no two words map to the same letter.

Example 1:

Input: pattern = "abba", s = "dog cat cat dog"

Output: true

Explanation:

The bijection can be established as:

- `'a'` maps to `"dog"`.
- `'b'` maps to `"cat"`.

Example 2:

Input: pattern = "abba", s = "dog cat cat fish"

Output: false

Example 3:

Input: pattern = "aaaa", s = "dog cat cat dog"

Output: false

Constraints:

- `1 <= pattern.length <= 300`
- `pattern` contains only lower-case English letters.
- `1 <= s.length <= 3000`
- `s` contains only lowercase English letters and spaces `' '`.
- `s` **does not contain** any leading or trailing spaces.
- All the words in `s` are separated by a **single space**.

SOLUTIONS (PYTHON 3)

Solution 1: Hash Table

> **How to think about it**
>
> The pattern and the words must be bijections; unequal lengths fail. As with isomorphic strings, two maps record char-to-word and word-to-char. A conflict with an existing mapping fails.

First, we split the string s into a word array ws with spaces. If the length of pattern and ws is not equal, return `false` directly. Otherwise, we use two hash tables d_1 and d_2 to record the correspondence between each character and word in pattern and ws.

Then, we traverse pattern and ws. For each character a and word b, if there is a mapping for a in d_1, and the mapped word is not b, or there is a mapping for b in d_2, and the mapped character is not a, return `false`. Otherwise, we add the mapping of a and b to d_1 and d_2 respectively.

After the traversal, return `true`.

The time complexity is O(m + n) and the space complexity is O(m + n). Here m and n are the length of pattern and string s.

Python 3

```
class Solution:
    def wordPattern(self, pattern: str, s: str) -> bool:
        ws = s.split()
        if len(pattern) != len(ws):
            return False
        d1 = {}
        d2 = {}
        for a, b in zip(pattern, ws):
            if (a in d1 and d1[a] != b) or (b in d2 and d2[b] != a):
                return False
            d1[a] = b
            d2[b] = a
        return True
```

Solution 2

> **How to think about it**
>
> The two maps can be replaced by checking that the number of distinct pattern characters equals the number of distinct words, then keeping a one-way map.

Python 3 (written for this guide: the doocs page has no Python 3 version of this solution)

```
class Solution:
    def wordPattern(self, pattern: str, s: str) -> bool:
        words = s.split()
        if len(pattern) != len(words) or len(set(pattern)) != len(set(words)):
            return False
        table = {}
        for letter, word in zip(pattern, words):
            if table.setdefault(letter, word) != word:
                return False
        return True
```

Complexity. Time: O(n). Space: O(n).

        return False

    return go(0, 0)
```

PATTERN 1 · HASH MAP / HASH SET · PROBLEM 6 OF 20

383. Ransom Note

Easy · Hash Table, String, Counting

leetcode.com/problems/ransom-note

PROBLEM

Given two strings `ransomNote` and `magazine`, return `true` *if* `ransomNote` *can be constructed by using the letters from* `magazine` *and* `false` *otherwise*.

Each letter in `magazine` can only be used once in `ransomNote`.

Example 1:

```
Input: ransomNote = "a", magazine = "b"
Output: false
```

Example 2:

```
Input: ransomNote = "aa", magazine = "ab"
Output: false
```

Example 3:

```
Input: ransomNote = "aa", magazine = "aab"
Output: true
```

Constraints:

- `1 <= ransomNote.length, magazine.length <= 10^5`
- `ransomNote` and `magazine` consist of lowercase English letters.

SOLUTION (PYTHON 3)

Solution 1: Hash Table or Array

> **How to think about it**
>
> Can `ransomNote` be formed from `magazine` letters? A multiset inclusion. Count magazine frequencies, then decrement along the note; a negative count means shortage. The alphabet has size 26.

We can use a hash table or an array cnt of length 26 to record the number of times each character appears in the string `magazine`. Then traverse the string `ransomNote`, for each character c in it, we decrease the number of c by 1 in cnt. If the number of c is less than 0 after the decrease, it means that the number of c in `magazine` is not enough, so it cannot be composed of `ransomNote`, just return false.

Otherwise, after the traversal, it means that each character in `ransomNote` can be found in `magazine`. Therefore, return true.

The time complexity is O(m + n), and the space complexity is O(C). Where m and n are the lengths of the strings `ransomNote` and `magazine` respectively; and C is the size of the character set, which is 26 in this question.

Python 3

```python
class Solution:
    def canConstruct(self, ransomNote: str, magazine: str) -> bool:
        cnt = Counter(magazine)
        for c in ransomNote:
            cnt[c] -= 1
            if cnt[c] < 0:
                return False
        return True
```

    return fewest
```

PATTERN 1 · HASH MAP / HASH SET · PROBLEM 7 OF 20

409. Longest Palindrome

Easy · Greedy, Hash Table, String

leetcode.com/problems/longest-palindrome

PROBLEM

Given a string `s` which consists of lowercase or uppercase letters, return the length of the **longest palindrome** that can be built with those letters.

Letters are **case sensitive**, for example, `"Aa"` is not considered a palindrome.

Example 1:

```
Input: s = "abccccdd"
Output: 7
Explanation: One longest palindrome that can be built is "dccaccd", whose length is 7.
```

Example 2:

```
Input: s = "a"
Output: 1
Explanation: The longest palindrome that can be built is "a", whose length is 1.
```

Constraints:

- `1 <= s.length <= 2000`
- `s` consists of lowercase **and/or** uppercase English letters only.

SOLUTIONS (PYTHON 3)

Solution 1: Counting

How to think about it

A palindrome allows at most one odd-count character; the rest must pair. We do not need to try permutations, only how many pairs each character can give. After counting, add v//2× 2 for every frequency v. If the total is still shorter than |s|, one leftover character can sit in the center. Taking pairs first, then the optional center, yields a maximum feasible length.

A valid palindrome string can have at most one character that appears an odd number of times, and the rest of the characters appear an even number of times.

Therefore, we can first traverse the string s, count the number of occurrences of each character, and record it in an array or hash table cnt.

Then, we traverse cnt, for each count v, we divide v by 2, take the integer part, multiply by 2, and add it to the answer ans.

Finally, if the answer is less than the length of the string s, we increment the answer by one and return ans.

The time complexity is O(n + |Σ|), and the space complexity is O(|Σ|). Where n is the length of the string s, and |Σ| is the size of the character set. In this problem, |Σ| = 128.

Python 3

```python
class Solution:
    def longestPalindrome(self, s: str) -> int:
        cnt = Counter(s)
        ans = sum(v // 2 * 2 for v in cnt.values())
        ans += int(ans < len(s))
        return ans
```

Solution 2: Bit Manipulation + Counting

> **How to think about it**
>
> Solution 1 counts, then sums. XORing a parity flag while scanning and tracking the number of odd characters cnt gives n-cnt+1 (keep one center) or n. The second pass over the frequency table disappears; space is still the alphabet size.

We can use an array or hash table odd to record whether each character in string s appears an odd number of times, and an integer variable cnt to record the number of characters that appear an odd number of times.

We iterate through the string s. For each character c, we flip odd[c], i.e., 0 → 1, 1 → 0. If odd[c] changes from 0 to 1, then we increment cnt by one; if odd[c] changes from 1 to 0, then we decrement cnt by one.

Finally, if cnt is greater than 0, the answer is n - cnt + 1, otherwise, the answer is n.

The time complexity is O(n), and the space complexity is O(|Σ|). Where n is the length of the string s, and |Σ| is the size of the character set. In this problem, |Σ| = 128.

Python 3

```python
class Solution:
    def longestPalindrome(self, s: str) -> int:
        odd = defaultdict(int)
        cnt = 0
        for c in s:
            odd[c] ^= 1
            cnt += 1 if odd[c] else -1
        return len(s) - cnt + 1 if cnt else len(s)
```

1128. Number of Equivalent Domino Pairs

Easy · Array, Hash Table, Counting

leetcode.com/problems/number-of-equivalent-domino-pairs

PROBLEM

Given a list of `dominoes`, `dominoes[i] = [a, b]` is **equivalent to** `dominoes[j] = [c, d]` if and only if either (`a == c` and `b == d`), or (`a == d` and `b == c`) - that is, one domino can be rotated to be equal to another domino.

Return *the number of pairs* `(i, j)` *for which* `0 <= i < j < dominoes.length`, *and* `dominoes[i]` ***is equivalent to*** `dominoes[j]`.

Example 1:

```
Input: dominoes = [[1,2],[2,1],[3,4],[5,6]]
Output: 1
```

Example 2:

```
Input: dominoes = [[1,2],[1,2],[1,1],[1,2],[2,2]]
Output: 3
```

Constraints:

- `1 <= dominoes.length <= 4 * 10^4`
- `dominoes[i].length == 2`
- `1 <= dominoes[i][j] <= 9`

SOLUTION (PYTHON 3)

Solution 1: Counting

> **How to think about it**
>
> Pairs treat [a,b] and [b,a] as the same. Scanning all earlier tiles for each new one is quadratic. Pack min(a,b) in the tens digit and max(a,b) in the ones, a key in 0..99. Add the current count of that key to the answer, then increment, so each tile pairs only with equivalents already seen.

We can concatenate the two numbers of each domino in order of size to form a two-digit number, so that equivalent dominoes can be concatenated into the same two-digit number. For example, both `[1, 2]` and `[2, 1]` are concatenated into the two-digit number `12`, and both `[3, 4]` and `[4, 3]` are concatenated into the two-digit number `34`.

Then we traverse all the dominoes, using an array cnt of length 100 to record the number of occurrences of each two-digit number. For each domino, the two-digit number we concatenate is x, then the answer will increase by cnt[x], and then we add 1 to the value of cnt[x]. Continue to traverse the next domino, and we can count the number of all equivalent domino pairs.

The time complexity is O(n), and the space complexity is O(C). Here, n is the number of dominoes, and C is the maximum number of two-digit numbers concatenated in the dominoes, which is 100.

Python 3

```python
class Solution:
    def numEquivDominoPairs(self, dominoes: List[List[int]]) -> int:
        cnt = Counter()
        ans = 0
        for a, b in dominoes:
            x = a * 10 + b if a < b else b * 10 + a
            ans += cnt[x]
            cnt[x] += 1
        return ans
```

PATTERN 1 · HASH MAP / HASH SET · PROBLEM 9 OF 20

49. Group Anagrams

Medium · Array, Hash Table, String, Sorting

leetcode.com/problems/group-anagrams

★ **TOP 10 PROBLEM** in Hash Map / Hash Set: master this one first

Also appears in pattern 6 String Manipulation / Parsing

PROBLEM

Given an array of strings `strs`, group the anagrams together. You can return the answer in **any order**.

Example 1:

Input: strs = ["eat","tea","tan","ate","nat","bat"]

Output: [["bat"],["nat","tan"],["ate","eat","tea"]]

Explanation:

- There is no string in strs that can be rearranged to form `"bat"`.
- The strings `"nat"` and `"tan"` are anagrams as they can be rearranged to form each other.
- The strings `"ate"`, `"eat"`, and `"tea"` are anagrams as they can be rearranged to form each other.

Example 2:

Input: strs = [""]

Output: [[""]]

Example 3:

Input: strs = ["a"]

Output: [["a"]]

Constraints:

- `1 <= strs.length <= 10^4`
- `0 <= strs[i].length <= 100`
- `strs[i]` consists of lowercase English letters.

SOLUTIONS (PYTHON 3)

Solution 1: Hash Table

How to think about it

The first idea is pairwise anagram checks: sort each string and compare. Correct, but n ≤ 10^4 and k ≤ 100 make O(n^2 · k log k) too slow. Pairwise comparison is the bottleneck. Anagrams share one sorted form — that string is the group id. Use the sorted string as key and a list of originals as value. One pass into a hash table clusters them; no pairwise matching.

1. Traverse the string array, sort each string in **character dictionary order** to get a new string.
2. Use the new string as `key` and `[str]` as `value`, and store them in the hash table (`HashMap<String, List<String>>`).
3. When encountering the same `key` during subsequent traversal, add it to the corresponding `value`.

Take `strs = ["eat", "tea", "tan", "ate", "nat", "bat"]` as an example. At the end of the traversal, the state of the hash table is:

key	value
`"aet"`	`["eat", "tea", "ate"]`

key	value
"ant"	["tan", "nat"]
"abt"	["bat"]

Finally, return the `value` list of the hash table.

The time complexity is O(n× k× log k), where n and k are the lengths of the string array and the maximum length of the string, respectively.

Python 3

```
class Solution:
    def groupAnagrams(self, strs: List[str]) -> List[List[str]]:
        d = defaultdict(list)
        for s in strs:
            k = ''.join(sorted(s))
            d[k].append(s)
        return list(d.values())
```

Solution 2: Counting

> **How to think about it**
>
> Solution 1 sorts every string, O(k log k) each. The alphabet is 26 lowercase letters; with k ≤ 100 the log k factor is waste. What it lacks is a cheaper key. Count each letter and use the length-26 tuple as the key. Same hash grouping, linear per string.

We can also change the sorting part in Solution 1 to counting, that is, use the characters in each string s and their occurrence times as `key`, and use the string s as `value` to store in the hash table.

The time complexity is O(n× (k + C)), where n and k are the lengths of the string array and the maximum length of the string, respectively, and C is the size of the character set. In this problem, C = 26.

Python 3

```
class Solution:
    def groupAnagrams(self, strs: List[str]) -> List[List[str]]:
        d = defaultdict(list)
        for s in strs:
            cnt = [0] * 26
            for c in s:
                cnt[ord(c) - ord('a')] += 1
            d[tuple(cnt)].append(s)
        return list(d.values())
```

```

PATTERN 1 · HASH MAP / HASH SET · PROBLEM 10 OF 20

347. Top K Frequent Elements

Medium · Array, Hash Table, Divide and Conquer, Bucket Sort, Counting, Quickselect, Sorting, Heap (Priority Queue)

leetcode.com/problems/top-k-frequent-elements

★ **TOP 10 PROBLEM** in Hash Map / Hash Set, Heap / Priority Queue: master this one first

Also appears in pattern 19 Heap / Priority Queue, 38 K-way Merge

PROBLEM

Given an integer array `nums` and an integer `k`, return *the* `k` *most frequent elements*. You may return the answer in **any order**.

Example 1:

Input: nums = [1,1,1,2,2,3], k = 2

Output: [1,2]

Example 2:

Input: nums = [1], k = 1

Output: [1]

Example 3:

Input: nums = [1,2,1,2,1,2,3,1,3,2], k = 2

Output: [1,2]

Constraints:

- `1 <= nums.length <= 10^5`
- `-10^4 <= nums[i] <= 10^4`
- `k` is in the range `[1, the number of unique elements in the array]`.
- It is **guaranteed** that the answer is **unique**.

Follow up: Your algorithm's time complexity must be better than `O(n log n)`, where n is the array's size.

SOLUTION (PYTHON 3)

Solution 1: Hash Table + Priority Queue (Min Heap)

How to think about it

The k most frequent values. Full sort is O(nlog n). Only the top k frequencies matter. Count, then select the k largest frequencies. `Counter.most_common(k)` is a heap selection in O(nlog k).

We can use a hash table cnt to count the occurrence of each element, and then use a min heap (priority queue) to store the top k frequent elements.

First, we traverse the array once to count the occurrence of each element. Then, we iterate through the hash table, storing each element and its count into the min heap. If the size of the min heap exceeds k, we pop the top element of the heap to ensure the heap size is always k.

Finally, we pop the elements from the min heap one by one and place them into the result array.

The time complexity is O(n log k), and the space complexity is O(k). Here, n is the length of the array.

Python 3

```
class Solution:
    def topKFrequent(self, nums: List[int], k: int) -> List[int]:
        cnt = Counter(nums)
        return [x for x, _ in cnt.most_common(k)]
```

```

128. Longest Consecutive Sequence

Medium · Union Find, Array, Hash Table

leetcode.com/problems/longest-consecutive-sequence

★ **TOP 10 PROBLEM** in Hash Map / Hash Set, Union-Find (Disjoint Set): master this one first

Also appears in pattern 31 Union-Find (Disjoint Set)

PROBLEM

Given an unsorted array of integers `nums`, return *the length of the longest consecutive elements sequence.*

You must write an algorithm that runs in `O(n)` time.

Example 1:

```
Input: nums = [100,4,200,1,3,2]
Output: 4
Explanation: The longest consecutive elements sequence is [1, 2, 3, 4]. Therefore its length is 4.
```

Example 2:

```
Input: nums = [0,3,7,2,5,8,4,6,0,1]
Output: 9
```

Example 3:

```
Input: nums = [1,0,1,2]
Output: 3
```

Constraints:

- `0 <= nums.length <= 10^5`
- `-10^9 <= nums[i] <= 10^9`

SOLUTIONS (PYTHON 3)

Solution 1: Hash Table

How to think about it

Sorting and scanning runs is O(nlog n); the problem asks for O(n). n ≤ 10^5. Put the values in a hash set. From each x still in the set, walk right until the run breaks, store that length at the start, and let earlier starts concatenate. Each number enters and leaves the set once.

We can use a hash table s to store all the elements in the array, a variable ans to record the length of the longest consecutive sequence, and a hash table d to record the length of the consecutive sequence each element x belongs to.

Next, we iterate through each element x in the array, using a temporary variable y to record the maximum value of the current consecutive sequence, initially y = x. Then, we continuously try to match y+1, y+2, y+3, … until we can no longer match. During this process, we remove the matched elements from the hash table s. The length of the consecutive sequence that the current element x belongs to is d[x] = d[y] + y - x, and then we update the answer ans = max(ans, d[x]).

After the iteration, we return the answer ans.

The time complexity is O(n), and the space complexity is O(n). Here, n is the length of the array nums.

Python 3

```python
class Solution:
    def longestConsecutive(self, nums: List[int]) -> int:
        s = set(nums)
        ans = 0
        d = defaultdict(int)
        for x in nums:
            y = x
            while y in s:
                s.remove(y)
                y += 1
            d[x] = d[y] + y - x
            ans = max(ans, d[x])
        return ans
```

Solution 2: Hash Table (Optimization)

> **How to think about it**
>
> Solution 1 stores each run's length so later starts can concatenate. If we only grow a run when x-1 is absent, x is already a start, so the extra map d is unnecessary. The code is shorter and still touches each number a constant number of times.

Similar to Solution 1, we use a hash table s to store all the elements in the array and a variable ans to record the length of the longest consecutive sequence. However, we no longer use a hash table d to record the length of the consecutive sequence each element x belongs to. During the iteration, we skip elements where x-1 is also in the hash table s. If x-1 is in the hash table s, then x is definitely not the start of a consecutive sequence, so we can directly skip x.

The time complexity is O(n), and the space complexity is O(n). Here, n is the length of the array nums.

Python 3

```python
class Solution:
    def longestConsecutive(self, nums: List[int]) -> int:
        s = set(nums)

560. Subarray Sum Equals K

Medium · Array, Hash Table, Prefix Sum

leetcode.com/problems/subarray-sum-equals-k

★ **TOP 10 PROBLEM** in Hash Map / Hash Set, Prefix Sum: master this one first

Also appears in pattern 5 Prefix Sum

PROBLEM

Given an array of integers `nums` and an integer `k`, return *the total number of subarrays whose sum equals to* `k`.

A subarray is a contiguous **non-empty** sequence of elements within an array.

Example 1:

```
Input: nums = [1,1,1], k = 2
Output: 2
```

Example 2:

```
Input: nums = [1,2,3], k = 3
Output: 2
```

Constraints:

- `1 <= nums.length <= 2 * 10^4`
- `-1000 <= nums[i] <= 1000`
- `-10^7 <= k <= 10^7`

SOLUTION (PYTHON 3)

Solution 1: Hash Table + Prefix Sum

How to think about it

Count subarrays whose sum is k. Pairwise endpoints are $O(n^2)$, tight for $n \le 2 \times 10^4$. A prefix s needs earlier prefixes equal to s-k. A hash map stores prefix frequencies, seeded with cnt[0]=1 for the empty prefix. Query first, then insert, so the current index is not reused.

We define a hash table `cnt` to store the number of times the prefix sum of the array `nums` appears. Initially, we set the value of `cnt[0]` to `1`, indicating that the prefix sum `0` appears once.

We traverse the array `nums`, calculate the prefix sum `s`, then add the value of `cnt[s - k]` to the answer, and increase the value of `cnt[s]` by `1`.

After the traversal, we return the answer.

The time complexity is `O(n)`, and the space complexity is `O(n)`. Where `n` is the length of the array `nums`.

Python 3

```python
class Solution:
    def subarraySum(self, nums: List[int], k: int) -> int:
        cnt = Counter({0: 1})
        ans = s = 0
        for x in nums:
            s += x
            ans += cnt[s - k]
            cnt[s] += 1
        return ans
```

        if total not in first_index:
            first_index[total] = i
    return None
```

PATTERN 1 · HASH MAP / HASH SET · PROBLEM 13 OF 20

287. Find the Duplicate Number

Medium · Bit Manipulation, Array, Two Pointers, Binary Search, Floyd Cycle Detection, Pigeonhole Principle

leetcode.com/problems/find-the-duplicate-number

★ **TOP 10 PROBLEM** in Fast & Slow Pointers (Linked List), Cyclic Sort: master this one first

Also appears in pattern 24 Fast & Slow Pointers (Linked List), 33 Cyclic Sort

PROBLEM

Given an array of integers `nums` containing `n + 1` integers where each integer is in the range `[1, n]` inclusive.

There is only **one repeated number** in `nums`, return *this repeated number*.

You must solve the problem **without** modifying the array `nums` and using only constant extra space.

Example 1:

```
Input: nums = [1,3,4,2,2]
Output: 2
```

Example 2:

```
Input: nums = [3,1,3,4,2]
Output: 3
```

Example 3:

```
Input: nums = [3,3,3,3,3]
Output: 3
```

Constraints:

- `1 <= n <= 10^5`
- `nums.length == n + 1`
- `1 <= nums[i] <= n`
- All the integers in `nums` appear only **once** except for **precisely one integer** which appears **two or more** times.

Follow up:

- How can we prove that at least one duplicate number must exist in `nums`?
- Can you solve the problem in linear runtime complexity?

SOLUTION (PYTHON 3)

Solution 1: Binary Search

How to think about it

We cannot mutate the array or use a hash table. By pigeonhole, if more than x values lie in [1,x], the duplicate is there. Binary-search the value range: count how many entries are ≤ mid; if that count exceeds mid, search the left half, otherwise the right.

We can observe that if the number of elements in [1,..x] is greater than x, then the duplicate number must be in [1,..x], otherwise the duplicate number must be in [x+1,..n].

Therefore, we can use binary search to find x, and check whether the number of elements in [1,..x] is greater than x at each iteration. This way, we can determine which interval the duplicate number is in, and narrow down the search range until we find the duplicate number.

The time complexity is O(n × log n), where n is the length of the array nums. The space complexity is O(1).

Python 3

```python
class Solution:
    def findDuplicate(self, nums: List[int]) -> int:
        def f(x: int) -> bool:
            return sum(v <= x for v in nums) > x

        return bisect_left(range(len(nums)), True, key=f)
```

        index = abs(x) - 1
        if nums[index] < 0:
            result.append(abs(x))
        else:
            nums[index] = -nums[index]
    return result
```

454. 4Sum II

Medium · Array, Hash Table

leetcode.com/problems/4sum-ii

★ **TOP 10 PROBLEM** in Hash Map / Hash Set: master this one first

PROBLEM

Given four integer arrays `nums1`, `nums2`, `nums3`, and `nums4` all of length `n`, return the number of tuples `(i, j, k, l)` such that:

- `0 <= i, j, k, l < n`
- `nums1[i] + nums2[j] + nums3[k] + nums4[l] == 0`

Example 1:

```
Input: nums1 = [1,2], nums2 = [-2,-1], nums3 = [-1,2], nums4 = [0,2]
Output: 2
Explanation:
The two tuples are:
1. (0, 0, 0, 1) -> nums1[0] + nums2[0] + nums3[0] + nums4[1] = 1 + (-2) + (-1) + 2 = 0
2. (1, 1, 0, 0) -> nums1[1] + nums2[1] + nums3[0] + nums4[0] = 2 + (-1) + (-1) + 0 = 0
```

Example 2:

```
Input: nums1 = [0], nums2 = [0], nums3 = [0], nums4 = [0]
Output: 1
```

Constraints:

- `n == nums1.length`
- `n == nums2.length`
- `n == nums3.length`
- `n == nums4.length`
- `1 <= n <= 200`
- -2^{28} `<= nums1[i], nums2[i], nums3[i], nums4[i] <=` 2^{28}

SOLUTION (PYTHON 3)

Solution 1: Hash Table

How to think about it

Four nested loops are $O(n^4)$ and $n \le 200$ is too large. A zero sum splits as $(a+b)+(c+d)=0$. Count every pair sum from nums1 and nums2, then enumerate c,d and add cnt[-(c+d)]. The $O(n^2)$ pair enumeration turns a 4-tuple search into a hash lookup.

We can add the elements a and b in arrays nums1 and nums2 respectively, and store all possible sums in a hash table cnt, where the key is the sum of the two numbers, and the value is the count of the sum.

Then we iterate through the elements c and d in arrays nums3 and nums4, let c+d be the target value, then the answer is the cumulative sum of cnt[-(c+d)].

The time complexity is $O(n^2)$, and the space complexity is $O(n^2)$, where n is the length of the array.

Python 3

```python
class Solution:
    def fourSumCount(
        self, nums1: List[int], nums2: List[int], nums3: List[int], nums4: List[int]
    ) -> int:
        cnt = Counter(a + b for a in nums1 for b in nums2)
        return sum(cnt[-(c + d)] for c in nums3 for d in nums4)
```

    return total
```

554. Brick Wall

Medium · Array, Hash Table

leetcode.com/problems/brick-wall

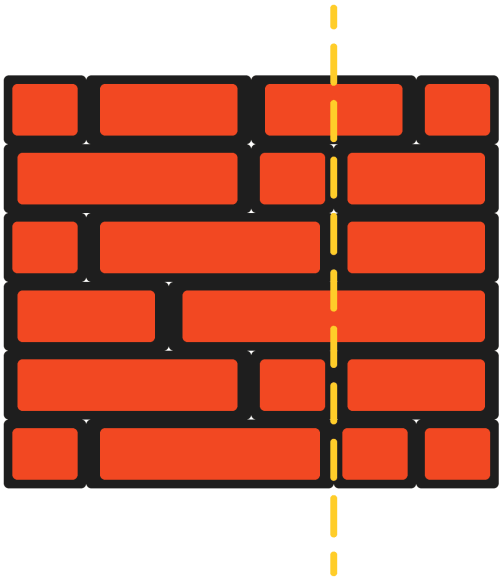
PROBLEM

There is a rectangular brick wall in front of you with `n` rows of bricks. The `i`th row has some number of bricks each of the same height (i.e., one unit) but they can be of different widths. The total width of each row is the same.

Draw a vertical line from the top to the bottom and cross the least bricks. If your line goes through the edge of a brick, then the brick is not considered as crossed. You cannot draw a line just along one of the two vertical edges of the wall, in which case the line will obviously cross no bricks.

Given the 2D array `wall` that contains the information about the wall, return *the minimum number of crossed bricks after drawing such a vertical line*.

Example 1:



```
Input: wall = [[1,2,2,1],[3,1,2],[1,3,2],[2,4],[3,1,2],[1,3,1,1]]
Output: 2
```

Example 2:

```
Input: wall = [[1],[1],[1]]
Output: 3
```

Constraints:

- `n == wall.length`
- `1 <= n <= 10`^{4}
- `1 <= wall[i].length <= 10`^{4}
- `1 <= sum(wall[i].length) <= 2 * 10`^{4}
- `sum(wall[i])` is the same for each row `i`.
- `1 <= wall[i][j] <= 2`^{31} `- 1`

SOLUTION (PYTHON 3)

Solution 1: Hash Table + Prefix Sum

How to think about it

A vertical line that never cuts a brick's interior crosses (rows - rows aligned on that gap) bricks. Recounting rows per gap repeats work. Prefix-sum each row except the last brick and count gap positions. The most frequent gap is crossed least often; the answer is rows minus that frequency. The wall's edges are excluded, or the line would cross zero bricks. A gap is a sum of widths up to 2^{31}-1, so it can exceed 2^{31}-1. Java and C++ keep that sum in a 64-bit integer; a 32-bit sum treats positions 2^{32} apart as one gap.

We can use a hash table cnt to record the prefix sum of each row except for the last brick. The key is the value of the prefix sum, and the value is the number of times the prefix sum appears.

Traverse each row, and for each brick in the current row, add it to the current prefix sum and update cnt.

Finally, we traverse cnt to find the prefix sum that appears the most times, which represents the situation where the least number of bricks are crossed. The final answer is the number of rows in the brick wall minus the number of bricks crossed.

The time complexity is O(m × n), and the space complexity is O(n). Here, m and n are the number of rows and the number of bricks in the brick wall, respectively.

Python 3

```python
class Solution:
    def leastBricks(self, wall: List[List[int]]) -> int:
        cnt = Counter()
        for row in wall:
            s = 0
            for x in row[:-1]:
                s += x
                cnt[s] += 1
        return len(wall) - max(cnt.values(), default=0)
```

1461. Check If a String Contains All Binary Codes of Size K

Medium · Bit Manipulation, Hash Table, String, Directed Acyclic Graph, Hash Function, Rolling Hash

leetcode.com/problems/check-if-a-string-contains-all-binary-codes-of-size-k

PROBLEM

Given a binary string `s` and an integer `k`, return `true` *if every binary code of length* `k` *is a substring of* `s`. Otherwise, return `false`.

Example 1:

```
Input: s = "00110110", k = 2
Output: true
Explanation: The binary codes of length 2 are "00", "01", "10" and "11". They can be all found as substrings at indices 0, 1, 3 and 2 respectively.
```

Example 2:

```
Input: s = "0110", k = 1
Output: true
Explanation: The binary codes of length 1 are "0" and "1", it is clear that both exist as a substring.
```

Example 3:

```
Input: s = "0110", k = 2
Output: false
Explanation: The binary code "00" is of length 2 and does not exist in the array.
```

Constraints:

- `1 <= s.length <= 5 * 10^5`
- `s[i]` is either `'0'` or `'1'`.
- `1 <= k <= 20`

SOLUTIONS (PYTHON 3)

Solution 1: Hash Table

> **How to think about it**
>
> There are 2^k binary strings of length k, and k≤ 20. If s has fewer than 2^k windows, fail; otherwise collect every length-k substring and test the set size.

First, for a string s of length n, the number of substrings of length k is n - k + 1. If n - k + 1 < 2^k, then there must exist a binary string of length k that is not a substring of s, so we return `false`.

Next, we traverse the string s and store all substrings of length k in a set ss. Finally, we check if the size of the set ss is equal to 2^k.

The time complexity is O(n × k), and the space complexity is O(n). Here, n is the length of the string s.

Python 3

```python
class Solution:
    def hasAllCodes(self, s: str, k: int) -> bool:
        n = len(s)
        m = 1 << k
        if n - k + 1 < m:
            return False
        ss = {s[i : i + k] for i in range(n - k + 1)}
        return len(ss) == m
```

Solution 2: Sliding Window

> **How to think about it**
>
> Method 1 copies k characters per window. Treat the window as an integer, shift in the new bit and drop the high bit, and insert in O(1).

In Solution 1, we stored all distinct substrings of length k, and processing each substring requires O(k) time. We can instead use a sliding window, where each time we add the latest character, we remove the leftmost character from the window. During this process, we use an integer x to store the substring.

The time complexity is O(n), and the space complexity is O(n). Here, n is the length of the string s.

Python 3

```python
class Solution:
    def hasAllCodes(self, s: str, k: int) -> bool:
        n = len(s)
        m = 1 << k
        if n - k + 1 < m:
            return False
        ss = set()
        x = int(s[:k], 2)
        ss.add(x)
        for i in range(k, n):
            a = int(s[i - k]) << (k - 1)
            b = int(s[i])
            x = (x - a) << 1 | b
            ss.add(x)
        return len(ss) == m
```

PATTERN 1 · HASH MAP / HASH SET · PROBLEM 17 OF 20

523. Continuous Subarray Sum

Medium · Array, Hash Table, Math, Prefix Sum, Pigeonhole Principle

leetcode.com/problems/continuous-subarray-sum

★ **TOP 10 PROBLEM** in Prefix Sum: master this one first

Also appears in pattern 5 Prefix Sum

PROBLEM

Given an integer array nums and an integer k, return `true` *if* `nums` *has a* ***good subarray*** *or* `false` *otherwise*.

A **good subarray** is a subarray where:

- its length is **at least two**, and
- the sum of the elements of the subarray is a multiple of `k`.

Note that:

- A **subarray** is a contiguous part of the array.
- An integer `x` is a multiple of `k` if there exists an integer `n` such that `x = n * k`. `0` is **always** a multiple of `k`.

Example 1:

```
Input: nums = [23,2,4,6,7], k = 6
Output: true
Explanation: [2, 4] is a continuous subarray of size 2 whose elements sum up to 6.
```

Example 2:

```
Input: nums = [23,2,6,4,7], k = 6
Output: true
Explanation: [23, 2, 6, 4, 7] is an continuous subarray of size 5 whose elements sum up to 42.
42 is a multiple of 6 because 42 = 7 * 6 and 7 is an integer.
```

Example 3:

```
Input: nums = [23,2,6,4,7], k = 13
Output: false
```

Constraints:

- `1 <= nums.length <= 10^5`
- `0 <= nums[i] <= 10^9`
- `0 <= sum(nums[i]) <= 2^31 - 1`
- `1 <= k <= 2^31 - 1`

SOLUTION (PYTHON 3)

Solution 1: Prefix Sum + Hash Table

How to think about it

We need a subarray of length at least 2 whose sum is a multiple of k. Checking all pairs is $O(n^2)$ and too slow for $n \le 10^5$. Equal prefix sums modulo k mean the interior sum is divisible by k. Store the first index of each remainder; a later repeat with gap greater than 1 is a hit. Remainder 0 is seeded at -1 so prefixes from the start are covered.

According to the problem description, if there exist two positions i and j (j < i) where the remainders of the prefix sums modulo k are the same, then the sum of the subarray nums[j+1..i] is a multiple of k.

Therefore, we can use a hash table to store the first occurrence of each remainder of the prefix sum modulo k. Initially, we store a key-value pair (0, -1) in the hash table, indicating that the remainder 0 of the prefix sum 0 appears at position -1.

As we iterate through the array, we calculate the current prefix sum's remainder modulo k. If the current prefix sum's remainder modulo k has not appeared in the hash table, we store the current prefix sum's remainder modulo k and its corresponding position in the hash table. Otherwise, if the current prefix sum's remainder modulo k has already appeared in the hash table at position j, then we have found a subarray nums[j+1..i] that meets the conditions, and thus return True.

After completing the iteration, if no subarray meeting the conditions is found, we return False.

The time complexity is O(n), and the space complexity is O(n), where n is the length of the array nums.

Python 3

```python
class Solution:
    def checkSubarraySum(self, nums: List[int], k: int) -> bool:
        d = {0: -1}
        s = 0
        for i, x in enumerate(nums):
            s = (s + x) % k
            if s not in d:
                d[s] = i
            elif i - d[s] > 1:
                return True
        return False
```

PATTERN 1 · HASH MAP / HASH SET · PROBLEM 18 OF 20

380. Insert Delete GetRandom O(1)

Medium · Design, Array, Hash Table, Math, Randomized

leetcode.com/problems/insert-delete-getrandom-o1

★ **TOP 10 PROBLEM** in Hash Map / Hash Set, Design Problems: master this one first

Also appears in pattern 29 Design Problems

PROBLEM

Implement the `RandomizedSet` class:

- `RandomizedSet()` Initializes the `RandomizedSet` object.
- `bool insert(int val)` Inserts an item `val` into the set if not present. Returns `true` if the item was not present, `false` otherwise.
- `bool remove(int val)` Removes an item `val` from the set if present. Returns `true` if the item was present, `false` otherwise.
- `int getRandom()` Returns a random element from the current set of elements (it's guaranteed that at least one element exists when this method is called). Each element must have the **same probability** of being returned.

You must implement the functions of the class such that each function works in **average** `O(1)` time complexity.

Example 1:

```
Input
["RandomizedSet", "insert", "remove", "insert", "getRandom", "remove", "insert", "getRandom"]
[[], [1], [2], [2], [], [1], [2], []]
Output
[null, true, false, true, 2, true, false, 2]

Explanation
RandomizedSet randomizedSet = new RandomizedSet();
randomizedSet.insert(1); // Inserts 1 to the set. Returns true as 1 was inserted successfully.
randomizedSet.remove(2); // Returns false as 2 does not exist in the set.
randomizedSet.insert(2); // Inserts 2 to the set, returns true. Set now contains [1,2].
randomizedSet.getRandom(); // getRandom() should return either 1 or 2 randomly.
randomizedSet.remove(1); // Removes 1 from the set, returns true. Set now contains [2].
randomizedSet.insert(2); // 2 was already in the set, so return false.
randomizedSet.getRandom(); // Since 2 is the only number in the set, getRandom() will always return 2.
```

Constraints:

- -2^{31} <= val <= 2^{31} - 1
- At most $2 * 10^5$ calls will be made to `insert`, `remove`, and `getRandom`.
- There will be **at least one** element in the data structure when `getRandom` is called.

SOLUTION (PYTHON 3)

Solution 1: Hash Table + Dynamic List

How to think about it

A set with insert, delete, and uniform random, all O(1). A hash map alone has no index; an array alone deletes in O(n). The array holds values, the map holds indices. Insert appends; delete swaps with the last element, pops, and repairs that index. Random is `choice` on the array.

We define a dynamic list q to store the elements in the set, and a hash table d to store the index of each element in q.

When inserting an element, if the element already exists in the hash table d, return `false` directly; otherwise, we insert the element into the end of the dynamic list q, and insert the element and its index in q into the hash table d at the same time,

and finally return `true`.

When deleting an element, if the element does not exist in the hash table d, return `false` directly; otherwise, we obtain the index of the element in the list q from the hash table, then swap the last element q[-1] in the list q with q[i], and then update the index of q[-1] in the hash table to i. Then delete the last element in q, and remove the element from the hash table at the same time, and finally return `true`.

When getting a random element, we can randomly select an element from the dynamic list q and return it.

Time complexity O(1), space complexity O(n), where n is the number of elements in the set.

Python 3

```
class RandomizedSet:
    def __init__(self):
        self.d = {}
        self.q = []

    def insert(self, val: int) -> bool:
        if val in self.d:
            return False
        self.d[val] = len(self.q)
        self.q.append(val)
        return True

    def remove(self, val: int) -> bool:
        if val not in self.d:
            return False
        i = self.d[val]
        self.d[self.q[-1]] = i
        self.q[i] = self.q[-1]
        self.q.pop()
        self.d.pop(val)
        return True

    def getRandom(self) -> int:
        return choice(self.q)

# Your RandomizedSet object will be instantiated and called as such:
# obj = RandomizedSet()
# param_1 = obj.insert(val)
# param_2 = obj.remove(val)
# param_3 = obj.getRandom()
```

PATTERN 1 · HASH MAP / HASH SET · PROBLEM 19 OF 20

992. Subarrays with K Different Integers

Hard · Array, Hash Table, Counting, Sliding Window

leetcode.com/problems/subarrays-with-k-different-integers

Also appears in pattern 2 Sliding Window

PROBLEM

Given an integer array `nums` and an integer `k`, return *the number of **good subarrays** of* `nums`.

A **good array** is an array where the number of different integers in that array is exactly `k`.

- For example, `[1,2,3,1,2]` has `3` different integers: `1`, `2`, and `3`.

A **subarray** is a **contiguous** part of an array.

Example 1:

```
Input: nums = [1,2,1,2,3], k = 2
Output: 7
Explanation: Subarrays formed with exactly 2 different integers: [1,2], [2,1], [1,2], [2,3], [1,2,1],
[2,1,2], [1,2,1,2]
```

Example 2:

```
Input: nums = [1,2,1,3,4], k = 3
Output: 3
Explanation: Subarrays formed with exactly 3 different integers: [1,2,1,3], [2,1,3], [1,3,4].
```

Constraints:

- `1 <= nums.length <= 2 * 10^4`
- `1 <= nums[i], k <= nums.length`

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Count subarrays with exactly k distinct values. n≤ 2× 10^4, so enumeration is too slow. The number of distinct values is monotone in the window, so “at most k” is a sliding window. Exactly k equals the leftmost index for “at most k” minus that for “at most k-1”, summed over every right end.

Python 3

```python
class Solution:
    def subarraysWithKDistinct(self, nums: List[int], k: int) -> int:
        def f(k):
            pos = [0] * len(nums)
            cnt = Counter()
            j = 0
            for i, x in enumerate(nums):
                cnt[x] += 1
                while len(cnt) > k:
                    cnt[nums[j]] -= 1
                    if cnt[nums[j]] == 0:
                        cnt.pop(nums[j])
                    j += 1
                pos[i] = j
            return pos

        return sum(a - b for a, b in zip(f(k - 1), f(k)))
```

Complexity. Time: O(n). Space: O(n).

PATTERN 1 · HASH MAP / HASH SET · PROBLEM 20 OF 20

41. First Missing Positive

Hard · Array, Hash Table

leetcode.com/problems/first-missing-positive

★ **TOP 10 PROBLEM** in Hash Map / Hash Set, Cyclic Sort: master this one first

Also appears in pattern 33 Cyclic Sort

PROBLEM

Given an unsorted integer array `nums`. Return the *smallest positive integer* that is *not present* in `nums`.

You must implement an algorithm that runs in `O(n)` time and uses `O(1)` auxiliary space.

Example 1:

```
Input: nums = [1,2,0]
Output: 3
Explanation: The numbers in the range [1,2] are all in the array.
```

Example 2:

```
Input: nums = [3,4,-1,1]
Output: 2
Explanation: 1 is in the array but 2 is missing.
```

Example 3:

```
Input: nums = [7,8,9,11,12]
Output: 1
Explanation: The smallest positive integer 1 is missing.
```

Constraints:

- `1 <= nums.length <= 10^5`
- `-2^31 <= nums[i] <= 2^31 - 1`

SOLUTION (PYTHON 3)

Solution 1: In-place Swap

How to think about it

The first idea is a hash set of seen numbers, then probe 1, 2, 3, …. Correct and O(n) time, but O(n) extra space. The problem asks for O(n) time and constant extra space; $n \le 10^5$ makes the set fail the space bound. The bottleneck is recording whether 1..n appear with extra memory. The missing positive must lie in [1, n+1], so we only care about 1..n — the array indices themselves can be that table. Swap value x to index x-1 when $x \in [1, n]$. In-place swap turns the array into a hash; one more scan finds the first hole.

We assume the length of the array nums is n, then the smallest positive integer must be in the range [1, .., n + 1]. We can traverse the array and swap each number x to its correct position, that is, the position x - 1. If x is not in the range [1, n + 1], then we can ignore it.

After the traversal, we traverse the array again. If i+1 is not equal to nums[i], then i+1 is the smallest positive integer we are looking for.

The time complexity is O(n), where n is the length of the array. The space complexity is O(1).

Python 3

```python
class Solution:
    def firstMissingPositive(self, nums: List[int]) -> int:
        n = len(nums)
        for i in range(n):
            while 1 <= nums[i] <= n and nums[i] != nums[nums[i] - 1]:
                j = nums[i] - 1
                nums[i], nums[j] = nums[j], nums[i]
        for i in range(n):
            if nums[i] != i + 1:
                return i + 1
        return n + 1
```

PATTERN 2 · SLIDING WINDOW · PROBLEM 1 OF 20

121. Best Time to Buy and Sell Stock

Easy · Array, Dynamic Programming

leetcode.com/problems/best-time-to-buy-and-sell-stock

★ **TOP 10 PROBLEM** in Sliding Window: master this one first

PROBLEM

You are given an array `prices` where `prices[i]` is the price of a given stock on the i^{th} day.

You want to maximize your profit by choosing a **single day** to buy one stock and choosing a **different day in the future** to sell that stock.

Return *the maximum profit you can achieve from this transaction*. If you cannot achieve any profit, return `0`.

Example 1:

```
Input: prices = [7,1,5,3,6,4]
Output: 5
Explanation: Buy on day 2 (price = 1) and sell on day 5 (price = 6), profit = 6-1 = 5.
Note that buying on day 2 and selling on day 1 is not allowed because you must buy before you sell.
```

Example 2:

```
Input: prices = [7,6,4,3,1]
Output: 0
Explanation: In this case, no transactions are done and the max profit = 0.
```

Constraints:

- `1 <= prices.length <=` 10^5
- `0 <= prices[i] <=` 10^4

SOLUTION (PYTHON 3)

Solution 1: Enumerate + Maintain the Minimum Value of the Prefix

How to think about it

One buy and one sell; trying every pair is $O(n^2)$ and n can reach 10^5. For a fixed sell day the best buy is the minimum price before it. Scan while keeping the prefix minimum, update the answer by today's price minus that minimum, then fold today into the prefix.

We can enumerate each element of the array nums as the selling price. Then we need to find a minimum value in front of it as the purchase price to maximize the profit.

Therefore, we use a variable mi to maintain the prefix minimum value of the array nums. Then we traverse the array nums and for each element v, calculate the difference between it and the minimum value mi in front of it, and update the answer to the maximum of the difference. Then update mi = min(mi, v). Continue to traverse the array nums until the traversal ends.

Finally, return the answer.

The time complexity is O(n), where n is the length of the array nums. The space complexity is O(1).

Python 3

```python
class Solution:
    def maxProfit(self, prices: List[int]) -> int:
        ans, mi = 0, inf
        for v in prices:
            ans = max(ans, v - mi)
            mi = min(mi, v)
        return ans
```

PATTERN 2 · SLIDING WINDOW · PROBLEM 2 OF 20

3. Longest Substring Without Repeating Characters

Medium · Hash Table, String, Sliding Window

leetcode.com/problems/longest-substring-without-repeating-characters

★ **TOP 10 PROBLEM** in Sliding Window: master this one first

PROBLEM

Given a string `s`, find the length of the **longest substring** without duplicate characters.

Example 1:

```
Input: s = "abcabcbb"
Output: 3
Explanation: The answer is "abc", with the length of 3. Note that "bca" and "cab" are also correct answers.
```

Example 2:

```
Input: s = "bbbbb"
Output: 1
Explanation: The answer is "b", with the length of 1.
```

Example 3:

```
Input: s = "pwwkew"
Output: 3
Explanation: The answer is "wke", with the length of 3.
Notice that the answer must be a substring, "pwke" is a subsequence and not a substring.
```

Constraints:

- `0 <= s.length <= 10^5`
- `s` consists of English letters, digits, symbols and spaces.

SOLUTION (PYTHON 3)

Solution 1: Sliding Window

How to think about it

The first idea is to try every substring and test uniqueness. Correct, but at least $O(n^2)$. $n \le 10^5$ will time out. The waste is overlap: once [l,r] has no repeats, adding a character c on the right only needs to fix whether c broke the window—not a full rescan. A duplicate means the valid answer cannot keep the extra c on the left, so l must move right. A count table telling whether cnt[c] > 1 is enough to decide shrinking; after c appears once, the window is the longest unique substring ending at r.

We can use two pointers l and r to maintain a sliding window that always satisfies the condition of having no repeating characters within the window. Initially, both l and r point to the first character of the string. We use a hash table or an array of length 128 called cnt to record the number of occurrences of each character, where cnt[c] represents the number of occurrences of character c.

Next, we move the right pointer r one step at a time. Each time we move it, we increment the value of cnt[s[r]] by 1, and then check if the value of cnt[s[r]] is greater than 1 within the current window [l, r]. If it is greater than 1, it means there are repeating characters within the current window, and we need to move the left pointer l until there are no repeating characters within the window. Then, we update the answer ans = max(ans, r - l + 1).

Finally, we return the answer ans.

The time complexity is O(n), where n is the length of the string. The space complexity is O(|Σ|), where Σ represents the character set, and the size of Σ is 128.

Python 3

```python
class Solution:
    def lengthOfLongestSubstring(self, s: str) -> int:
        cnt = Counter()
        ans = l = 0
        for r, c in enumerate(s):
            cnt[c] += 1
            while cnt[c] > 1:
                cnt[s[l]] -= 1
                l += 1
            ans = max(ans, r - l + 1)
        return ans
```

```

PATTERN 2 · SLIDING WINDOW · PROBLEM 3 OF 20

209. Minimum Size Subarray Sum

Medium · Array, Binary Search, Prefix Sum, Sliding Window

leetcode.com/problems/minimum-size-subarray-sum

★ **TOP 10 PROBLEM** in Sliding Window: master this one first

PROBLEM

Given an array of positive integers `nums` and a positive integer `target`, return *the **minimal length** of a subarray whose sum is greater than or equal to* `target`. If there is no such subarray, return `0` instead.

Example 1:

```
Input: target = 7, nums = [2,3,1,2,4,3]
Output: 2
Explanation: The subarray [4,3] has the minimal length under the problem constraint.
```

Example 2:

```
Input: target = 4, nums = [1,4,4]
Output: 1
```

Example 3:

```
Input: target = 11, nums = [1,1,1,1,1,1,1,1]
Output: 0
```

Constraints:

- `1 <= target <= 10^9`
- `1 <= nums.length <= 10^5`
- `1 <= nums[i] <= 10^4`

Follow up:

If you have figured out the

`O(n)`

solution, try coding another solution of which the time complexity is

`O(n log(n))`

.

SOLUTIONS (PYTHON 3)

Solution 1: Prefix Sum + Binary Search

How to think about it

Summing every subarray is O(n^2). All elements are positive, so prefix sums are monotone and the shortest right end for a fixed left end can be binary-searched. After building s, for each s[i] we find the least j with s[j] ≥ s[i]+target and update the length by j-i.

First, we preprocess the prefix sum array s of the array nums, where s[i] represents the sum of the first i elements of the array nums. Since all elements in the array nums are positive integers, the array s is also monotonically increasing. Also, we initialize the answer ans = n + 1, where n is the length of the array nums.

Next, we traverse the prefix sum array s. For each element s[i], we can find the smallest index j that satisfies s[j] ≥ s[i] + target by binary search. If j ≤ n, it means that there exists a subarray that satisfies the condition, and we can update the answer, i.e., ans = min(ans, j - i).

Finally, if ans ≤ n, it means that there exists a subarray that satisfies the condition, return ans, otherwise return 0.

The time complexity is O(n × log n), and the space complexity is O(n). Here, n is the length of the array nums.

Python 3

```python
class Solution:
    def minSubArrayLen(self, target: int, nums: List[int]) -> int:
        n = len(nums)
        s = list(accumulate(nums, initial=0))
        ans = n + 1
        for i, x in enumerate(s):
            j = bisect_left(s, x + target)
            if j <= n:
                ans = min(ans, j - i)
        return ans if ans <= n else 0
```

Solution 2: Two Pointers

> **How to think about it**
>
> Prefix sums still use O(n) space and a log factor. Positivity makes the window sum grow with the right end and shrink when the left end moves right. Two pointers therefore suffice: add on the right, and while the sum is at least target, shrink from the left and record the shortest length.

We can use two pointers j and i to maintain a window, where the sum of all elements in the window is less than target. Initially, j = 0, and the answer ans = n + 1, where n is the length of the array nums.

Next, the pointer i starts to move to the right from 0, moving one step each time. We add the element corresponding to the pointer i to the window and update the sum of the elements in the window. If the sum of the elements in the window is greater than or equal to target, it means that the current subarray satisfies the condition, and we can update the answer, i.e., ans = min(ans, i - j + 1). Then we continuously remove the element nums[j] from the window until the sum of the elements in the window is less than target, and then repeat the above process.

Finally, if ans ≤ n, it means that there exists a subarray that satisfies the condition, return ans, otherwise return 0.

The time complexity is O(n), and the space complexity is O(1). Here, n is the length of the array nums.

Python 3

```python
class Solution:
    def minSubArrayLen(self, target: int, nums: List[int]) -> int:
        l = s = 0
        ans = inf

PATTERN 2 · SLIDING WINDOW · PROBLEM 4 OF 20

424. Longest Repeating Character Replacement

Medium · Hash Table, String, Sliding Window

leetcode.com/problems/longest-repeating-character-replacement

★ **TOP 10 PROBLEM** in Sliding Window: master this one first

PROBLEM

You are given a string `s` and an integer `k`. You can choose any character of the string and change it to any other uppercase English character. You can perform this operation at most `k` times.

Return *the length of the longest substring containing the same letter you can get after performing the above operations*.

Example 1:

```
Input: s = "ABAB", k = 2
Output: 4
Explanation: Replace the two 'A's with two 'B's or vice versa.
```

Example 2:

```
Input: s = "AABABBA", k = 1
Output: 4
Explanation: Replace the one 'A' in the middle with 'B' and form "AABBBBA".
The substring "BBBB" has the longest repeating letters, which is 4.
There may exists other ways to achieve this answer too.
```

Constraints:

- `1 <= s.length <= 10^5`
- `s` consists of only uppercase English letters.
- `0 <= k <= s.length`

SOLUTION (PYTHON 3)

Solution 1: Two Pointers

How to think about it

A window can be made uniform with at most k changes iff its length minus the majority count is at most k. Trying every pair of ends is O(n^2). Expand the right end while tracking the maximum frequency mx. When r-l+1-mx>k, shift the left end by one. The longest legal window has length n-l. There is no need to decrease mx on a left move: we only want the maximum length, and an overestimate of mx only makes the test stricter.

We use a hash table `cnt` to count the occurrence of each character in the string, and two pointers `l` and `r` to maintain a sliding window, such that the size of the window minus the count of the most frequent character does not exceed k.

We iterate through the string, updating the right boundary `r` of the window each time, updating the count of characters within the window, and updating the maximum count `mx` of the characters that have appeared. When the size of the window minus `mx` is greater than k, we need to shrink the left boundary `l` of the window, updating the count of characters within the window, until the size of the window minus `mx` is no longer greater than k.

Finally, the answer is n - l, where n is the length of the string.

The time complexity is O(n), and the space complexity is O(|Σ|). Where n is the length of the string, and |Σ| is the size of the character set. In this problem, the character set is uppercase English letters, so |Σ| = 26.

Python 3

```python
class Solution:
    def characterReplacement(self, s: str, k: int) -> int:
        cnt = Counter()
        l = mx = 0
        for r, c in enumerate(s):
            cnt[c] += 1
            mx = max(mx, cnt[c])
            if r - l + 1 - mx > k:
                cnt[s[l]] -= 1
                l += 1
        return len(s) - l
```

PATTERN 2 · SLIDING WINDOW · PROBLEM 5 OF 20

567. Permutation in String

Medium · Hash Table, Two Pointers, String, Sliding Window

leetcode.com/problems/permutation-in-string

★ **TOP 10 PROBLEM** in Sliding Window: master this one first

Also appears in pattern 7 String Matching / Pattern Search

PROBLEM

Given two strings `s1` and `s2`, return `true` if `s2` contains a permutation of `s1`, or `false` otherwise.

In other words, return `true` if one of `s1`'s permutations is the substring of `s2`.

Example 1:

```
Input: s1 = "ab", s2 = "eidbaooo"
Output: true
Explanation: s2 contains one permutation of s1 ("ba").
```

Example 2:

```
Input: s1 = "ab", s2 = "eidboaoo"
Output: false
```

Constraints:

- `1 <= s1.length, s2.length <=` 10^4
- `s1` and `s2` consist of lowercase English letters.

SOLUTION (PYTHON 3)

Solution 1: Sliding Window

How to think about it

A permutation of s1 is a window of length |s1| with the same counts. Sorting every window is wasteful. A sliding window stores the remaining counts versus s1 and need is how many letters are still off. Add the right end, drop the left, and succeed when need=0. Fixed length, one scan.

We use an array cnt to record the characters and their counts that need to be matched, and a variable need to record the number of different characters that still need to be matched. Initially, cnt contains the character counts from the string s1, and need is the number of different characters in s1.

Then we traverse the string s2. For each character, we decrement its corresponding value in cnt. If the decremented value equals 0, it means the current character's count in s1 is satisfied, and we decrement need. If the current index i is greater than or equal to the length of s1, we need to increment the corresponding value in cnt for s2[i-s1]. If the incremented value equals 1, it means the current character's count in s1 is no longer satisfied, and we increment need. During the traversal, if the value of need equals 0, it means all character counts are satisfied, and we have found a valid substring, so we return true.

Otherwise, if the traversal ends without finding a valid substring, we return false.

The time complexity is O(m + n), where m and n are the lengths of strings s1 and s2, respectively. The space complexity is O(|Σ|), where Σ is the character set. In this problem, the character set is lowercase letters, so the space complexity is constant.

Python 3

```
class Solution:
    def checkInclusion(self, s1: str, s2: str) -> bool:
        cnt = Counter(s1)
        need = len(cnt)
        m = len(s1)
        for i, c in enumerate(s2):
            cnt[c] -= 1
            if cnt[c] == 0:
                need -= 1
            if i >= m:
                cnt[s2[i - m]] += 1
                if cnt[s2[i - m]] == 1:
                    need += 1
            if need == 0:
                return True
        return False
```

```

PATTERN 2 · SLIDING WINDOW · PROBLEM 6 OF 20

438. Find All Anagrams in a String

Medium · Hash Table, String, Sliding Window

leetcode.com/problems/find-all-anagrams-in-a-string

★ **TOP 10 PROBLEM** in Sliding Window, String Matching / Pattern Search: master this one first

Also appears in pattern 7 String Matching / Pattern Search

PROBLEM

Given two strings `s` and `p`, return an array of all the start indices of `p`'s anagrams in `s`. You may return the answer in **any order**.

Example 1:

```
Input: s = "cbaebabacd", p = "abc"
Output: [0,6]
Explanation:
The substring with start index = 0 is "cba", which is an anagram of "abc".
The substring with start index = 6 is "bac", which is an anagram of "abc".
```

Example 2:

```
Input: s = "abab", p = "ab"
Output: [0,1,2]
Explanation:
The substring with start index = 0 is "ab", which is an anagram of "ab".
The substring with start index = 1 is "ba", which is an anagram of "ab".
The substring with start index = 2 is "ab", which is an anagram of "ab".
```

Constraints:

- `1 <= s.length, p.length <= 3 * 10^4`
- `s` and `p` consist of lowercase English letters.

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

An anagram is a same-length substring with the same letter counts. Sorting every window is too slow. Keep a window of length n=|p| and compare its counter with p's. Prefill n-1 characters, then on each step add the right character, compare, and drop the left one. The window length stays n, so only two 26-slot counters are compared.

Python 3

```python
class Solution:
    def findAnagrams(self, s: str, p: str) -> List[int]:
        m, n = len(s), len(p)
        ans = []
        if m < n:
            return ans
        cnt1 = Counter(p)
        cnt2 = Counter(s[: n - 1])
        for i in range(n - 1, m):
            cnt2[s[i]] += 1
            if cnt1 == cnt2:
                ans.append(i - n + 1)
            cnt2[s[i - n + 1]] -= 1
        return ans
```

Complexity. Time: O(m * C), m = len(s), C = 26 (comparing two counters). Space: O(C).

Solution 2

> **How to think about it**
>
> Solution 1 compares the whole counter each time. After adding the right character, shrink the left end while any letter exceeds p's quota. When every letter is within quota and the length equals n, the window is an anagram. The O(|Σ|) equality test becomes a length check; the scan is still linear.

Python 3

```python
class Solution:
    def findAnagrams(self, s: str, p: str) -> List[int]:
        m, n = len(s), len(p)
        ans = []
        if m < n:
            return ans
        cnt1 = Counter(p)
        cnt2 = Counter()
        j = 0
        for i, c in enumerate(s):
            cnt2[c] += 1
            while cnt2[c] > cnt1[c]:
                cnt2[s[j]] -= 1
                j += 1
            if i - j + 1 == n:
                ans.append(j)
        return ans
```

PATTERN 2 · SLIDING WINDOW · PROBLEM 7 OF 20

904. Fruit Into Baskets

Medium · Array, Hash Table, Sliding Window

leetcode.com/problems/fruit-into-baskets

★ **TOP 10 PROBLEM** in Sliding Window: master this one first

PROBLEM

You are visiting a farm that has a single row of fruit trees arranged from left to right. The trees are represented by an integer array `fruits` where `fruits[i]` is the **type** of fruit the i^{th} tree produces.

You want to collect as much fruit as possible. However, the owner has some strict rules that you must follow:

- You only have **two** baskets, and each basket can only hold a **single type** of fruit. There is no limit on the amount of fruit each basket can hold.
- Starting from any tree of your choice, you must pick **exactly one fruit** from **every** tree (including the start tree) while moving to the right. The picked fruits must fit in one of your baskets.
- Once you reach a tree with fruit that cannot fit in your baskets, you must stop.

Given the integer array `fruits`, return *the **maximum** number of fruits you can pick*.

Example 1:

```
Input: fruits = [1,2,1]
Output: 3
Explanation: We can pick from all 3 trees.
```

Example 2:

```
Input: fruits = [0,1,2,2]
Output: 3
Explanation: We can pick from trees [1,2,2].
If we had started at the first tree, we would only pick from trees [0,1].
```

Example 3:

```
Input: fruits = [1,2,3,2,2]
Output: 4
Explanation: We can pick from trees [2,3,2,2].
If we had started at the first tree, we would only pick from trees [1,2].
```

Constraints:

- `1 <= fruits.length <= 10^5`
- `0 <= fruits[i] < fruits.length`

SOLUTIONS (PYTHON 3)

Solution 1: Hash Table + Sliding Window

How to think about it

We need the longest subarray with at most two fruit types. n≤ 10^5, so enumerating endpoints and recounting types is too slow. After the right end absorbs a fruit, the left end must move if the window has more than two types. A counter tracks frequencies; the number of keys is the number of types. Shrink from the left while that exceeds 2, and keep the maximum window length.

We use a hash table cnt to maintain the types and corresponding quantities of fruits in the current window, and use two pointers j and i to maintain the left and right boundaries of the window.

We traverse the fruits array, add the current fruit x to the window, i.e., cnt[x]++, then judge whether the types of fruits in the current window exceed 2. If it exceeds 2, we need to move the left boundary j of the window to the right until the types of fruits in the window do not exceed 2. Then we update the answer, i.e., ans = max(ans, i - j + 1).

After the traversal ends, we can get the final answer.

```
1 2 3 2 2 1 4
^   ^
j   i

1 2 3 2 2 1 4
  ^ ^
  j i

1 2 3 2 2 1 4
  ^     ^
  j     i
```

The time complexity is O(n), and the space complexity is O(1). Here, n is the length of the fruits array.

Python 3

```python
class Solution:
    def totalFruit(self, fruits: List[int]) -> int:
        cnt = Counter()
        ans = j = 0
        for i, x in enumerate(fruits):
            cnt[x] += 1
            while len(cnt) > 2:
                y = fruits[j]
                cnt[y] -= 1
                if cnt[y] == 0:
                    cnt.pop(y)
                j += 1
            ans = max(ans, i - j + 1)
        return ans
```

Solution 2: Monotonic Variable-Length Sliding Window

> **How to think about it**
>
> Method 1 shrinks the window and updates the answer on every step, yet only the maximum length is required, so shorter historical windows can be ignored. Grow the window monotonically: when a third type appears, advance the left end once. The final n-j is the largest feasible window.

In Solution 1, we find that the window size sometimes increases and sometimes decreases, which requires us to update the answer each time.

But what this problem actually asks for is the maximum number of fruits, that is, the "largest" window. We don't need to shrink the window, we just need to let the window monotonically increase. So the code omits the operation of updating the answer each time, and only needs to return the size of the window as the answer after the traversal ends.

The time complexity is O(n), and the space complexity is O(n), where n is the length of the fruits array.

Python 3

```
class Solution:
    def totalFruit(self, fruits: List[int]) -> int:
        cnt = Counter()
        j = 0
        for x in fruits:
            cnt[x] += 1
            if len(cnt) > 2:
                y = fruits[j]
                cnt[y] -= 1
                if cnt[y] == 0:
                    cnt.pop(y)
                j += 1
        return len(fruits) - j
```

PATTERN 2 · SLIDING WINDOW · PROBLEM 8 OF 20

1004. Max Consecutive Ones III

Medium · Array, Binary Search, Prefix Sum, Sliding Window

leetcode.com/problems/max-consecutive-ones-iii

★ **TOP 10 PROBLEM** in Sliding Window: master this one first

PROBLEM

Given a binary array `nums` and an integer `k`, return *the maximum number of consecutive* `1`*'s in the array if you can flip at most* `k` `0`'s.

Example 1:

```
Input: nums = [1,1,1,0,0,0,1,1,1,1,0], k = 2
Output: 6
Explanation: [1,1,1,0,0,1,1,1,1,1,1]
Bolded numbers were flipped from 0 to 1. The longest subarray is underlined.
```

Example 2:

```
Input: nums = [0,0,1,1,0,0,1,1,1,0,1,1,0,0,0,1,1,1,1], k = 3
Output: 10
Explanation: [0,0,1,1,1,1,1,1,1,1,1,1,0,0,0,1,1,1,1]
Bolded numbers were flipped from 0 to 1. The longest subarray is underlined.
```

Constraints:

- `1 <= nums.length <= 10^5`
- `nums[i]` is either 0 or 1.
- `0 <= k <= nums.length`

SOLUTION (PYTHON 3)

Solution 1: Sliding Window

How to think about it

Checking every subarray for its number of zeros is O(n^2), which fails for n≤ 10^5. Flipping at most k zeros to maximize consecutive ones is the same as the longest window that contains at most k zeros. When the right end advances and the zero count exceeds k, the left end must advance to restore feasibility. Only the maximum length is required, so the window is allowed to grow monotonically: the left end moves at most one step per iteration. We keep l and cnt for the current window. After the right end visits every index, n-l is the length of the longest feasible window.

We can iterate through the array, using a variable cnt to record the current number of 0s in the window. When cnt > k, we move the left boundary of the window to the right by one position.

After the iteration ends, the length of the window is the maximum number of consecutive 1s.

Note that in the process above, we do not need to loop to move the left boundary of the window to the right. Instead, we directly move the left boundary to the right by one position. This is because the problem asks for the maximum number of consecutive 1s, so the length of the window will only increase, not decrease. Therefore, we do not need to loop to move the left boundary to the right.

The time complexity is O(n), where n is the length of the array. The space complexity is O(1).

PATTERN 2 · SLIDING WINDOW · PROBLEM 9 OF 20

713. Subarray Product Less Than K

Medium · Array, Binary Search, Prefix Sum, Sliding Window

leetcode.com/problems/subarray-product-less-than-k

Also appears in pattern 35 Sliding Window Maximum / Minimum (Specific Variants)

PROBLEM

You are given an array of integers `nums` and an integer `k`.

Return the number of contiguous subarrays where the **product** of all the elements in the **subarray** is **strictly less** than `k`.

Example 1:

```
Input: nums = [10,5,2,6], k = 100
Output: 8
Explanation: The 8 subarrays that have product less than 100 are:
[10], [5], [2], [6], [10, 5], [5, 2], [2, 6], [5, 2, 6]
Note that [10, 5, 2] is not included as the product of 100 is not strictly less than k.
```

Example 2:

```
Input: nums = [1,2,3], k = 0
Output: 0
```

Constraints:

- `1 <= nums.length <= 3 * 10^4`
- `1 <= nums[i] <= 1000`
- `0 <= k <= 10^6`

SOLUTION (PYTHON 3)

Solution 1: Two Pointers

How to think about it

Count contiguous subarrays whose product is strictly less than k. n can be 3× 10^4, so enumerating both ends is O(n^2). All values are positive, so the window product is monotone as the right end grows. Once it reaches k, only advancing the left end restores a legal window—each pointer moves at most once. Keep product p and left l. After multiplying by x, divide out nums[l] while p≥ k. Then r-l+1 subarrays end at r. One pass suffices.

We can use two pointers to maintain a sliding window, where the product of all elements in the window is less than k.

Define two pointers l and r pointing to the left and right boundaries of the sliding window, initially l = r = 0. We use a variable p to record the product of all elements in the window, initially p = 1.

Each time, we move r one step to the right, adding the element x pointed to by r to the window, and update p = p × x. Then, if p ≥ k, we move l one step to the right in a loop and update p = p ÷ nums[l] until p < k or l > r. Thus, the number of contiguous subarrays ending at r with a product less than k is r - l + 1. We then add this number to the answer and continue moving r until r reaches the end of the array.

The time complexity is O(n), where n is the length of the array. The space complexity is O(1).

Python 3

```
class Solution:
    def numSubarrayProductLessThanK(self, nums: List[int], k: int) -> int:
        ans = l = 0
        p = 1
        for r, x in enumerate(nums):
            p *= x
            while l <= r and p >= k:
                p //= nums[l]
                l += 1
            ans += r - l + 1
        return ans
```

    return result
```

PATTERN 2 · SLIDING WINDOW · PROBLEM 10 OF 20

1493. Longest Subarray of 1's After Deleting One Element

Medium · Array, Dynamic Programming, Sliding Window

leetcode.com/problems/longest-subarray-of-1s-after-deleting-one-element

PROBLEM

You are given a binary array `nums`, you should delete **one** element from it.

Return the size of the **longest non-empty subarray** containing only 1's in the resulting array. Return 0 if there is no such **subarray**.

Example 1:

```
Input: nums = [1,1,0,1]
Output: 3
Explanation: After deleting the number in position 2, [1,1,1] contains 3 numbers with value of 1's.
```

Example 2:

```
Input: nums = [0,1,1,1,0,1,1,0,1]
Output: 5
Explanation: After deleting the number in position 4, [0,1,1,1,1,1,0,1] longest subarray with value of
1's is [1,1,1,1,1].
```

Example 3:

```
Input: nums = [1,1,1]
Output: 2
Explanation: You must delete one element.
```

Constraints:

- `1 <= nums.length <= 10^5`
- `nums[i]` is either 0 or 1.

SOLUTIONS (PYTHON 3)

Solution 1: Enumeration

> **How to think about it**
>
> Exactly one element is deleted, so the answer is the ones immediately left of i plus those immediately right. n≤ 10^5. Precompute longest ones ending before i and starting after i, then maximize over the deleted index.

We can enumerate each position i to be deleted, then calculate the number of consecutive 1s on the left and right, and finally take the maximum value.

Specifically, we use two arrays left and right of length n+1, where left[i] represents the number of consecutive 1s ending with nums[i-1], and right[i] represents the number of consecutive 1s starting with nums[i].

The final answer is $\max_{0 \le i < n} \{left[i] + right[i+1]\}$.

The time complexity is O(n), and the space complexity is O(n). Where n is the length of the array nums.

Python 3

```python
class Solution:
    def longestSubarray(self, nums: List[int]) -> int:
        n = len(nums)
        left = [0] * (n + 1)
        right = [0] * (n + 1)
        for i, x in enumerate(nums, 1):
            if x:
                left[i] = left[i - 1] + 1
        for i in range(n - 1, -1, -1):
            if nums[i]:
                right[i] = right[i + 1] + 1
        return max(left[i] + right[i + 1] for i in range(n))
```

Solution 2: Two Pointers

> **How to think about it**
>
> Method 1 stores two arrays. Equivalently, find the longest window with at most one 0; after deleting that 0 (or one 1) the length is i-j. Expand the right end and shrink while the zero count exceeds 1.

The problem is actually asking us to find the longest subarray that contains at most one 0. The remaining length after deleting one element from this subarray is the answer.

Therefore, we can use two pointers j and i to point to the left and right boundaries of the subarray, initially j = 0, i = 0. In addition, we use a variable cnt to record the number of 0s in the subarray.

Next, we move the right pointer i. If nums[i] = 0, then cnt is incremented by 1. When cnt > 1, we need to move the left pointer j until cnt ≤ 1. Then, we update the answer, i.e., ans = max(ans, i - j). Continue to move the right pointer i until i reaches the end of the array.

The time complexity is O(n), where n is the length of the array nums. The space complexity is O(1).

Python 3

```python
class Solution:
    def longestSubarray(self, nums: List[int]) -> int:
        ans = 0
        cnt = j = 0
        for i, x in enumerate(nums):
            cnt += x ^ 1
            while cnt > 1:
                cnt -= nums[j] ^ 1
                j += 1
            ans = max(ans, i - j)
        return ans
```

Solution 3: Two Pointers (Optimization)

> **How to think about it**
>
> Method 2 may shrink the window when zeros exceed one. We only need the maximum length, so move the left end once whenever the count is too large and keep the window non-decreasing. The answer is n-l-1.

In Solution 2, we move the left pointer in a loop until cnt ≤ 1. Since the problem asks for the longest subarray, it means we don't need to reduce the length of the subarray. Therefore, if cnt > 1, we only move the left pointer once, and the right pointer continues to move to the right. This ensures that the length of the subarray does not decrease.

Finally, the answer we return is n - l - 1, where l is the position of the left pointer.

The time complexity is O(n), where n is the length of the array nums. The space complexity is O(1).

Python 3

```python
class Solution:
    def longestSubarray(self, nums: List[int]) -> int:
        cnt = l = 0
        for x in nums:
            cnt += x ^ 1
            if cnt > 1:
                cnt -= nums[l] ^ 1
                l += 1
        return len(nums) - l - 1
```

PATTERN 2 · SLIDING WINDOW · PROBLEM 11 OF 20

1456. Maximum Number of Vowels in a Substring of Given Length

Medium · String, Sliding Window

leetcode.com/problems/maximum-number-of-vowels-in-a-substring-of-given-length

PROBLEM

Given a string `s` and an integer `k`, return *the maximum number of vowel letters in any substring of* `s` *with length* `k`.

Vowel letters in English are `'a'`, `'e'`, `'i'`, `'o'`, and `'u'`.

Example 1:

```
Input: s = "abciiidef", k = 3
Output: 3
Explanation: The substring "iii" contains 3 vowel letters.
```

Example 2:

```
Input: s = "aeiou", k = 2
Output: 2
Explanation: Any substring of length 2 contains 2 vowels.
```

Example 3:

```
Input: s = "leetcode", k = 3
Output: 2
Explanation: "lee", "eet" and "ode" contain 2 vowels.
```

Constraints:

- `1 <= s.length <= 10^5`
- `s` consists of lowercase English letters.
- `1 <= k <= s.length`

SOLUTION (PYTHON 3)

Solution 1: Sliding Window

> **How to think about it**
>
> We want the most vowels in any length-k window. n≤ 10^5, so count the first k characters, then add/remove one character as the window slides.

First, we count the number of vowels in the first k characters, denoted as cnt, and initialize the answer ans as cnt.

Then we start traversing the string from k. For each iteration, we add the current character to the window. If the current character is a vowel, we increment cnt. We remove the first character from the window. If the removed character is a vowel, we decrement cnt. Then, we update the answer ans = max(ans, cnt).

After the traversal, we return the answer.

The time complexity is O(n), where n is the length of the string s. The space complexity is O(1).

Python 3

```python
class Solution:
    def maxVowels(self, s: str, k: int) -> int:
        vowels = set("aeiou")
        ans = cnt = sum(c in vowels for c in s[:k])

PATTERN 2 · SLIDING WINDOW · PROBLEM 12 OF 20

1248. Count Number of Nice Subarrays

Medium · Array, Hash Table, Math, Prefix Sum, Sliding Window

leetcode.com/problems/count-number-of-nice-subarrays

Also appears in pattern 5 Prefix Sum

PROBLEM

Given an array of integers `nums` and an integer `k`. A continuous subarray is called **nice** if there are `k` odd numbers on it.

Return *the number of **nice** sub-arrays*.

Example 1:

```
Input: nums = [1,1,2,1,1], k = 3
Output: 2
Explanation: The only sub-arrays with 3 odd numbers are [1,1,2,1] and [1,2,1,1].
```

Example 2:

```
Input: nums = [2,4,6], k = 1
Output: 0
Explanation: There are no odd numbers in the array.
```

Example 3:

```
Input: nums = [2,2,2,1,2,2,1,2,2,2], k = 2
Output: 16
```

Constraints:

- `1 <= nums.length <= 50000`
- `1 <= nums[i] <= 10^5`
- `1 <= k <= nums.length`

SOLUTION (PYTHON 3)

Solution 1: Prefix Sum + Array or Hash Table

> **How to think about it**
>
> We want subarrays with exactly k odds, n ≤ 5× 10^4. Treating odds as 1 and evens as 0, these are intervals whose prefix sums differ by k. While scanning we keep the odd count t, look up how often t-k has appeared, then record t. The prefix sum turns “exactly k odds” into one map query.

The problem asks for the number of subarrays that contain exactly k odd numbers. We can calculate the number of odd numbers t in each prefix array and record it in an array or hash table cnt. For each prefix array, we only need to find the number of prefix arrays with t-k odd numbers, which is the number of subarrays ending with the current prefix array.

The time complexity is O(n), and the space complexity is O(n). Where n is the length of the array nums.

Python 3

```python
class Solution:
    def numberOfSubarrays(self, nums: List[int], k: int) -> int:
        cnt = Counter({0: 1})
        ans = t = 0
        for v in nums:
            t += v & 1
            ans += cnt[t - k]
            cnt[t] += 1
        return ans
```

            best = length
    return best
```

PATTERN 2 · SLIDING WINDOW · PROBLEM 13 OF 20

930. Binary Subarrays With Sum

Medium · Array, Hash Table, Prefix Sum, Sliding Window

leetcode.com/problems/binary-subarrays-with-sum

Also appears in pattern 5 Prefix Sum

PROBLEM

Given a binary array `nums` and an integer `goal`, return *the number of non-empty **subarrays** with a sum* `goal`.

A **subarray** is a contiguous part of the array.

Example 1:

```
Input: nums = [1,0,1,0,1], goal = 2
Output: 4
Explanation: The 4 subarrays are bolded and underlined below:
[1,0,1,0,1]
[1,0,1,0,1]
[1,0,1,0,1]
[1,0,1,0,1]
```

Example 2:

```
Input: nums = [0,0,0,0,0], goal = 0
Output: 15
```

Constraints:

- `1 <= nums.length <= 3 * 10^4`
- `nums[i]` is either `0` or `1`.
- `0 <= goal <= nums.length`

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

Count subarrays of a 0/1 array whose sum is goal. n is large, so enumerating intervals is too slow. When the prefix sum is s, the number of earlier prefixes equal to s-goal is the number of good subarrays ending here. A counter of prefix frequencies, starting at cnt[0]=1, answers each step in O(1).

Python 3

```python
class Solution:
    def numSubarraysWithSum(self, nums: List[int], goal: int) -> int:
        cnt = Counter({0: 1})
        ans = s = 0
        for v in nums:
            s += v
            ans += cnt[s - goal]
            cnt[s] += 1
        return ans
```

Solution 2

How to think about it

Method 1 uses linear extra space. Because the array is non-negative, the window sum is monotone in the left end. Two left pointers keep the first index whose sum exceeds goal and the first whose sum is at least goal; their difference is the number of windows with sum exactly goal.

Python 3

```python
class Solution:
    def numSubarraysWithSum(self, nums: List[int], goal: int) -> int:
        i1 = i2 = s1 = s2 = j = ans = 0
        n = len(nums)
        while j < n:
            s1 += nums[j]
            s2 += nums[j]
            while i1 <= j and s1 > goal:
                s1 -= nums[i1]
                i1 += 1
            while i2 <= j and s2 >= goal:
                s2 -= nums[i2]
                i2 += 1
            ans += i2 - i1
            j += 1
        return ans
```

Complexity. Time: O(n). Space: O(1).

    return count
```

PATTERN 2 · SLIDING WINDOW · PROBLEM 14 OF 20

1695. Maximum Erasure Value

Medium · Array, Hash Table, Sliding Window

leetcode.com/problems/maximum-erasure-value

Also appears in pattern 35 Sliding Window Maximum / Minimum (Specific Variants)

PROBLEM

You are given an array of positive integers `nums` and want to erase a subarray containing **unique elements**. The **score** you get by erasing the subarray is equal to the **sum** of its elements.

Return *the **maximum score** you can get by erasing **exactly one** subarray.*

An array `b` is called to be a subarray of `a` if it forms a contiguous subsequence of `a`, that is, if it is equal to `a[l],a[l+1],...,a[r]` for some `(l,r)`.

Example 1:

```
Input: nums = [4,2,4,5,6]
Output: 17
Explanation: The optimal subarray here is [2,4,5,6].
```

Example 2:

```
Input: nums = [5,2,1,2,5,2,1,2,5]
Output: 8
Explanation: The optimal subarray here is [5,2,1] or [1,2,5].
```

Constraints:

- `1 <= nums.length <= 10^5`
- `1 <= nums[i] <= 10^4`

SOLUTIONS (PYTHON 3)

Solution 1: Array or Hash Table + Prefix Sum

How to think about it

We want the maximum sum of a contiguous subarray of distinct values. n is 10^5; the last-seen index pushes the left end j past duplicates, and prefix sums give the range sum. Array d stores the latest index of each value. On v, set j=max(j,d[v]) and update with s[i]-s[j].

We use an array or hash table d to record the last occurrence position of each number, and use a prefix sum array s to record the sum from the starting point to the current position. We use a variable j to record the left endpoint of the current non-repeating subarray.

We iterate through the array. For each number v, if d[v] exists, we update j to max(j, d[v]), which ensures that the current non-repeating subarray does not contain v. Then we update the answer to max(ans, s[i] - s[j]), and finally update d[v] to i.

The time complexity is O(n), and the space complexity is O(n), where n is the length of the array nums.

Python 3

```python
class Solution:
    def maximumUniqueSubarray(self, nums: List[int]) -> int:
        d = [0] * (max(nums) + 1)
        s = list(accumulate(nums, initial=0))
        ans = j = 0
        for i, v in enumerate(nums, 1):
            j = max(j, d[v])
            ans = max(ans, s[i] - s[j])
            d[v] = i
        return ans
```

Solution 2: Two Pointers (Sliding Window)

> **How to think about it**
>
> Solution 1 uses prefix sums and an index table. A sliding window can store the live distinct sum: shrink from the left on a duplicate and skip the prefix array.

The problem is essentially asking us to find the longest subarray where all elements are distinct. We can use two pointers i and j to point to the left and right boundaries of the subarray, initially i = 0 and j = 0. Additionally, we use a hash table vis to record the elements in the subarray.

We iterate through the array. For each number x, if x is in vis, we continuously remove nums[i] from vis until x is no longer in vis. This way, we find a subarray that contains no duplicate elements. We add x to vis, update the subarray sum s, and then update the answer ans = max(ans, s).

After the iteration, we can get the maximum subarray sum.

The time complexity is O(n), and the space complexity is O(n), where n is the length of the array nums.

Python 3

```python
class Solution:
    def maximumUniqueSubarray(self, nums: List[int]) -> int:
        vis = set()
        ans = s = i = 0
        for x in nums:
            while x in vis:
                y = nums[i]
                s -= y
                vis.remove(y)
                i += 1
            vis.add(x)
            s += x
            ans = max(ans, s)
        return ans
```

    return best
```

1052. Grumpy Bookstore Owner

Medium · Array, Sliding Window

leetcode.com/problems/grumpy-bookstore-owner

Also appears in pattern 35 Sliding Window Maximum / Minimum (Specific Variants)

PROBLEM

There is a bookstore owner that has a store open for `n` minutes. You are given an integer array `customers` of length `n` where `customers[i]` is the number of the customers that enter the store at the start of the i^{th} minute and all those customers leave after the end of that minute.

During certain minutes, the bookstore owner is grumpy. You are given a binary array grumpy where `grumpy[i]` is `1` if the bookstore owner is grumpy during the i^{th} minute, and is `0` otherwise.

When the bookstore owner is grumpy, the customers entering during that minute are not **satisfied**. Otherwise, they are satisfied.

The bookstore owner knows a secret technique to remain **not grumpy** for `minutes` consecutive minutes, but this technique can only be used **once**.

Return the **maximum** number of customers that can be *satisfied* throughout the day.

Example 1:

Input: customers = [1,0,1,2,1,1,7,5], grumpy = [0,1,0,1,0,1,0,1], minutes = 3

Output: 16

Explanation:

The bookstore owner keeps themselves not grumpy for the last 3 minutes.

The maximum number of customers that can be satisfied = 1 + 1 + 1 + 1 + 7 + 5 = 16.

Example 2:

Input: customers = [1], grumpy = [0], minutes = 1

Output: 1

Constraints:

- `n == customers.length == grumpy.length`
- `1 <= minutes <= n <= 2 * 10^4`
- `0 <= customers[i] <= 1000`
- `grumpy[i]` is either `0` or `1`.

SOLUTION (PYTHON 3)

Solution 1: Sliding Window

How to think about it

Customers in calm minutes always count; the technique covers only a window of minutes angry minutes. n≤ 2× 10^4 calls for one pass. Sum the calm flow, then take the maximum angry flow over every window of length minutes. The window adds customers[i]· grumpy[i] and drops the value that leaves. The answer is the calm sum plus that maximum.

According to the problem description, we only need to count the number of customers when the boss is not angry tot, and add the maximum number of customers when the boss is angry within a sliding window of size `minutes` mx.

We define a variable cnt to record the number of customers when the boss is angry within the sliding window, the initial value is the number of customers when the boss is angry in the first `minutes`. Then we traverse the array, each time we move the sliding window, we update the value of cnt, and at the same time update the value of mx.

Finally, return tot + mx.

The time complexity is O(n), where n is the length of the array `customers`. The space complexity is O(1).

Python 3

```python
class Solution:
    def maxSatisfied(
        self, customers: List[int], grumpy: List[int], minutes: int
    ) -> int:
        mx = cnt = sum(c * g for c, g in zip(customers[:minutes], grumpy))
        for i in range(minutes, len(customers)):
            cnt += customers[i] * grumpy[i]
            cnt -= customers[i - minutes] * grumpy[i - minutes]
            mx = max(mx, cnt)
        return sum(c * (g ^ 1) for c, g in zip(customers, grumpy)) + mx
```

PATTERN 2 · SLIDING WINDOW · PROBLEM 16 OF 20

1838. Frequency of the Most Frequent Element

Medium · Greedy, Array, Binary Search, Prefix Sum, Sorting, Sliding Window

leetcode.com/problems/frequency-of-the-most-frequent-element

Also appears in pattern 35 Sliding Window Maximum / Minimum (Specific Variants)

PROBLEM

The **frequency** of an element is the number of times it occurs in an array.

You are given an integer array `nums` and an integer `k`. In one operation, you can choose an index of `nums` and increment the element at that index by `1`.

Return *the **maximum possible frequency** of an element after performing **at most** `k` operations*.

Example 1:

```
Input: nums = [1,2,4], k = 5
Output: 3
Explanation: Increment the first element three times and the second element two times to make nums = [4,4,4].
4 has a frequency of 3.
```

Example 2:

```
Input: nums = [1,4,8,13], k = 5
Output: 2
Explanation: There are multiple optimal solutions:
- Increment the first element three times to make nums = [4,4,8,13]. 4 has a frequency of 2.
- Increment the second element four times to make nums = [1,8,8,13]. 8 has a frequency of 2.
- Increment the third element five times to make nums = [1,4,13,13]. 13 has a frequency of 2.
```

Example 3:

```
Input: nums = [3,9,6], k = 2
Output: 1
```

Constraints:

- `1 <= nums.length <= 10^5`
- `1 <= nums[i] <= 10^5`
- `1 <= k <= 10^5`

SOLUTIONS (PYTHON 3)

Solution 1: Sorting + Prefix Sum + Binary Search

How to think about it

We may increment elements at most k times and want the highest achievable frequency. The target must be some original value, and the raised elements form a contiguous prefix of the sorted array. Brute-forcing every right endpoint is too slow for $n \le 10^5$. After sorting, feasibility is monotone in the window length, so we binary-search the frequency. Prefix sums test whether some window of that length can be raised to its rightmost value with cost at most k.

According to the problem description, we can draw three conclusions:

1. After several operations, the element with the highest frequency in the array must be an element in the original array. Why? Suppose the elements operated are $a_1, a_2, \ldots, a_m$, where the maximum is a_m. These elements have all been changed to the same value x, where $x \ge a_m$. Then we can also change these elements all to a_m, and the number of operations will not increase.

2. The elements operated must be a continuous subarray in the sorted array.
3. If a frequency m satisfies the condition, then all m' < m also satisfy the condition. This inspires us to consider using binary search to find the maximum frequency that satisfies the condition.

Therefore, we can sort the array nums and then calculate the prefix sum array s of the sorted array, where s[i] represents the sum of the first i elements.

Next, we define the left boundary of the binary search as l = 1, and the right boundary as r = n. For each binary search, we take the middle value m = (l + r + 1) / 2, and then check whether there exists a continuous subarray of length m such that all elements in the subarray can be changed to an element in the array, and the number of operations does not exceed k. If such a subarray exists, we can update the left boundary l to m, otherwise update the right boundary r to m - 1.

Finally, return the left boundary l.

The time complexity is O(n × log n), and the space complexity is O(n). Where n is the length of the array nums.

Python 3

```python
class Solution:
    def maxFrequency(self, nums: List[int], k: int) -> int:
        def check(m: int) -> bool:
            for i in range(m, n + 1):
                if nums[i - 1] * m - (s[i] - s[i - m]) <= k:
                    return True
            return False

        n = len(nums)
        nums.sort()
        s = list(accumulate(nums, initial=0))
        l, r = 1, n
        while l < r:
            mid = (l + r + 1) >> 1
            if check(mid):
                l = mid
            else:
                r = mid - 1
        return l
```

Solution 2: Sorting + Two Pointers

> **How to think about it**
>
> Solution 1 needs prefix sums and a binary search. The window cost grows with the right end, so two pointers suffice: when i advances we raise the window to nums[i], and we move j while the cost exceeds k. One scan yields the longest valid window.

We can also use two pointers to maintain a sliding window, where all elements in the window can be changed to the maximum value in the window. The number of operations for the elements in the window is s, and s ≤ k.

Initially, we set the left pointer j to point to the first element of the array, and the right pointer i also points to the first element of the array. Next, we move the right pointer i each time, changing all elements in the window to nums[i]. At this time, the number of operations to be increased is (nums[i] - nums[i - 1]) × (i - j). If this number of operations exceeds k, then we need to move the left pointer j until the number of operations for the elements in the window does not exceed k. Then, we update the answer to the maximum length of the window.

The time complexity is O(n log n), and the space complexity is O(log n). Where n is the length of the array nums.

Python 3

```python
class Solution:
    def maxFrequency(self, nums: List[int], k: int) -> int:
        nums.sort()
        ans = 1
        s = j = 0
        for i in range(1, len(nums)):
            s += (nums[i] - nums[i - 1]) * (i - j)
            while s > k:
                s -= nums[i] - nums[j]
                j += 1
            ans = max(ans, i - j + 1)
        return ans
```

PATTERN 2 · SLIDING WINDOW · PROBLEM 17 OF 20

1888. Minimum Number of Flips to Make the Binary String Alternating

Medium · String, Dynamic Programming, Sliding Window

leetcode.com/problems/minimum-number-of-flips-to-make-the-binary-string-alternating

Also appears in pattern 35 Sliding Window Maximum / Minimum (Specific Variants)

PROBLEM

You are given a binary string `s`. You are allowed to perform two types of operations on the string in any sequence:

- **Type-1: Remove** the character at the start of the string `s` and **append** it to the end of the string.
- **Type-2: Pick** any character in `s` and **flip** its value, i.e., if its value is `'0'` it becomes `'1'` and vice-versa.

Return *the **minimum** number of **type-2** operations you need to perform such that* `s` *becomes **alternating**.*

The string is called **alternating** if no two adjacent characters are equal.

- For example, the strings `"010"` and `"1010"` are alternating, while the string `"0100"` is not.

Example 1:

```
Input: s = "111000"
Output: 2
Explanation: Use the first operation two times to make s = "100011".
Then, use the second operation on the third and sixth elements to make s = "101010".
```

Example 2:

```
Input: s = "010"
Output: 0
Explanation: The string is already alternating.
```

Example 3:

```
Input: s = "1110"
Output: 1
Explanation: Use the second operation on the second element to make s = "1010".
```

Constraints:

- `1 <= s.length <= 10^5`
- `s[i]` is either `'0'` or `'1'`.

SOLUTION (PYTHON 3)

Solution 1: Sliding Window

How to think about it

Type 1 makes the string circular; type 2 flips bits to an alternating pattern. Comparing every rotation bit by bit is $O(n^2)$ and too slow for $n \le 10^5$. Only two targets exist, and their costs sum to n. A window of length n on the circular string is one rotation; slide it while updating the mismatch count and keep min(cnt,n-cnt).

We notice that operation 1 effectively turns the string into a cycle, and operation 2 makes a substring of length n within the cycle into an alternating binary string.

Therefore, we only need to enumerate each substring of length n, calculate the cost to make it an alternating binary string, and take the minimum.

We can pre-calculate the number of differences between string s and the two types of alternating binary strings, denoted as cnt. The cost to make s into the first type of alternating binary string is cnt, and the cost to make s into the second type is n - cnt. We initialize ans = min(cnt, n - cnt).

Next, we enumerate each substring of length n and update the value of cnt. For each position i, we subtract the difference of s[i] from the first type of alternating binary string, and add the difference of s[i] to the second type. We update ans = min(ans, cnt, n - cnt).

Finally, return ans.

The time complexity is O(n), where n is the length of the string. The space complexity is O(1).

Python 3

```python
class Solution:
    def minFlips(self, s: str) -> int:
        n = len(s)
        target = "01"
        cnt = sum(c != target[i & 1] for i, c in enumerate(s))
        ans = min(cnt, n - cnt)
        for i in range(n):
            cnt -= s[i] != target[i & 1]
            cnt += s[i] != target[(i + n) & 1]
            ans = min(ans, cnt, n - cnt)
        return ans
```

PATTERN 2 · SLIDING WINDOW · PROBLEM 18 OF 20

76. Minimum Window Substring

Hard · Hash Table, String, Sliding Window

leetcode.com/problems/minimum-window-substring

★ **TOP 10 PROBLEM** in Sliding Window, Sliding Window Maximum / Minimum (Specific Variants): master this one first

Also appears in pattern 6 String Manipulation / Parsing, 7 String Matching / Pattern Search, 35 Sliding Window Maximum / Minimum (Specific Variants)

PROBLEM

Given two strings `s` and `t` of lengths `m` and `n` respectively, return *the* ***minimum window substring*** *of* `s` *such that every character in* `t` *(****including duplicates****) is included in the window*. If there is no such substring, return *the empty string* `""`.

The testcases will be generated such that the answer is **unique**.

Example 1:

```
Input: s = "ADOBECODEBANC", t = "ABC"
Output: "BANC"
Explanation: The minimum window substring "BANC" includes 'A', 'B', and 'C' from string t.
```

Example 2:

```
Input: s = "a", t = "a"
Output: "a"
Explanation: The entire string s is the minimum window.
```

Example 3:

```
Input: s = "a", t = "aa"
Output: ""
Explanation: Both 'a's from t must be included in the window.
Since the largest window of s only has one 'a', return empty string.
```

Constraints:

- `m == s.length`
- `n == t.length`
- `1 <= m, n <=` 10^5
- `s` and `t` consist of uppercase and lowercase English letters.

Follow up: Could you find an algorithm that runs in `O(m + n)` time?

SOLUTION (PYTHON 3)

Solution 1: Counting + Two Pointers

How to think about it

Enumerate every substring of s and test coverage of t: O(m^2) windows, m ≤ 10^5 will TLE. The follow-up wants O(m+n). Once a window covers, extra characters on the left can go; if it does not cover, only the right end can grow. need stores t's quota, window stores the window, and cnt counts how many required occurrences are met, so coverage is O(1). Scan s with the right pointer; while valid, shrink the left and record the shortest span.

We use a hash table or array need to count the occurrences of each character in string t, and another hash table or array window to count the occurrences of each character in the sliding window. Additionally, we define two pointers l and r to point to the left and right boundaries of the window, a variable cnt to represent how many characters from t are already included in the window, and variables k and mi to represent the starting position and length of the minimum window substring.

We traverse the string s from left to right. For the current character s[r]:

- We add it to the window, i.e., window[s[r]] = window[s[r]] + 1. If need[s[r]] ≥ window[s[r]], it means s[r] is a "necessary character", and we increment cnt by one.
- If cnt equals the length of t, it means the window already contains all characters from t, and we can try to update the starting position and length of the minimum window substring. If r - l + 1 < mi, it means the current window represents a shorter substring, so we update mi = r - l + 1 and k = l.
- Then, we try to move the left boundary l. If need[s[l]] ≥ window[s[l]], it means s[l] is a "necessary character", and moving the left boundary will remove s[l] from the window. Therefore, we need to decrement cnt by one, update window[s[l]] = window[s[l]] - 1, and move l one position to the right.
- If cnt is not equal to the length of t, it means the window does not yet contain all characters from t, so we do not need to move the left boundary. Instead, we move r one position to the right and continue traversing.

After the traversal, if no minimum window substring is found, return an empty string. Otherwise, return s[k:k+mi].

The time complexity is O(m + n), and the space complexity is O(|Σ|). Here, m and n are the lengths of strings s and t, respectively; and |Σ| is the size of the character set, which is 128 in this problem.

Python 3

```python
class Solution:
    def minWindow(self, s: str, t: str) -> str:
        need = Counter(t)
        window = Counter()
        cnt = l = 0
        k, mi = -1, inf
        for r, c in enumerate(s):
            window[c] += 1
            if need[c] >= window[c]:
                cnt += 1
            while cnt == len(t):
                if r - l + 1 < mi:
                    mi = r - l + 1
                    k = l
                if need[s[l]] >= window[s[l]]:
                    cnt -= 1
                window[s[l]] -= 1
                l += 1
        return "" if k < 0 else s[k : k + mi]
```

PATTERN 2 · SLIDING WINDOW · PROBLEM 19 OF 20

239. Sliding Window Maximum

Hard · Queue, Array, Sliding Window, Monotonic Queue, Heap (Priority Queue), Range Query

leetcode.com/problems/sliding-window-maximum

★ **TOP 10 PROBLEM** in Sliding Window, Queue / Deque, Sliding Window Maximum / Minimum (Specific Variants): master this one first

Also appears in pattern 9 Monotonic Stack / Queue (Specific Variants), 10 Queue / Deque, 35 Sliding Window Maximum / Minimum (Specific Variants)

PROBLEM

You are given an array of integers `nums`, there is a sliding window of size `k` which is moving from the very left of the array to the very right. You can only see the `k` numbers in the window. Each time the sliding window moves right by one position.

Return *the max sliding window*.

Example 1:

```
Input: nums = [1,3,-1,-3,5,3,6,7], k = 3
Output: [3,3,5,5,6,7]
Explanation:
Window position Max
--------------- -----
[1 3 -1] -3 5 3 6 7 3
 1 [3 -1 -3] 5 3 6 7 3
 1 3 [-1 -3 5] 3 6 7 5
 1 3 -1 [-3 5 3] 6 7 5
 1 3 -1 -3 [5 3 6] 7 6
 1 3 -1 -3 5 [3 6 7] 7
```

Example 2:

```
Input: nums = [1], k = 1
Output: [1]
```

Constraints:

- `1 <= nums.length <= 10^5`
- `-10^4 <= nums[i] <= 10^4`
- `1 <= k <= nums.length`

SOLUTIONS (PYTHON 3)

Solution 1: Priority Queue (Max-Heap)

How to think about it

A linear scan inside every window is O(nk). A max-heap reports the current maximum in logarithmic time; stale indices are popped only when they reach the top. Load the first k-1 values, then push each new index, drop expired tops, and record the top.

We can use a priority queue (max-heap) to maintain the maximum value in the sliding window.

First, add the first k-1 elements to the priority queue. Then, starting from the k-th element, add the new element to the priority queue and check if the top element of the heap is out of the window. If it is, remove the top element. Then, add the top element of the heap to the result array.

The time complexity is O(n × log k), and the space complexity is O(k). Here, n is the length of the array.

Python 3

```python
class Solution:
    def maxSlidingWindow(self, nums: List[int], k: int) -> List[int]:
        q = [(-v, i) for i, v in enumerate(nums[: k - 1])]
        heapify(q)
        ans = []
        for i in range(k - 1, len(nums)):
            heappush(q, (-nums[i], i))
            while q[0][1] <= i - k:
                heappop(q)
            ans.append(-q[0][0])
        return ans
```

Solution 2: Monotonic Queue

> **How to think about it**
>
> The heap may hold stale indices and still pays a log factor. Only a decreasing sequence of candidates can become the window maximum. A monotonic queue of indices drops the front when it leaves the window and the back when it is ≤ the new value; the front is the maximum, in linear time.

To find the maximum value in a sliding window, a common method is to use a monotonic queue.

We can maintain a queue q that is monotonically decreasing from the front to the back, storing the indices of the elements. As we traverse the array nums, for the current element nums[i], we first check if the front element of the queue is out of the window. If it is, we remove the front element. Then, we compare the current element nums[i] with the elements at the back of the queue. If the elements at the back are less than or equal to the current element, we remove them until the element at the back is greater than the current element or the queue is empty. Then, we add the index of the current element to the queue. At this point, the front element of the queue is the maximum value of the current sliding window. Note that we add the front element of the queue to the result array when the index i is greater than or equal to k-1.

The time complexity is O(n), and the space complexity is O(k). Here, n is the length of the array nums.

Python 3

```python
class Solution:
    def maxSlidingWindow(self, nums: List[int], k: int) -> List[int]:
        q = deque()
        ans = []
        for i, x in enumerate(nums):
            if q and i - q[0] >= k:
                q.popleft()
            while q and nums[q[-1]] <= x:
                q.pop()
            q.append(i)
            if i >= k - 1:
                ans.append(nums[q[0]])
        return ans
```

PATTERN 3 OF 41

Two Pointers

20 problems · 9 Easy · 9 Medium · 2 Hard

THE IDEA

Two indexes walk over the data (towards each other, or in the same direction) so each element is looked at a constant number of times. Usually needs sorted input or a partition rule.

Signals: sorted array and a pair or triple with a sum, remove or compact in place, palindrome checks, merge two sorted lists, container with most water.

A TEMPLATE TO KEEP IN YOUR HANDS (PYTHON)

```
i, j = 0, len(a) - 1
while i < j:
    total = a[i] + a[j]
    if total == target:
        return [i, j]
    if total < target:
        i += 1          # need more: move the small side up
    else:
        j -= 1          # need less: move the big side down
```

PATTERN 3 · TWO POINTERS · PROBLEM 1 OF 20

125. Valid Palindrome

Easy · Two Pointers, String

leetcode.com/problems/valid-palindrome

★ **TOP 10 PROBLEM** in Two Pointers: master this one first

PROBLEM

A phrase is a **palindrome** if, after converting all uppercase letters into lowercase letters and removing all non-alphanumeric characters, it reads the same forward and backward. Alphanumeric characters include letters and numbers.

Given a string `s`, return `true` *if it is a* ***palindrome****, or* `false` *otherwise*.

Example 1:

```
Input: s = "A man, a plan, a canal: Panama"
Output: true
Explanation: "amanaplanacanalpanama" is a palindrome.
```

Example 2:

```
Input: s = "race a car"
Output: false
Explanation: "raceacar" is not a palindrome.
```

Example 3:

```
Input: s = " "
Output: true
Explanation: s is an empty string "" after removing non-alphanumeric characters.
Since an empty string reads the same forward and backward, it is a palindrome.
```

Constraints:

- `1 <= s.length <= 2 * 10^5`
- `s` consists only of printable ASCII characters.

SOLUTION (PYTHON 3)

Solution 1: Two Pointers

How to think about it

Check whether the string is a palindrome after ignoring case and non-alphanumeric characters. Filtering into a new string and reversing works at n ≤ 2× 10^5, but uses O(n) extra space. A palindrome only needs matching pairs. Two pointers walk inward: skip illegal characters, compare legal ones case-insensitively. One pass, constant space.

We use two pointers i and j to point to the two ends of the string s, and then loop through the following process until i ≥ j:

1. If s[i] is not a letter or a number, move the pointer i one step to the right and continue to the next loop.
2. If s[j] is not a letter or a number, move the pointer j one step to the left and continue to the next loop.
3. If the lowercase form of s[i] and s[j] are not equal, return `false`.
4. Otherwise, move the pointer i one step to the right and the pointer j one step to the left, and continue to the next loop.

At the end of the loop, return `true`.

The time complexity is O(n), where n is the length of the string s. The space complexity is O(1).

Python 3

```python
class Solution:
    def isPalindrome(self, s: str) -> bool:
        i, j = 0, len(s) - 1
        while i < j:
            if not s[i].isalnum():
                i += 1
            elif not s[j].isalnum():
                j -= 1
            elif s[i].lower() != s[j].lower():
                return False
            else:
                i, j = i + 1, j - 1
        return True
```

        if length > best_length:
            best_length = length
            best_start = left + 1
    return s[best_start:best_start + best_length]
```

PATTERN 3 · TWO POINTERS · PROBLEM 2 OF 20

344. Reverse String

Easy · Two Pointers, String

leetcode.com/problems/reverse-string

PROBLEM

Write a function that reverses a string. The input string is given as an array of characters `s`.

You must do this by modifying the input array in-place with `O(1)` extra memory.

Example 1:

```
Input: s = ["h","e","l","l","o"]
Output: ["o","l","l","e","h"]
```

Example 2:

```
Input: s = ["H","a","n","n","a","h"]
Output: ["h","a","n","n","a","H"]
```

Constraints:

- `1 <= s.length <= 10^5`
- `s[i]` is a printable ascii character.

SOLUTION (PYTHON 3)

Solution 1: Two Pointers

> **How to think about it**
>
> Reverse a character array in place. A second buffer uses O(n) space. Swapping ends is enough. Two pointers i,j start at the ends, swap, and move inward until they meet. One pass, constant extra space.

We use two pointers i and j, initially pointing to the start and end of the array respectively. Each time, we swap the elements at i and j, then move i forward and j backward, until i and j meet.

The time complexity is O(n), where n is the length of the array. The space complexity is O(1).

Python 3

```python
class Solution:
    def reverseString(self, s: List[str]) -> None:
        i, j = 0, len(s) - 1
        while i < j:
            s[i], s[j] = s[j], s[i]
            i, j = i + 1, j - 1
```

283. Move Zeroes

Easy · Array, Two Pointers

leetcode.com/problems/move-zeroes

★ **TOP 10 PROBLEM** in Two Pointers: master this one first

Also appears in pattern 33 Cyclic Sort

PROBLEM

Given an integer array `nums`, move all `0`'s to the end of it while maintaining the relative order of the non-zero elements.

Note that you must do this in-place without making a copy of the array.

Example 1:

```
Input: nums = [0,1,0,3,12]
Output: [1,3,12,0,0]
```

Example 2:

```
Input: nums = [0]
Output: [0]
```

Constraints:

- `1 <= nums.length <= 10^4`
- `-2^31 <= nums[i] <= 2^31 - 1`

Follow up:

Could you minimize the total number of operations done?

SOLUTION (PYTHON 3)

Solution 1: Two Pointers

How to think about it

Zeros must go to the end while nonzeros keep their order. Let k be the next slot for a nonzero. Each nonzero is swapped with nums[k] and k advances, so the prefix of length k is the original nonzero sequence.

We use a pointer k to record the current position to insert, initially k = 0.

Then we iterate through the array nums, and each time we encounter a non-zero number, we swap it with nums[k] and increment k by 1.

This way, we can ensure that the first k elements of nums are non-zero, and their relative order is the same as in the original array.

The time complexity is O(n), where n is the length of the array nums. The space complexity is O(1).

Python 3

```python
class Solution:
    def moveZeroes(self, nums: List[int]) -> None:
        k = 0
        for i, x in enumerate(nums):
            if x:
                nums[k], nums[i] = nums[i], nums[k]
                k += 1
```

    return writes
```

PATTERN 3 · TWO POINTERS · PROBLEM 4 OF 20

27. Remove Element

Easy · Array, Two Pointers

leetcode.com/problems/remove-element

PROBLEM

Given an integer array `nums` and an integer `val`, remove all occurrences of `val` in `nums` **in-place**. The order of the elements may be changed. Then return *the number of elements in* `nums` *which are not equal to* `val`.

Consider the number of elements in `nums` which are not equal to `val` be `k`, to get accepted, you need to do the following things:

- Change the array `nums` such that the first `k` elements of `nums` contain the elements which are not equal to `val`. The remaining elements of `nums` are not important as well as the size of `nums`.
- Return `k`.

Custom Judge:

The judge will test your solution with the following code:

```
int[] nums = [...]; // Input array
int val = ...; // Value to remove
int[] expectedNums = [...]; // The expected answer with correct length.
                            // It is sorted with no values equaling val.

int k = removeElement(nums, val); // Calls your implementation

assert k == expectedNums.length;
sort(nums, 0, k); // Sort the first k elements of nums
for (int i = 0; i < actualLength; i++) {
    assert nums[i] == expectedNums[i];
}
```

If all assertions pass, then your solution will be **accepted**.

Example 1:

```
Input: nums = [3,2,2,3], val = 3
Output: 2, nums = [2,2,_,_]
Explanation: Your function should return k = 2, with the first two elements of nums being 2.
It does not matter what you leave beyond the returned k (hence they are underscores).
```

Example 2:

```
Input: nums = [0,1,2,2,3,0,4,2], val = 2
Output: 5, nums = [0,1,4,0,3,_,_,_]
Explanation: Your function should return k = 5, with the first five elements of nums containing 0, 0,
1, 3, and 4.
Note that the five elements can be returned in any order.
It does not matter what you leave beyond the returned k (hence they are underscores).
```

Constraints:

- `0 <= nums.length <= 100`
- `0 <= nums[i] <= 50`
- `0 <= val <= 100`

SOLUTION (PYTHON 3)

Solution 1: One Pass

How to think about it

The first idea is a fresh array of everything not equal to val. n ≤ 100 would pass, but the problem asks for an in-place rewrite, so the extra allocation is unnecessary. The bottleneck is "deleting" with something like erase: later elements shift again and again, worst case $O(n^2)$. The judge only cares that the first k slots hold every non-val value; order may change. So overwrite the front of the array with the values we keep. k counts how many we have written: when x ≠ val, store it at nums[k] and increment k. One pass, O(1) extra space.

We use the variable k to record the number of elements that are not equal to val.

Traverse the array nums, if the current element x is not equal to val, then assign x to nums[k], and increment k by 1.

Finally, return k.

The time complexity is O(n) and the space complexity is O(1), where n is the length of the array nums.

Python 3

```
class Solution:
    def removeElement(self, nums: List[int], val: int) -> int:
        k = 0
        for x in nums:
            if x != val:
                nums[k] = x
                k += 1
        return k
```

PATTERN 3 · TWO POINTERS · PROBLEM 5 OF 20

977. Squares of a Sorted Array

Easy · Array, Two Pointers, Sorting

leetcode.com/problems/squares-of-a-sorted-array

★ **TOP 10 PROBLEM** in Two Pointers: master this one first

PROBLEM

Given an integer array `nums` sorted in **non-decreasing** order, return *an array of **the squares of each number** sorted in non-decreasing order*.

Example 1:

```
Input: nums = [-4,-1,0,3,10]
Output: [0,1,9,16,100]
Explanation: After squaring, the array becomes [16,1,0,9,100].
After sorting, it becomes [0,1,9,16,100].
```

Example 2:

```
Input: nums = [-7,-3,2,3,11]
Output: [4,9,9,49,121]
```

Constraints:

- `1 <= nums.length <= 10^4`
- `-10^4 <= nums[i] <= 10^4`
- `nums` is sorted in **non-decreasing** order.

Follow up:

Squaring each element and sorting the new array is very trivial, could you find an

`O(n)`

solution using a different approach?

SOLUTION (PYTHON 3)

Solution 1: Two Pointers

How to think about it

A sorted array may contain negatives, so the squares must be reordered. Squaring then sorting is O(nlog n). After squaring, the ends are large and the middle is small, so two pointers pick the larger square and write from the back (or append then reverse), in linear time.

Since the array nums is already sorted in non-decreasing order, the square values of the negative numbers in the array are decreasing, and the square values of the positive numbers are increasing. We can use two pointers, each pointing to the ends of the array. Each time we compare the square values of the elements pointed to by the two pointers, we put the larger square value at the end of the result array.

The time complexity is O(n), where n is the length of the array nums. Ignoring the space consumption of the answer array, the space complexity is O(1).

Python 3

```python
class Solution:
    def sortedSquares(self, nums: List[int]) -> List[int]:
        ans = []
        i, j = 0, len(nums) - 1
        while i <= j:
            a = nums[i] * nums[i]
            b = nums[j] * nums[j]
            if a > b:
                ans.append(a)
                i += 1
            else:
                ans.append(b)
                j -= 1
        return ans[::-1]
```

```

PATTERN 3 · TWO POINTERS · PROBLEM 6 OF 20

26. Remove Duplicates from Sorted Array

Easy · Array, Two Pointers

leetcode.com/problems/remove-duplicates-from-sorted-array

PROBLEM

Given an integer array `nums` sorted in **non-decreasing order**, remove the duplicates **in-place** such that each unique element appears only **once**. The **relative order** of the elements should be kept the **same**.

Consider the number of *unique elements* in `nums` to be `k□□□□□□□`. After removing duplicates, return the number of unique elements `k`.

The first `k` elements of `nums` should contain the unique numbers in **sorted order**. The remaining elements beyond index `k - 1` can be ignored.

Custom Judge:

The judge will test your solution with the following code:

```
int[] nums = [...]; // Input array
int[] expectedNums = [...]; // The expected answer with correct length

int k = removeDuplicates(nums); // Calls your implementation

assert k == expectedNums.length;
for (int i = 0; i < k; i++) {
    assert nums[i] == expectedNums[i];
}
```

If all assertions pass, then your solution will be **accepted**.

Example 1:

```
Input: nums = [1,1,2]
Output: 2, nums = [1,2,_]
Explanation: Your function should return k = 2, with the first two elements of nums being 1 and 2
respectively.
It does not matter what you leave beyond the returned k (hence they are underscores).
```

Example 2:

```
Input: nums = [0,0,1,1,1,2,2,3,3,4]
Output: 5, nums = [0,1,2,3,4,_,_,_,_,_]
Explanation: Your function should return k = 5, with the first five elements of nums being 0, 1, 2, 3,
and 4 respectively.
It does not matter what you leave beyond the returned k (hence they are underscores).
```

Constraints:

- `1 <= nums.length <= 3 * 10^4`
- `-100 <= nums[i] <= 100`
- `nums` is sorted in **non-decreasing** order.

SOLUTION (PYTHON 3)

Solution 1: Single Pass

How to think about it

The first idea is a hash set of seen values, then write them back. n ≤ 3× 10^4 would pass, but the problem wants an in-place rewrite, so the extra table is wasteful. The bottleneck is the "have we seen this" query. The array is non-decreasing, so equals sit next to each other and a global lookup is unnecessary. Compare x with the last value already written. If it differs (or nothing has been written yet), write it at index k; otherwise skip. k is both the write pointer and the unique length. One pass, O(1) extra space.

We use a variable k to record the current length of the processed array. Initially, k=0 represents an empty array.

Then we traverse the array from left to right. For each element x we encounter, if k=0 or x ≠ nums[k-1], we place x in the position of nums[k], and then increment k by 1. Otherwise, x is the same as nums[k-1], so we skip this element. Continue to traverse until the entire array is traversed.

In this way, when the traversal ends, the first k elements in nums are the answer we are looking for, and k is the length of the answer.

The time complexity is O(n), and the space complexity is O(1). Here, n is the length of the array.

Supplement:

The original problem requires that the same number appear at most once. We can extend it to keep at most k identical numbers.

- Since the same number can be kept at most k times, we can directly keep the first k elements of the original array;
- For the following numbers, the premise of being able to keep them is: the current number x is compared with the last kth element of the previously retained numbers. If they are different, keep them, otherwise skip them.

```

PATTERN 3 · TWO POINTERS · PROBLEM 7 OF 20

680. Valid Palindrome II

Easy · Greedy, Two Pointers, String

leetcode.com/problems/valid-palindrome-ii

PROBLEM

Given a string `s`, return `true` *if the* `s` *can be palindrome after deleting* ***at most one*** *character from it*.

Example 1:

```
Input: s = "aba"
Output: true
```

Example 2:

```
Input: s = "abca"
Output: true
Explanation: You could delete the character 'c'.
```

Example 3:

```
Input: s = "abc"
Output: false
```

Constraints:

- `1 <= s.length <= 10^5`
- `s` consists of lowercase English letters.

SOLUTION (PYTHON 3)

Solution 1: Two Pointers

How to think about it

Delete at most one character to make a palindrome. Trying every deletion is quadratic for $n \le 10^5$. Two pointers meet a mismatch at most once: check the remaining interval after skipping the left or the right character. The extra scan is still linear.

We use two pointers to point to the left and right ends of the string, respectively. Each time, we check whether the characters pointed to by the two pointers are the same. If they are not the same, we check whether the string is a palindrome after deleting the character corresponding to the left pointer, or we check whether the string is a palindrome after deleting the character corresponding to the right pointer. If the characters pointed to by the two pointers are the same, we move both pointers towards the middle by one position, until the two pointers meet.

If we have not encountered a situation where the characters pointed to by the pointers are different by the end of the traversal, then the string itself is a palindrome, and we return `true`.

The time complexity is O(n), where n is the length of the string s. The space complexity is O(1).

Python 3

```python
class Solution:
    def validPalindrome(self, s: str) -> bool:
        def check(i, j):
            while i < j:
                if s[i] != s[j]:
                    return False
                i, j = i + 1, j - 1
            return True

        i, j = 0, len(s) - 1
        while i < j:
            if s[i] != s[j]:
                return check(i, j - 1) or check(i + 1, j)
            i, j = i + 1, j - 1
        return True
```

PATTERN 3 · TWO POINTERS · PROBLEM 8 OF 20

844. Backspace String Compare

Easy · Stack, Two Pointers, String, Simulation

leetcode.com/problems/backspace-string-compare

Also appears in pattern 8 Stack

PROBLEM

Given two strings `s` and `t`, return `true` *if they are equal when both are typed into empty text editors*. `'#'` means a backspace character.

Note that after backspacing an empty text, the text will continue empty.

Example 1:

```
Input: s = "ab#c", t = "ad#c"
Output: true
Explanation: Both s and t become "ac".
```

Example 2:

```
Input: s = "ab##", t = "c#d#"
Output: true
Explanation: Both s and t become "".
```

Example 3:

```
Input: s = "a#c", t = "b"
Output: false
Explanation: s becomes "c" while t becomes "b".
```

Constraints:

- `1 <= s.length, t.length <= 200`
- `s` and `t` only contain lowercase letters and `'#'` characters.

Follow up: Can you solve it in `O(n)` time and `O(1)` space?

SOLUTION (PYTHON 3)

Solution 1

How to think about it

We compare two strings after applying backspaces. Building the cleaned strings uses extra linear space; the intended scan works on the originals. Walk right to left, letting a skip counter consume `#` and the characters they delete, then compare the next live characters. If one side runs out first, they differ.

Python 3

```python
class Solution:
    def backspaceCompare(self, s: str, t: str) -> bool:
        i, j, skip1, skip2 = len(s) - 1, len(t) - 1, 0, 0
        while i >= 0 or j >= 0:
            while i >= 0:
                if s[i] == '#':
                    skip1 += 1
                    i -= 1
                elif skip1:
                    skip1 -= 1
                    i -= 1
                else:
                    break
            while j >= 0:
                if t[j] == '#':
                    skip2 += 1
                    j -= 1
                elif skip2:
                    skip2 -= 1
                    j -= 1
                else:
                    break
            if i >= 0 and j >= 0:
                if s[i] != t[j]:
                    return False
            elif i >= 0 or j >= 0:
                return False
            i, j = i - 1, j - 1
        return True
```

Complexity. Time: O(n + m). Space: O(1).

PATTERN 3 · TWO POINTERS · PROBLEM 9 OF 20

167. Two Sum II - Input Array Is Sorted

Medium · Array, Two Pointers, Binary Search

leetcode.com/problems/two-sum-ii-input-array-is-sorted

★ **TOP 10 PROBLEM** in Two Pointers: master this one first

PROBLEM

You are given a **1-indexed** array of integers `numbers` that is already **sorted in non-decreasing order**.

Find **two** numbers such that they add up to a specific `target` number. Let these two numbers be `numbers[index1]` and `numbers[index2]` where `1 <= index1 < index2 <= numbers.length`.

Return the indices of the two numbers `index1` and `index2` as an integer array `[index1, index2]` of length 2.

The tests are generated such that there is **exactly one solution**. You **may not** use the same element twice.

Your solution must use only constant extra space.

Example 1:

```
Input: numbers = [2,7,11,15], target = 9
Output: [1,2]
Explanation: The sum of 2 and 7 is 9. Therefore, index1 = 1, index2 = 2. We return [1, 2].
```

Example 2:

```
Input: numbers = [2,3,4], target = 6
Output: [1,3]
Explanation: The sum of 2 and 4 is 6. Therefore index1 = 1, index2 = 3. We return [1, 3].
```

Example 3:

```
Input: numbers = [-1,0], target = -1
Output: [1,2]
Explanation: The sum of -1 and 0 is -1. Therefore index1 = 1, index2 = 2. We return [1, 2].
```

Constraints:

- `2 <= numbers.length <= 3 * 10^4`
- `-1000 <= numbers[i] <= 1000`
- `numbers` is sorted in **non-decreasing order**.
- `-1000 <= target <= 1000`
- The tests are generated such that there is **exactly one solution**.

SOLUTIONS (PYTHON 3)

Solution 1: Binary Search

How to think about it

Two sum on a sorted array, 1-based indices, exactly one pair. A hash map uses O(n) space. For each numbers[i] binary-search target-numbers[i] on the right. n≤ 3× 10^4, so O(nlog n) time and O(1) space.

Note that the array is sorted in non-decreasing order, so for each `numbers[i]`, we can find the position of `target - numbers[i]` by binary search, and return [i + 1, j + 1] if it exists.

The time complexity is O(n × log n), where n is the length of the array `numbers`. The space complexity is O(1).

Python 3

```python
class Solution:
    def twoSum(self, numbers: List[int], target: int) -> List[int]:
        n = len(numbers)
        for i in range(n - 1):
            x = target - numbers[i]
            j = bisect_left(numbers, x, lo=i + 1)
            if j < n and numbers[j] == x:
                return [i + 1, j + 1]
```

Solution 2: Two Pointers

> **How to think about it**
>
> Solution 1 binary-searches at every left index. Two pointers from the ends: a small sum moves the left pointer right, a large sum moves the right pointer left. Sorted order cannot miss the unique pair, and the time becomes O(n).

We define two pointers i and j, which point to the first element and the last element of the array respectively. Each time we calculate numbers[i] + numbers[j]. If the sum is equal to the target value, return [i + 1, j + 1] directly. If the sum is less than the target value, move i to the right by one position, and if the sum is greater than the target value, move j to the left by one position.

The time complexity is O(n), where n is the length of the array `numbers`. The space complexity is O(1).

Python 3

```python
class Solution:
    def twoSum(self, numbers: List[int], target: int) -> List[int]:
        i, j = 0, len(numbers) - 1
        while i < j:
            x = numbers[i] + numbers[j]
            if x == target:
                return [i + 1, j + 1]
            if x < target:
                i += 1
            else:
                j -= 1
```

PATTERN 3 · TWO POINTERS · PROBLEM 10 OF 20

80. Remove Duplicates from Sorted Array II

Medium · Array, Two Pointers

leetcode.com/problems/remove-duplicates-from-sorted-array-ii

★ **TOP 10 PROBLEM** in Two Pointers: master this one first

PROBLEM

Given an integer array `nums` sorted in **non-decreasing order**, remove some duplicates **in-place** such that each unique element appears **at most twice**. The **relative order** of the elements should be kept the **same**.

Since it is impossible to change the length of the array in some languages, you must instead have the result be placed in the **first part** of the array `nums`. More formally, if there are `k` elements after removing the duplicates, then the first `k` elements of `nums` should hold the final result. It does not matter what you leave beyond the first `k` elements.

Return `k` *after placing the final result in the first* `k` *slots of* `nums`.

Do **not** allocate extra space for another array. You must do this by **modifying the input array in-place** with O(1) extra memory.

Custom Judge:

The judge will test your solution with the following code:

```
int[] nums = [...]; // Input array
int[] expectedNums = [...]; // The expected answer with correct length

int k = removeDuplicates(nums); // Calls your implementation

assert k == expectedNums.length;
for (int i = 0; i < k; i++) {
    assert nums[i] == expectedNums[i];
}
```

If all assertions pass, then your solution will be **accepted**.

Example 1:

```
Input: nums = [1,1,1,2,2,3]
Output: 5, nums = [1,1,2,2,3,_]
Explanation: Your function should return k = 5, with the first five elements of nums being 1, 1, 2, 2
and 3 respectively.
It does not matter what you leave beyond the returned k (hence they are underscores).
```

Example 2:

```
Input: nums = [0,0,1,1,1,1,2,3,3]
Output: 7, nums = [0,0,1,1,2,3,3,_,_]
Explanation: Your function should return k = 7, with the first seven elements of nums being 0, 0, 1, 1,
2, 3 and 3 respectively.
It does not matter what you leave beyond the returned k (hence they are underscores).
```

Constraints:

- $1 <= nums.length <= 3 * 10^4$
- $-10^4 <= nums[i] <= 10^4$
- `nums` is sorted in **non-decreasing** order.

SOLUTION (PYTHON 3)

Solution 1: Single Pass

How to think about it

Copy into a new array, at most two of each value: correct, but the problem wants in-place O(1) extra space. $n \le 3\times 10^4$, so one pass. Sorted runs are contiguous; problem 26 keeps one copy, here we keep two. Let k be the length of the kept prefix: x may be written iff fewer than two are kept, or it differs from the second-to-last kept value — otherwise it would be a third copy. Write at nums[k], bump k, return k.

We use a variable k to record the current length of the array that has been processed. Initially, k=0, representing an empty array.

Then we traverse the array from left to right. For each element x we traverse, if k < 2 or x ≠ nums[k-2], we put x in the position of nums[k], and then increment k by 1. Otherwise, x is the same as nums[k-2], we directly skip this element. Continue to traverse until the entire array is traversed.

In this way, when the traversal ends, the first k elements in nums are the answer we want, and k is the length of the answer.

The time complexity is O(n), and the space complexity is O(1). Here, n is the length of the array.

Supplement:

The original problem requires that the same number appears at most 2 times. We can extend it to keep at most k identical numbers.

- Since the same number can be kept at most k times, we can directly keep the first k elements of the original array;
- For the later numbers, the premise of being able to keep them is: the current number x compares with the kth element from the end of the previously kept numbers. If they are different, keep it, otherwise skip it.

```

PATTERN 3 · TWO POINTERS · PROBLEM 11 OF 20

75. Sort Colors

Medium · Array, Two Pointers, Bubble Sort, Sorting, Quick Sort

leetcode.com/problems/sort-colors

★ **TOP 10 PROBLEM** in Two Pointers, Sorting, Cyclic Sort: master this one first

Also appears in pattern 23 Sorting, 33 Cyclic Sort

PROBLEM

You are given an array `nums` with `n` objects colored red, white, or blue, sort them **in-place** so that objects of the same color are adjacent, with the colors in the order red, white, and blue.

We will use the integers 0, 1, and 2 to represent the color red, white, and blue, respectively.

You must solve this problem without using the library's sort function.

Example 1:

Input: nums = [2,0,2,1,1,0]

Output: [0,0,1,1,2,2]

Explanation:

The array has two 0s, two 1s, and two 2s. Sorting them in-place places all 0s first, then all 1s, then all 2s.

Example 2:

Input: nums = [2,0,1]

Output: [0,1,2]

Explanation:

The array has one each of 0, 1, and 2, arranged in-place in the order 0, 1, 2.

Constraints:

- `n == nums.length`
- `1 <= n <= 300`
- `nums[i]` is either 0, 1, or 2.

Follow up: Could you come up with a one-pass algorithm using only constant extra space?

SOLUTION (PYTHON 3)

Solution 1: Three Pointers

How to think about it

Count 0,1,2 then overwrite: two passes. Sorting would also work for n ≤ 300. The problem forbids library sort, and the follow-up wants one scan and O(1) space. Three values only need a partition into all 0s, all 1s, and all 2s. Let i and j bound the 0s and 2s already placed, and let k scan the unknown middle. A swap toward 2 brings an unseen value, so k stays; a swap toward 0 brings a value from the scanned range, so k advances too. One pass finishes the three segments.

We define three pointers i, j, and k. Pointer i is used to point to the rightmost boundary of the elements with a value of 0 in the array, and pointer j is used to point to the leftmost boundary of the elements with a value of 2 in the array. Initially, i=-1, j=n. Pointer k is used to point to the current element being traversed, initially k=0.

When k < j, we perform the following operations:

- If nums[k] = 0, then swap it with nums[i+1], then increment both i and k by 1;
- If nums[k] = 2, then swap it with nums[j-1], then decrement j by 1;

- If nums[k] = 1, then increment k by 1.

After the traversal, the elements in the array are divided into three parts: [0,i], [i+1,j-1] and [j,n-1].

The time complexity is O(n), where n is the length of the array. Only one traversal of the array is needed. The space complexity is O(1).

Python 3

```
class Solution:
    def sortColors(self, nums: List[int]) -> None:
        i, j, k = -1, len(nums), 0
        while k < j:
            if nums[k] == 0:
                i += 1
                nums[i], nums[k] = nums[k], nums[i]
                k += 1
            elif nums[k] == 2:
                j -= 1
                nums[j], nums[k] = nums[k], nums[j]
            else:
                k += 1
```

```

PATTERN 3 · TWO POINTERS · PROBLEM 12 OF 20

189. Rotate Array

Medium · Array, Math, Two Pointers

leetcode.com/problems/rotate-array

★ **TOP 10 PROBLEM** in Simulation / Array Rearrangement: master this one first

Also appears in pattern 36 Simulation / Array Rearrangement

PROBLEM

Given an integer array `nums`, rotate the array to the right by `k` steps, where `k` is non-negative.

Example 1:

```
Input: nums = [1,2,3,4,5,6,7], k = 3
Output: [5,6,7,1,2,3,4]
Explanation:
rotate 1 steps to the right: [7,1,2,3,4,5,6]
rotate 2 steps to the right: [6,7,1,2,3,4,5]
rotate 3 steps to the right: [5,6,7,1,2,3,4]
```

Example 2:

```
Input: nums = [-1,-100,3,99], k = 2
Output: [3,99,-1,-100]
Explanation:
rotate 1 steps to the right: [99,-1,-100,3]
rotate 2 steps to the right: [3,99,-1,-100]
```

Constraints:

- `1 <= nums.length <= 10^5`
- `-2^31 <= nums[i] <= 2^31 - 1`
- `0 <= k <= 10^5`

Follow up:

- Try to come up with as many solutions as you can. There are at least **three** different ways to solve this problem.
- Could you do it in-place with `O(1)` extra space?

SOLUTION (PYTHON 3)

Solution 1: Reverse three times

How to think about it

Rotate right by k. A second array is O(n) space; n≤ 10^5, and the follow-up wants in-place. A right rotate by k moves the last k items to the front. Reverse the whole array, then reverse the first k and the last n-k. Three reversals, only swaps.

We can assume the length of the array is n and calculate the actual number of steps needed by taking the module of k and n, which is k mod n.

Next, let us reverse three times to get the final result:

1. Reverse the entire array.
2. Reverse the first k elements.
3. Reverse the last n - k elements.

For example, for the array [1, 2, 3, 4, 5, 6, 7], k = 3, n = 7, k mod n = 3.

1. In the first reverse, reverse the entire array. We get [7, 6, 5, 4, 3, 2, 1].
2. In the second reverse, reverse the first k elements. We get [5, 6, 7, 4, 3, 2, 1].

3. In the third reverse, reverse the last n - k elements. We get [5, 6, 7, 1, 2, 3, 4], which is the final result.

The time complexity is O(n), where n is the length of the array. The space complexity is O(1).

Python 3

```python
class Solution:
    def rotate(self, nums: List[int], k: int) -> None:
        def reverse(i: int, j: int):
            while i < j:
                nums[i], nums[j] = nums[j], nums[i]
                i, j = i + 1, j - 1

        n = len(nums)
        k %= n
        reverse(0, n - 1)
        reverse(0, k - 1)
        reverse(k, n - 1)
```

PATTERN 3 · TWO POINTERS · PROBLEM 13 OF 20

18. 4Sum

Medium · Array, Two Pointers, Sorting

leetcode.com/problems/4sum

★ **TOP 10 PROBLEM** in Two Pointers: master this one first

PROBLEM

Given an array `nums` of `n` integers, return *an array of all the **unique** quadruplets* `[nums[a], nums[b], nums[c], nums[d]]` such that:

- `0 <= a, b, c, d < n`
- `a`, `b`, `c`, and `d` are **distinct**.
- `nums[a] + nums[b] + nums[c] + nums[d] == target`

You may return the answer in **any order**.

Example 1:

```
Input: nums = [1,0,-1,0,-2,2], target = 0
Output: [[-2,-1,1,2],[-2,0,0,2],[-1,0,0,1]]
```

Example 2:

```
Input: nums = [2,2,2,2,2], target = 8
Output: [[2,2,2,2]]
```

Constraints:

- `1 <= nums.length <= 200`
- -10^9 `<= nums[i] <=` 10^9
- -10^9 `<= target <=` 10^9

SOLUTION (PYTHON 3)

Solution 1: Sorting + Double Pointers

How to think about it

The first idea is four nested loops plus a set. With n≤ 200, $O(n^4)$ is tight, and deduplication is messy. The bottleneck is the same as 3Sum: after fixing two numbers, the rest is two-sum. Brute force is $O(n^2)$; sorted two pointers are O(n). After sorting, duplicates sit together, so skipping equal i and j keeps quadruplets unique. So we enumerate two indices and squeeze the rest with a pair of pointers, $O(n^3)$, with no hash table.

We notice that the problem requires us to find non-repeating quadruplets. Therefore, we can first sort the array, which makes it easy to skip duplicate elements.

Next, we enumerate the first two elements of the quadruplet, nums[i] and nums[j], where i < j. During the enumeration process, we skip duplicate nums[i] and nums[j]. Then, we use two pointers k and l to point to the two ends behind nums[i] and nums[j]. Let x = nums[i] + nums[j] + nums[k] + nums[l], we compare x with target and perform the following operations:

- If x < target, then update k = k + 1 to get a larger x;
- If x > target, then update l = l - 1 to get a smaller x;
- Otherwise, it means that a quadruplet (nums[i], nums[j], nums[k], nums[l]) is found. Add it to the answer, then we update the pointers k and l, and skip all duplicate elements to prevent the answer from containing duplicate quadruplets, and continue to find the next quadruplet.

The time complexity is $O(n^3)$, and the space complexity is O(log n). Here, n is the length of the array.

Python 3

```python
class Solution:
    def fourSum(self, nums: List[int], target: int) -> List[List[int]]:
        n = len(nums)
        ans = []
        if n < 4:
            return ans
        nums.sort()
        for i in range(n - 3):
            if i and nums[i] == nums[i - 1]:
                continue
            for j in range(i + 1, n - 2):
                if j > i + 1 and nums[j] == nums[j - 1]:
                    continue
                k, l = j + 1, n - 1
                while k < l:
                    x = nums[i] + nums[j] + nums[k] + nums[l]
                    if x < target:
                        k += 1
                    elif x > target:
                        l -= 1
                    else:
                        ans.append([nums[i], nums[j], nums[k], nums[l]])
                        k, l = k + 1, l - 1
                        while k < l and nums[k] == nums[k - 1]:
                            k += 1
                        while k < l and nums[l] == nums[l + 1]:
                            l -= 1
        return ans
```

```

PATTERN 3 · TWO POINTERS · PROBLEM 14 OF 20

922. Sort Array By Parity II

Easy · Array, Two Pointers, Sorting

leetcode.com/problems/sort-array-by-parity-ii

PROBLEM

Given an array of integers `nums`, half of the integers in `nums` are **odd**, and the other half are **even**.

Sort the array so that whenever `nums[i]` is odd, `i` is **odd**, and whenever `nums[i]` is even, `i` is **even**.

Return *any answer array that satisfies this condition*.

Example 1:

```
Input: nums = [4,2,5,7]
Output: [4,5,2,7]
Explanation: [4,7,2,5], [2,5,4,7], [2,7,4,5] would also have been accepted.
```

Example 2:

```
Input: nums = [2,3]
Output: [2,3]
```

Constraints:

- `2 <= nums.length <= 2 * 10^4`
- `nums.length` is even.
- Half of the integers in `nums` are even.
- `0 <= nums[i] <= 1000`

Follow Up: Could you solve it in-place?

SOLUTION (PYTHON 3)

Solution 1: Two Pointers

> **How to think about it**
>
> Even indices must hold evens and odd indices odds, and the two kinds are equally many. An extra array would work, but we can swap in place. i walks even indices; when that slot is odd, j walks odd indices until an even is found and they swap. j only increases, so the pass is linear.

We use two pointers i and j to point to even and odd indices, respectively. Initially, i = 0 and j = 1.

When i points to an even index, if nums[i] is odd, we need to find an odd index j such that nums[j] is even, and then swap nums[i] and nums[j]. Continue traversing until i reaches the end of the array.

The time complexity is O(n), where n is the length of the array nums. The space complexity is O(1).

Python 3

```python
class Solution:
    def sortArrayByParityII(self, nums: List[int]) -> List[int]:
        n, j = len(nums), 1
        for i in range(0, n, 2):
            if nums[i] % 2:
                while nums[j] % 2:
                    j += 2
                nums[i], nums[j] = nums[j], nums[i]
        return nums
```

PATTERN 3 · TWO POINTERS · PROBLEM 15 OF 20

11. Container With Most Water

Medium · Greedy, Array, Two Pointers

leetcode.com/problems/container-with-most-water

★ **TOP 10 PROBLEM** in Two Pointers: master this one first

PROBLEM

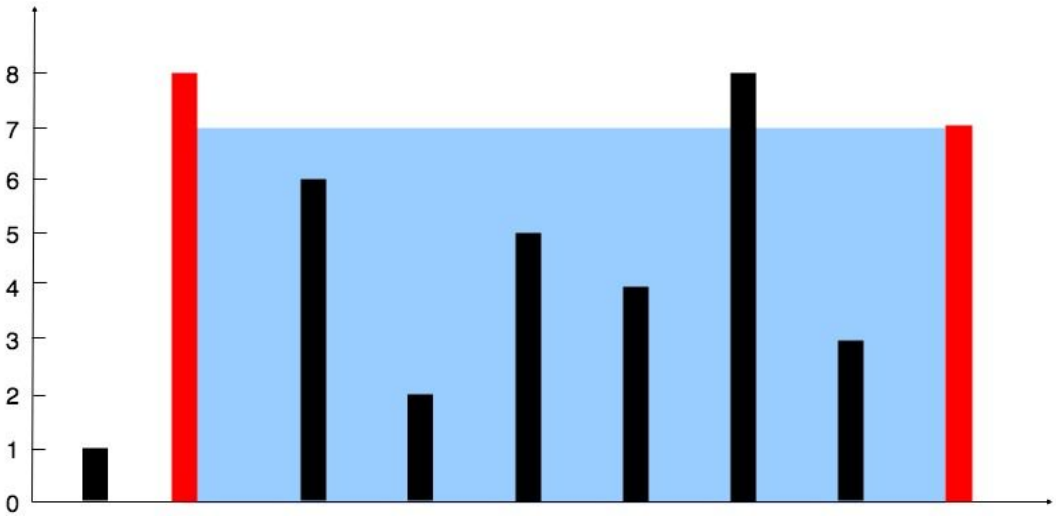
You are given an integer array `height` of length `n`. There are `n` vertical lines drawn such that the two endpoints of the i^{th} line are `(i, 0)` and `(i, height[i])`.

Find two lines that together with the x-axis form a container, such that the container contains the most water.

Return *the maximum amount of water a container can store*.

Notice that you may not slant the container.

Example 1:



```
Input: height = [1,8,6,2,5,4,8,3,7]
Output: 49
Explanation: The above vertical lines are represented by array [1,8,6,2,5,4,8,3,7]. In this case, the
max area of water (blue section) the container can contain is 49.
```

Example 2:

```
Input: height = [1,1]
Output: 1
```

Constraints:

- `n == height.length`
- `2 <= n <= 10^5`
- `0 <= height[i] <= 10^4`

SOLUTION (PYTHON 3)

Solution 1: Two Pointers

How to think about it

The first idea is to try every pair (i,j) and take min(height[i],height[j])×(j-i). Correct, but O(n^2). n ≤ 10^5 will time out. The bottleneck is treating every pair independently and ignoring that height is fixed by the shorter line. Start from the widest interval [0,n-1]: moving the taller end inward shrinks the width while the height is still capped by the shorter line, so the area cannot improve. We must drop the shorter line and look for a taller one. So we shrink from both ends, always moving the shorter side. Each index is visited at most once.

We use two pointers l and r to point to the left and right ends of the array, respectively, i.e., l = 0 and r = n - 1, where n is the length of the array.

Next, we use a variable ans to record the maximum capacity of the container, initially set to 0.

Then, we start a loop. In each iteration, we calculate the current capacity of the container, i.e., min(height[l], height[r]) × (r - l), and compare it with ans, assigning the larger value to ans. Then, we compare the values of height[l] and height[r]. If height[l] < height[r], moving the r pointer will not improve the result because the height of the container is determined by the shorter vertical line, so we move the l pointer. Otherwise, we move the r pointer.

After the iteration, we return ans.

The time complexity is O(n), where n is the length of the array height. The space complexity is O(1).

Python 3

```python
class Solution:
    def maxArea(self, height: List[int]) -> int:
        l, r = 0, len(height) - 1
        ans = 0
        while l < r:
            t = min(height[l], height[r]) * (r - l)
            ans = max(ans, t)
            if height[l] < height[r]:
                l += 1
            else:
                r -= 1
        return ans
```

PATTERN 3 · TWO POINTERS · PROBLEM 16 OF 20

763. Partition Labels

Medium · Greedy, Hash Table, Two Pointers, String

leetcode.com/problems/partition-labels

★ **TOP 10 PROBLEM** in Greedy: master this one first

Also appears in pattern 20 Intervals (Merge / Insert / Overlap), 21 Greedy

PROBLEM

You are given a string `s`. We want to partition the string into as many parts as possible so that each letter appears in at most one part. For example, the string `"ababcc"` can be partitioned into `["abab", "cc"]`, but partitions such as `["aba", "bcc"]` or `["ab", "ab", "cc"]` are invalid.

Note that the partition is done so that after concatenating all the parts in order, the resultant string should be `s`.

Return *a list of integers representing the size of these parts*.

Example 1:

```
Input: s = "ababcbacadefegdehijhklij"
Output: [9,7,8]
Explanation:
The partition is "ababcbaca", "defegde", "hijhklij".
This is a partition so that each letter appears in at most one part.
A partition like "ababcbacadefegde", "hijhklij" is incorrect, because it splits s into less parts.
```

Example 2:

```
Input: s = "eccbbbbdec"
Output: [10]
```

Constraints:

- `1 <= s.length <= 500`
- `s` consists of lowercase English letters.

SOLUTION (PYTHON 3)

Solution 1: Greedy

How to think about it

Split s into as many parts as possible so no letter appears in two parts. A letter's last index is how far its part must reach. Scan left to right, extending the current end by last[c]. When the scan index meets that end, the part is closed. Build last, then cut in one pass. O(n).

We first use an array or hash table last to record the last occurrence of each letter in the string s.

Next, we use a greedy approach to partition the string into as many segments as possible.

Traverse the string s from left to right, while maintaining the start index j and end index i of the current segment, both initially set to 0.

For each letter c visited, get the last occurrence position last[c]. Since the end index of the current segment must not be less than last[c], let mx = max(mx, last[c]).

When visiting the index mx, it means the current segment ends. The index range of the current segment is [j,.. i], and the length is i - j + 1. We add this length to the result array. Then set j = i + 1 and continue to find the next segment.

Repeat the above process until the string traversal is complete to get the lengths of all segments.

Time complexity is O(n), and space complexity is O(|Σ|). Where n is the length of the string s, and |Σ| is the size of the character set. In this problem, |Σ| = 26.

Python 3

```python
class Solution:
    def partitionLabels(self, s: str) -> List[int]:
        last = {c: i for i, c in enumerate(s)}
        mx = j = 0
        ans = []
        for i, c in enumerate(s):
            mx = max(mx, last[c])
            if mx == i:
                ans.append(i - j + 1)
                j = i + 1
        return ans
```

```

PATTERN 3 · TWO POINTERS · PROBLEM 17 OF 20

881. Boats to Save People

Medium · Greedy, Array, Two Pointers, Sorting, Timsort

leetcode.com/problems/boats-to-save-people

★ **TOP 10 PROBLEM** in Two Pointers: master this one first

Also appears in pattern 21 Greedy, 23 Sorting

PROBLEM

You are given an array `people` where `people[i]` is the weight of the i^{th} person, and an **infinite number of boats** where each boat can carry a maximum weight of `limit`. Each boat carries at most two people at the same time, provided the sum of the weight of those people is at most `limit`.

Return *the minimum number of boats to carry every given person*.

Example 1:

```
Input: people = [1,2], limit = 3
Output: 1
Explanation: 1 boat (1, 2)
```

Example 2:

```
Input: people = [3,2,2,1], limit = 3
Output: 3
Explanation: 3 boats (1, 2), (2) and (3)
```

Example 3:

```
Input: people = [3,5,3,4], limit = 5
Output: 4
Explanation: 4 boats (3), (3), (4), (5)
```

Constraints:

- `1 <= people.length <= 5 * 10^4`
- `1 <= people[i] <= limit <= 3 * 10^4`

SOLUTION (PYTHON 3)

Solution 1: Greedy + Two Pointers

How to think about it

Each boat holds at most two people whose weights sum to at most limit. $n \le 5 \cdot 10^4$, so pair the heaviest with the lightest when possible. Sort and use two pointers: if the ends fit, both board; otherwise the heavier one goes alone. Each step uses one boat until the pointers cross.

After sorting, use two pointers to point to the beginning and end of the array respectively. Each time, compare the sum of the elements pointed to by the two pointers with `limit`. If it is less than or equal to `limit`, then both pointers move one step towards the middle. Otherwise, only the right pointer moves. Accumulate the answer.

The time complexity is $O(n \times \log n)$, and the space complexity is $O(\log n)$. Here, n is the length of the array `people`.

Python 3

```python
class Solution:
    def numRescueBoats(self, people: List[int], limit: int) -> int:
        people.sort()
        ans = 0
        i, j = 0, len(people) - 1
        while i <= j:
            if people[i] + people[j] <= limit:
                i += 1
            j -= 1
            ans += 1
        return ans
```

1498. Number of Subsequences That Satisfy the Given Sum Condition

Medium · Array, Two Pointers, Binary Search, Sorting

leetcode.com/problems/number-of-subsequences-that-satisfy-the-given-sum-condition

PROBLEM

You are given an array of integers `nums` and an integer `target`.

Return *the number of **non-empty** subsequences of* `nums` *such that the sum of the minimum and maximum element on it is less or equal to* `target`. Since the answer may be too large, return it **modulo** $10^9 + 7$.

Example 1:

```
Input: nums = [3,5,6,7], target = 9
Output: 4
Explanation: There are 4 subsequences that satisfy the condition.
[3] -> Min value + max value <= target (3 + 3 <= 9)
[3,5] -> (3 + 5 <= 9)
[3,5,6] -> (3 + 6 <= 9)
[3,6] -> (3 + 6 <= 9)
```

Example 2:

```
Input: nums = [3,3,6,8], target = 10
Output: 6
Explanation: There are 6 subsequences that satisfy the condition. (nums can have repeated numbers).
[3] , [3] , [3,3], [3,6] , [3,6] , [3,3,6]
```

Example 3:

```
Input: nums = [2,3,3,4,6,7], target = 12
Output: 61
Explanation: There are 63 non-empty subsequences, two of them do not satisfy the condition ([6,7],
[7]).
Number of valid subsequences (63 - 2 = 61).
```

Constraints:

- $1 \le$ `nums.length` $\le 10^5$
- $1 \le$ `nums[i]` $\le 10^6$
- $1 \le$ `target` $\le 10^6$

SOLUTION (PYTHON 3)

Solution 1: Sorting + Binary Search

> **How to think about it**
>
> A subsequence is judged only by its min and max, so sorting does not change those pairs. n≤ 10^5. Fix the minimum nums[i], binary-search the largest legal nums[j], and multiply by 2^{j-i} for free choices in between. Precompute powers of two. Once 2· nums[i]>target, larger minima are impossible.

Since the problem is about subsequences and involves the sum of the minimum and maximum elements, we can first sort the array nums.

Then we enumerate the minimum element nums[i]. For each nums[i], we can find the maximum element nums[j] in nums[i + 1] to nums[n - 1] such that nums[i] + nums[j] ≤ target. The number of valid subsequences in this case is $2^{j - i}$, where $2^{j - i}$ represents all possible subsequences from nums[i + 1] to nums[j]. We sum up the counts of all such subsequences.

The time complexity is O(n × log n), and the space complexity is O(n), where n is the length of the array nums.

Python 3

```python
class Solution:
    def numSubseq(self, nums: List[int], target: int) -> int:
        mod = 10**9 + 7
        nums.sort()
        n = len(nums)
        f = [1] + [0] * n
        for i in range(1, n + 1):
            f[i] = f[i - 1] * 2 % mod
        ans = 0
        for i, x in enumerate(nums):
            if x * 2 > target:
                break
            j = bisect_right(nums, target - x, i + 1) - 1
            ans = (ans + f[j - i]) % mod
        return ans
```

PATTERN 3 · TWO POINTERS · PROBLEM 19 OF 20

42. Trapping Rain Water

Hard · Stack, Array, Two Pointers, Dynamic Programming, Monotonic Stack

leetcode.com/problems/trapping-rain-water

★ **TOP 10 PROBLEM** in Two Pointers, Monotonic Stack / Queue (Specific Variants): master this one first

Also appears in pattern 9 Monotonic Stack / Queue (Specific Variants)

PROBLEM

Given `n` non-negative integers representing an elevation map where the width of each bar is `1`, compute how much water it can trap after raining.

Example 1:

```
Input: height = [0,1,0,2,1,0,1,3,2,1,2,1]
Output: 6
Explanation: The above elevation map (black section) is represented by array
[0,1,0,2,1,0,1,3,2,1,2,1]. In this case, 6 units of rain water (blue section) are being trapped.
```

Example 2:

```
Input: height = [4,2,0,3,2,5]
Output: 9
```

Constraints:

- `n == height.length`
- `1 <= n <= 2 * 10^4`
- `0 <= height[i] <= 10^5`

SOLUTION (PYTHON 3)

Solution 1: Dynamic Programming

How to think about it

The first idea is, for each i, scan left and right for the tallest bars; water is min(leftMax, rightMax) - height[i]. Correct, but $O(n^2)$. $n \le 2 \times 10^4$ can time out. The bottleneck is recomputing left/right maxima at every i. Those maxima only depend on one side and can be precomputed in linear time. Store, at each index, the highest bar to the left (inclusive) and to the right (inclusive), then sum. The water level is the shorter of the two walls — that is the DP state.

We define left[i] as the height of the highest bar to the left of and including the position at index i, and right[i] as the height of the highest bar to the right of and including the position at index i. Therefore, the amount of rainwater that can be trapped at index i is min(left[i], right[i]) - height[i]. We traverse the array to calculate left[i] and right[i], and the final answer is $\sum_{i=0}^{n-1}$ min(left[i], right[i]) - height[i].

The time complexity is O(n), and the space complexity is O(n). Here, n is the length of the array.

Python 3

```
class Solution:
    def trap(self, height: List[int]) -> int:
        n = len(height)
        left = [height[0]] * n
        right = [height[-1]] * n
        for i in range(1, n):
            left[i] = max(left[i - 1], height[i])
            right[n - i - 1] = max(right[n - i], height[n - i - 1])
        return sum(min(l, r) - h for l, r, h in zip(left, right, height))
```

```

PATTERN 3 · TWO POINTERS · PROBLEM 20 OF 20

727. Minimum Window Subsequence

Hard · String, Dynamic Programming, Sliding Window

leetcode.com/problems/minimum-window-subsequence

PROBLEM

Given strings `s1` and `s2`, return *the minimum contiguous substring part of* `s1`*, so that* `s2` *is a subsequence of the part*.

If there is no such window in `s1` that covers all characters in `s2`, return the empty string `""`. If there are multiple such minimum-length windows, return the one with the **left-most starting index**.

Example 1:

```
Input: s1 = "abcdebdde", s2 = "bde"
Output: "bcde"
Explanation:
"bcde" is the answer because it occurs before "bdde" which has the same length.
"deb" is not a smaller window because the elements of s2 in the window must occur in order.
```

Example 2:

```
Input: s1 = "jmeqksfrsdcmsiwvaovztaqenprpvnbstl", s2 = "u"
Output: ""
```

Constraints:

- `1 <= s1.length <= 2 * 10^4`
- `1 <= s2.length <= 100`
- `s1` and `s2` consist of lowercase English letters.

SOLUTION (PYTHON 3)

Solution 1: Dynamic Programming

How to think about it

Find the shortest window of s_1 that contains s_2 as a subsequence. $|s_1| \le 2 \times 10^4$ and $|s_2| \le 100$ make "try every window" unattractive. When s_2's last character is matched, the window length is determined by where that match started. Threading the start index through the DP recovers every candidate. f[i][j] is that start: on a match it inherits f[i-1][j-1] (or i when j=1), otherwise f[i-1][j]. Whenever f[i][n]>0 we update the shortest slice.

We define f[i][j] to represent the starting position of the shortest substring of the first i characters of string s1 that contains the first j characters of string s2. If it does not exist, it is 0.

We can derive the state transition equation:

f[i][j] = cases i, & j = 1 and s1[i-1] = s2[j] \ f[i - 1][j - 1], & j > 1 and s1[i-1] = s2[j-1] \ f[i - 1][j], & s1[i-1] ≠ s2[j-1] cases

Next, we only need to traverse s1. If f[i][n] > 0, update the starting position and length of the shortest substring. Finally, return the shortest substring.

The time complexity is O(m × n), and the space complexity is O(m × n). Here, m and n are the lengths of strings s1 and s2, respectively.

Python 3

```python
class Solution:
    def minWindow(self, s1: str, s2: str) -> str:
        m, n = len(s1), len(s2)
        f = [[0] * (n + 1) for _ in range(m + 1)]
        for i, a in enumerate(s1, 1):
            for j, b in enumerate(s2, 1):
                if a == b:
                    f[i][j] = i if j == 1 else f[i - 1][j - 1]
                else:
                    f[i][j] = f[i - 1][j]
        p, k = 0, m + 1
        for i, a in enumerate(s1, 1):
            if a == s2[n - 1] and f[i][n]:
                j = f[i][n] - 1
                if i - j < k:
                    k = i - j
                    p = j
        return "" if k > m else s1[p : p + k]
```

PATTERN 4 · BINARY SEARCH · PROBLEM 1 OF 20

704. Binary Search

Easy · Array, Binary Search

leetcode.com/problems/binary-search

★ **TOP 10 PROBLEM** in Binary Search: master this one first

PROBLEM

Given an array of integers `nums` which is sorted in ascending order, and an integer `target`, write a function to search `target` in `nums`. If `target` exists, then return its index. Otherwise, return `-1`.

You must write an algorithm with `O(log n)` runtime complexity.

Example 1:

```
Input: nums = [-1,0,3,5,9,12], target = 9
Output: 4
Explanation: 9 exists in nums and its index is 4
```

Example 2:

```
Input: nums = [-1,0,3,5,9,12], target = 2
Output: -1
Explanation: 2 does not exist in nums so return -1
```

Constraints:

- `1 <= nums.length <= 10^4`
- `-10^4 < nums[i], target < 10^4`
- All the integers in `nums` are **unique**.
- `nums` is sorted in ascending order.

SOLUTION (PYTHON 3)

Solution 1: Binary Search

How to think about it

Search target in a strictly increasing array. n ≤ 10^4 would allow a scan, but each comparison can discard half of a sorted range. If nums[mid] ≥ target, the answer is not to the right, so r moves to mid; otherwise it lies past mid, so l becomes mid+1. When l=r we sit on the first value that is not smaller than the target, then compare once. Time O(log n), extra space O(1).

We define the left boundary l=0 and the right boundary r=n-1 for binary search.

In each iteration, we calculate the middle position mid=(l+r)/2, then compare the size of nums[mid] and target.

- If nums[mid] ≥ target, it means target is in the left half, so we move the right boundary r to mid;
- Otherwise, it means target is in the right half, so we move the left boundary l to mid+1.

The loop ends when l<r, at this point nums[l] is the target value we are looking for. If nums[l]=target, return l; otherwise, return -1.

The time complexity is O(log n), where n is the length of the array nums. The space complexity is O(1).

Python 3

```python
class Solution:
    def search(self, nums: List[int], target: int) -> int:
        l, r = 0, len(nums) - 1
        while l < r:
            mid = (l + r) >> 1
            if nums[mid] >= target:
                r = mid
            else:
                l = mid + 1
        return l if nums[l] == target else -1
```

    right = 1
    while read(right) < target:
        right *= 2
    left = right // 2
    while left <= right:
        mid = (left + right) // 2
        value = read(mid)
        if value == target:
            return mid
        if value < target:
            left = mid + 1
        else:
            right = mid - 1
    return -1
```

PATTERN 4 · BINARY SEARCH · PROBLEM 2 OF 20

35. Search Insert Position

Easy · Array, Binary Search

leetcode.com/problems/search-insert-position

★ **TOP 10 PROBLEM** in Binary Search: master this one first

PROBLEM

Given a sorted array of distinct integers and a target value, return the index if the target is found. If not, return the index where it would be if it were inserted in order.

You must write an algorithm with `O(log n)` runtime complexity.

Example 1:

```
Input: nums = [1,3,5,6], target = 5
Output: 2
```

Example 2:

```
Input: nums = [1,3,5,6], target = 2
Output: 1
```

Example 3:

```
Input: nums = [1,3,5,6], target = 7
Output: 4
```

Constraints:

- `1 <= nums.length <= 10^4`
- `-10^4 <= nums[i] <= 10^4`
- `nums` contains **distinct** values sorted in **ascending** order.
- `-10^4 <= target <= 10^4`

SOLUTIONS (PYTHON 3)

Solution 1: Binary Search

How to think about it

The first idea is to scan left to right until the first index ≥ target. Correct, and n ≤ 10^4 would pass, but the array is strictly increasing, so a linear scan wastes the order. The insertion point is exactly the first index not smaller than target — a standard lower bound. Keep a half-open interval [l,r): if nums[mid] ≥ target the answer lies in the left half (including mid), otherwise it lies to the right of mid. When l=r, l is the insertion index.

Since the array nums is already sorted, we can use the binary search method to find the insertion position of the target value target.

The time complexity is O(log n), and the space complexity is O(1). Here, n is the length of the array nums.

Python 3

```python
class Solution:
    def searchInsert(self, nums: List[int], target: int) -> int:
        l, r = 0, len(nums)
        while l < r:
            mid = (l + r) >> 1
            if nums[mid] >= target:
                r = mid
            else:
                l = mid + 1
        return l
```

Solution 2: Binary Search (Built-in Function)

> **How to think about it**
>
> Method 1 is already O(log n); what it still lacks is only that we need not write the binary search by hand. Languages already expose a lower bound: Python's `bisect_left`, C++'s `lower_bound`, Java's `Arrays.binarySearch` (returning -i-1 when absent). The meaning matches Method 1; we just call the builtin.

We can also directly use the built-in function for binary search.

The time complexity is O(log n), where n is the length of the array nums. The space complexity is O(1).

Python 3

```python
class Solution:
    def searchInsert(self, nums: List[int], target: int) -> int:
        return bisect_left(nums, target)
```

    if position == 0:
        return nums[0]
    if position == len(nums):
        return nums[-1]
    before, after = nums[position - 1], nums[position]
    if target - before <= after - target:
        return before
    return after
```

PATTERN 4 · BINARY SEARCH · PROBLEM 3 OF 20

69. Sqrt(x)

Easy · Math, Binary Search, Newton's Method

leetcode.com/problems/sqrtx

★ **TOP 10 PROBLEM** in Binary Search: master this one first

Also appears in pattern 34 Math / Number Theory

PROBLEM

Given a non-negative integer `x`, return *the square root of* `x` *rounded down to the nearest integer*. The returned integer should be **non-negative** as well.

You **must not use** any built-in exponent function or operator.

- For example, do not use `pow(x, 0.5)` in c++ or `x ** 0.5` in python.

Example 1:

```
Input: x = 4
Output: 2
Explanation: The square root of 4 is 2, so we return 2.
```

Example 2:

```
Input: x = 8
Output: 2
Explanation: The square root of 8 is 2.82842..., and since we round it down to the nearest integer, 2
is returned.
```

Constraints:

- $0 <= x <= 2^{31} - 1$

SOLUTION (PYTHON 3)

Solution 1: Binary Search

How to think about it

The first idea is to scan i from 0 to x and keep the largest i with $i^2 \le x$. x can be 2^{31}-1, so a linear scan is too slow, i^2 overflows easily, and `pow` is forbidden. The answer is monotone: if $mid^2 \le x$, a larger candidate might still work; otherwise we must go left. So we binary-search [0, x]. Compare with mid > x / mid to avoid overflow. Use the upper mid and shrink toward the largest feasible value; the left endpoint is the integer square root.

We define the left boundary of the binary search as l = 0 and the right boundary as r = x, then we search for the square root within the range [l, r].

In each step of the search, we find the middle value mid = (l + r + 1) / 2. If mid > x / mid, it means the square root is within the range [l, mid - 1], so we set r = mid - 1. Otherwise, it means the square root is within the range [mid, r], so we set l = mid.

After the search ends, we return l.

The time complexity is O(log x), and the space complexity is O(1).

Python 3

```python
class Solution:
    def mySqrt(self, x: int) -> int:
        l, r = 0, x
        while l < r:
            mid = (l + r + 1) >> 1
            if mid > x // mid:
                r = mid - 1
            else:
                l = mid
        return l
```

PATTERN 4 · BINARY SEARCH · PROBLEM 4 OF 20

34. Find First and Last Position of Element in Sorted Array

Medium · Array, Binary Search

leetcode.com/problems/find-first-and-last-position-of-element-in-sorted-array

★ **TOP 10 PROBLEM** in Binary Search: master this one first

PROBLEM

Given an array of integers `nums` sorted in non-decreasing order, find the starting and ending position of a given `target` value.

If `target` is not found in the array, return `[-1, -1]`.

You must write an algorithm with `O(log n)` runtime complexity.

Example 1:

```
Input: nums = [5,7,7,8,8,10], target = 8
Output: [3,4]
```

Example 2:

```
Input: nums = [5,7,7,8,8,10], target = 6
Output: [-1,-1]
```

Example 3:

```
Input: nums = [], target = 0
Output: [-1,-1]
```

Constraints:

- `0 <= nums.length <=` 10^5
- -10^9 `<= nums[i] <=` 10^9
- `nums` is a non-decreasing array.
- -10^9 `<= target <=` 10^9

SOLUTION (PYTHON 3)

Solution 1: Binary Search

How to think about it

The first idea is a linear scan that records the first and last hits. Correct, but $n \le 10^5$ and the problem requires O(log n). Expanding outward from one match is still O(n) in the worst case. The array is non-decreasing, so the two endpoints are separate binary-search questions; we need not find both in one pass. The left endpoint is the first index ≥ target; the right endpoint is the first index ≥ target+1, minus one. Two lower-bound queries suffice; if they land on the same index, target is absent.

We can perform two binary searches to find the left boundary and the right boundary.

The time complexity is O(log n), where n is the length of the array nums. The space complexity is O(1).

Python 3

```python
class Solution:
    def searchRange(self, nums: List[int], target: int) -> List[int]:
        l = bisect_left(nums, target)
        r = bisect_left(nums, target + 1)
        return [-1, -1] if l == r else [l, r - 1]
```

```

PATTERN 4 · BINARY SEARCH · PROBLEM 5 OF 20

33. Search in Rotated Sorted Array

Medium · Array, Binary Search

leetcode.com/problems/search-in-rotated-sorted-array

★ **TOP 10 PROBLEM** in Binary Search: master this one first

PROBLEM

There is an integer array `nums` sorted in ascending order (with **distinct** values).

Prior to being passed to your function, `nums` is **possibly left rotated** at an unknown index `k` (`1 <= k < nums.length`) such that the resulting array is `[nums[k], nums[k+1], ..., nums[n-1], nums[0], nums[1], ..., nums[k-1]]` (**0-indexed**). For example, `[0,1,2,4,5,6,7]` might be left rotated by `3` indices and become `[4,5,6,7,0,1,2]`.

Given the array `nums` **after** the possible rotation and an integer `target`, return *the index of* `target` *if it is in* `nums`*, or* `-1` *if it is not in* `nums`.

You must write an algorithm with `O(log n)` runtime complexity.

Example 1:

```
Input: nums = [4,5,6,7,0,1,2], target = 0
Output: 4
```

Example 2:

```
Input: nums = [4,5,6,7,0,1,2], target = 3
Output: -1
```

Example 3:

```
Input: nums = [1], target = 0
Output: -1
```

Constraints:

- `1 <= nums.length <= 5000`
- `-10^4 <= nums[i] <= 10^4`
- All values of `nums` are **unique**.
- `nums` is an ascending array that is possibly rotated.
- `-10^4 <= target <= 10^4`

SOLUTION (PYTHON 3)

Solution 1: Binary Search

How to think about it

The first idea is a left-to-right scan. Correct, but n ≤ 5000 and the problem requires O(log n). After the rotation the array is no longer fully sorted, so ordinary binary search cannot tell which half holds target. The key is that any cut leaves at least one half monotonic. Comparing nums[0] with nums[mid] tells us whether the left half is sorted; then we check whether target lies in that sorted range and discard the other half. So we can still binary-search: the sorted half decides keep-or-drop, and the unsorted half is cut again in the next round.

We use binary search to divide the array into two parts, [left,.. mid] and [mid + 1,.. right]. At this point, we can find that one part must be sorted.

Therefore, we can determine whether target is in this part based on the sorted part:

- If the elements in the range [0,.. mid] form a sorted array:
  - If nums[0] ≤ target ≤ nums[mid], then our search range can be narrowed down to [left,.. mid];
  - Otherwise, search in [mid + 1,.. right];
- If the elements in the range [mid + 1, n - 1] form a sorted array:
  - If nums[mid] < target ≤ nums[n - 1], then our search range can be narrowed down to [mid + 1,.. right];
  - Otherwise, search in [left,.. mid].

The termination condition for binary search is left ≥ right. If at the end we find that nums[left] is not equal to target, it means that there is no element with a value of target in the array, and we return -1. Otherwise, we return the index left.

The time complexity is O(log n), where n is the length of the array nums. The space complexity is O(1).

Python 3

```python
class Solution:
    def search(self, nums: List[int], target: int) -> int:
        n = len(nums)
        left, right = 0, n - 1
        while left < right:
            mid = (left + right) >> 1
            if nums[0] <= nums[mid]:
                if nums[0] <= target <= nums[mid]:
                    right = mid
                else:
                    left = mid + 1
            else:
                if nums[mid] < target <= nums[n - 1]:
                    left = mid + 1
                else:
                    right = mid
        return left if nums[left] == target else -1
```

```

PATTERN 4 · BINARY SEARCH · PROBLEM 6 OF 20

81. Search in Rotated Sorted Array II

Medium · Array, Binary Search

leetcode.com/problems/search-in-rotated-sorted-array-ii

PROBLEM

There is an integer array `nums` sorted in non-decreasing order (not necessarily with **distinct** values).

Before being passed to your function, `nums` is **rotated** at an unknown pivot index `k` (`0 <= k < nums.length`) such that the resulting array is `[nums[k], nums[k+1], ..., nums[n-1], nums[0], nums[1], ..., nums[k-1]]` (**0-indexed**). For example, `[0,1,2,4,4,4,5,6,6,7]` might be rotated at pivot index `5` and become `[4,5,6,6,7,0,1,2,4,4]`.

Given the array `nums` **after** the rotation and an integer `target`, return `true` *if* `target` *is in* `nums`*, or* `false` *if it is not in* `nums`.

You must decrease the overall operation steps as much as possible.

Example 1:

```
Input: nums = [2,5,6,0,0,1,2], target = 0
Output: true
```

Example 2:

```
Input: nums = [2,5,6,0,0,1,2], target = 3
Output: false
```

Constraints:

- `1 <= nums.length <= 5000`
- -10^4 `<= nums[i] <=` 10^4
- `nums` is guaranteed to be rotated at some pivot.
- -10^4 `<= target <=` 10^4

Follow up: This problem is similar to Search in Rotated Sorted Array, but `nums` may contain **duplicates**. Would this affect the runtime complexity? How and why?

SOLUTION (PYTHON 3)

Solution 1: Binary Search

How to think about it

The first idea is a linear scan: compare each element with target. Correct, but the problem asks to minimize operations, and the array is two sorted halves after rotation. n ≤ 5000 would pass a scan, yet that ignores the order. The bottleneck is not using “at least one half is sorted.” Ordinary binary search needs a fully sorted range; comparing nums[mid] with nums[r] tells us which side is ordered, then whether target lies in that half. Unlike Search in Rotated Sorted Array, duplicates are allowed. When nums[mid] = nums[r] we cannot tell which side is ordered, so we only decrement r. If the whole range is equal this degrades to O(n) — the unavoidable cost of duplicates.

We define the left boundary of the binary search as l = 0 and the right boundary as r = n - 1, where n is the length of the array.

Each time during the binary search, we get the current midpoint mid = (l + r) / 2.

- If nums[mid] > nums[r], it means [l, mid] is ordered. If nums[l] ≤ target ≤ nums[mid], it means target is in [l, mid]. Otherwise, target is in [mid + 1, r].

- If nums[mid] < nums[r], it means [mid + 1, r] is ordered. If nums[mid] < target ≤ nums[r], it means target is in [mid + 1, r]. Otherwise, target is in [l, mid].
- If nums[mid] = nums[r], it means the elements nums[mid] and nums[r] are equal. In this case, we cannot determine which interval target is in, so we can only decrease r by 1.

After the binary search, if nums[l] = target, it means the target value target exists in the array. Otherwise, it does not exist.

The time complexity is O(n), where n is the length of the array. The space complexity is O(1).

Python 3

```
class Solution:
    def search(self, nums: List[int], target: int) -> bool:
        n = len(nums)
        l, r = 0, n - 1
        while l < r:
            mid = (l + r) >> 1

PATTERN 4 · BINARY SEARCH · PROBLEM 7 OF 20

153. Find Minimum in Rotated Sorted Array

Medium · Array, Binary Search

leetcode.com/problems/find-minimum-in-rotated-sorted-array

★ **TOP 10 PROBLEM** in Binary Search: master this one first

PROBLEM

Suppose an array of length `n` sorted in ascending order is **rotated** between `1` and `n` times. For example, the array `nums = [0,1,2,4,5,6,7]` might become:

- `[4,5,6,7,0,1,2]` if it was rotated `4` times.
- `[0,1,2,4,5,6,7]` if it was rotated `7` times.

Notice that **rotating** an array `[a[0], a[1], a[2], ..., a[n-1]]` 1 time results in the array `[a[n-1], a[0], a[1], a[2], ..., a[n-2]]`.

Given the sorted rotated array `nums` of **unique** elements, return *the minimum element of this array*.

You must write an algorithm that runs in `O(log n) time`.

Example 1:

```
Input: nums = [3,4,5,1,2]
Output: 1
Explanation: The original array was [1,2,3,4,5] rotated 3 times.
```

Example 2:

```
Input: nums = [4,5,6,7,0,1,2]
Output: 0
Explanation: The original array was [0,1,2,4,5,6,7] and it was rotated 4 times.
```

Example 3:

```
Input: nums = [11,13,15,17]
Output: 11
Explanation: The original array was [11,13,15,17] and it was rotated 4 times.
```

Constraints:

- `n == nums.length`
- `1 <= n <= 5000`
- `-5000 <= nums[i] <= 5000`
- All the integers of `nums` are **unique**.
- `nums` is sorted and rotated between `1` and `n` times.

SOLUTION (PYTHON 3)

Solution 1: Binary Search

How to think about it

A rotated sorted array with distinct values; a linear scan is O(n) and n≤ 5000 is fine, but order allows log n. The minimum splits the array into two increasing runs. Compare the mid to the last value: larger means the min is on the right, otherwise on the left (including mid). Shrink to one index.

We can use binary search to solve this problem.

First, we define two pointers l and r pointing to the start and end of the array respectively. Then we enter a loop until l is no longer less than r.

In each iteration, we calculate the middle position mid and compare nums[mid] with nums[n-1]. If nums[mid] is greater than nums[n-1], the minimum value is to the right of mid, so we update l to mid + 1. Otherwise, the minimum value is at mid or to its left, so we update r to mid. When the loop ends, pointer l will point to the minimum value, and we return nums[l].

The time complexity is O(log n), where n is the length of array nums. The space complexity is O(1).

Python 3

```python
class Solution:
    def findMin(self, nums: List[int]) -> int:
        l, r = 0, len(nums) - 1
        while l < r:
            mid = (l + r) >> 1
            if nums[mid] > nums[-1]:
                l = mid + 1
            else:
                r = mid
        return nums[l]
```

    return nums[(low + k - 1) % len(nums)]
```

PATTERN 4 · BINARY SEARCH · PROBLEM 8 OF 20

74. Search a 2D Matrix

Medium · Array, Binary Search, Matrix

leetcode.com/problems/search-a-2d-matrix

PROBLEM

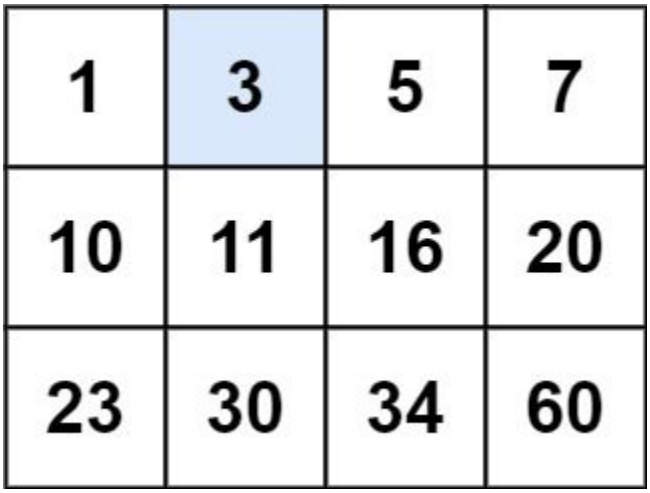
You are given an `m x n` integer matrix `matrix` with the following two properties:

- Each row is sorted in non-decreasing order.
- The first integer of each row is greater than the last integer of the previous row.

Given an integer `target`, return `true` *if* `target` *is in* `matrix` *or* `false` *otherwise*.

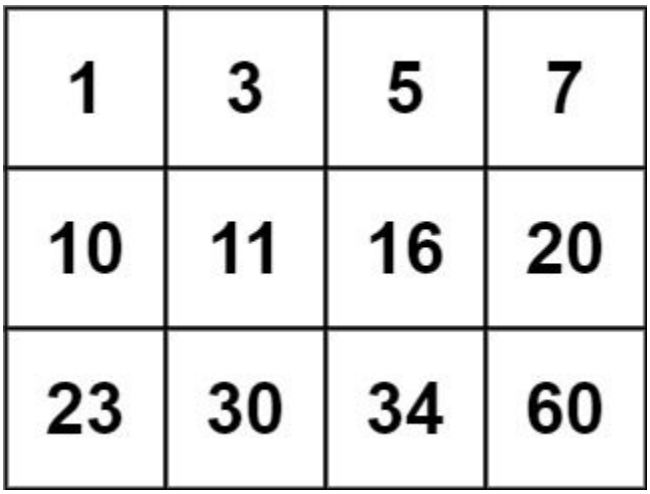
You must write a solution in `O(log(m * n))` time complexity.

Example 1:



```
Input: matrix = [[1,3,5,7],[10,11,16,20],[23,30,34,60]], target = 3
Output: true
```

Example 2:



```
Input: matrix = [[1,3,5,7],[10,11,16,20],[23,30,34,60]], target = 13
Output: false
```

Constraints:

- `m == matrix.length`

- `n == matrix[i].length`
- `1 <= m, n <= 100`
- -10^4 `<= matrix[i][j], target <=` 10^4

SOLUTIONS (PYTHON 3)

Solution 1: Binary Search

> **How to think about it**
>
> A full scan is O(mn). m,n ≤ 100 would pass, but the problem asks for O(log(mn)). Two dimensions hide a single binary search. Each row increases, and the last of row i is less than the first of row i+1, so concatenating rows is a sorted array of length mn. Logical index mid maps to matrix[floor(mid/n)][mid mod n], so we binary-search [0,mn-1] without materializing the flatten.

We can logically unfold the two-dimensional matrix and then perform binary search.

The time complexity is O(log(m × n)), where m and n are the number of rows and columns of the matrix, respectively. The space complexity is O(1).

Python 3

```
class Solution:
    def searchMatrix(self, matrix: List[List[int]], target: int) -> bool:
        m, n = len(matrix), len(matrix[0])
        left, right = 0, m * n - 1
        while left < right:
            mid = (left + right) >> 1
            x, y = divmod(mid, n)
            if matrix[x][y] >= target:
                right = mid
            else:
                left = mid + 1
        return matrix[left // n][left % n] == target
```

Solution 2: Search from the Bottom Left or Top Right

> **How to think about it**
>
> Method 1 flattens the matrix and binary-searches, which is O(log(mn)), but it maps mid to coordinates and needs the last of one row to be less than the first of the next. Without that index map, row/column monotonicity lets a corner walk drop a whole row or column per comparison. The code is simpler; the cost is O(m+n) time.

Here, we start searching from the bottom left corner and move towards the top right direction. We compare the current element matrix[i][j] with target:

- If matrix[i][j] = target, we have found the target value and return `true`.
- If matrix[i][j] > target, all elements to the right of the current position in this row are greater than target, so we should move the pointer i upwards, i.e., i = i - 1.
- If matrix[i][j] < target, all elements above the current position in this column are less than target, so we should move the pointer j to the right, i.e., j = j + 1.

If we still can't find target after the search, return `false`.

The time complexity is O(m + n), where m and n are the number of rows and columns of the matrix, respectively. The space complexity is O(1).

Python 3

```python
class Solution:
    def searchMatrix(self, matrix: List[List[int]], target: int) -> bool:
        m, n = len(matrix), len(matrix[0])
        i, j = m - 1, 0
        while i >= 0 and j < n:
            if matrix[i][j] == target:
                return True
            if matrix[i][j] > target:
                i -= 1
            else:
                j += 1
        return False
```

            col += 1
        else:
            row -= 1
```

```
    return count
```

PATTERN 4 · BINARY SEARCH · PROBLEM 9 OF 20

875. Koko Eating Bananas

Medium · Array, Binary Search

leetcode.com/problems/koko-eating-bananas

★ **TOP 10 PROBLEM** in Binary Search: master this one first

PROBLEM

Koko loves to eat bananas. There are `n` piles of bananas, the `i`th pile has `piles[i]` bananas. The guards have gone and will come back in `h` hours.

Koko can decide her bananas-per-hour eating speed of `k`. Each hour, she chooses some pile of bananas and eats `k` bananas from that pile. If the pile has less than `k` bananas, she eats all of them instead and will not eat any more bananas during this hour.

Koko likes to eat slowly but still wants to finish eating all the bananas before the guards return.

Return *the minimum integer* `k` *such that she can eat all the bananas within* `h` *hours*.

Example 1:

```
Input: piles = [3,6,7,11], h = 8
Output: 4
```

Example 2:

```
Input: piles = [30,11,23,4,20], h = 5
Output: 30
```

Example 3:

```
Input: piles = [30,11,23,4,20], h = 6
Output: 23
```

Constraints:

- `1 <= piles.length <= 10`^{4}
- `piles.length <= h <= 10`^{9}
- `1 <= piles[i] <= 10`^{9}

SOLUTION (PYTHON 3)

Solution 1: Binary Search

How to think about it

A larger speed k finishes sooner; we want the smallest k that finishes within h hours. h and pile sizes reach 10^9, so we binary-search the monotone predicate “can finish in h hours”. Search [1,max piles]; the check sums ceil(x/k) over piles. The first feasible speed is the answer.

We notice that if Koko can eat all the bananas at a speed of k within h hours, then she can also eat all the bananas at a speed of k' > k within h hours. This shows monotonicity, so we can use binary search to find the smallest k that satisfies the condition.

We define the left boundary of the binary search as l = 1, and the right boundary as r = max(piles). For each binary search, we take the middle value mid = (l + r)/2, and then calculate the time s required to eat bananas at a speed of mid. If s ≤ h, it means that the speed of mid can meet the condition, and we update the right boundary r to mid; otherwise, we update the left boundary l to mid + 1. Finally, when l = r, we find the smallest k that satisfies the condition.

The time complexity is O(n × log M), where n and M are the length and maximum value of the array piles respectively. The space complexity is O(1).

Python 3

```python
class Solution:
    def minEatingSpeed(self, piles: List[int], h: int) -> int:
        def check(k: int) -> bool:
            return sum((x + k - 1) // k for x in piles) <= h

        return 1 + bisect_left(range(1, max(piles) + 1), True, key=check)
```

    return low, hours_needed(piles, low)
```

1011. Capacity To Ship Packages Within D Days

Medium · Array, Binary Search

leetcode.com/problems/capacity-to-ship-packages-within-d-days

PROBLEM

A conveyor belt has packages that must be shipped from one port to another within `days` days.

The i^{th} package on the conveyor belt has a weight of `weights[i]`. Each day, we load the ship with packages on the conveyor belt (in the order given by `weights`). We may not load more weight than the maximum weight capacity of the ship.

Return the least weight capacity of the ship that will result in all the packages on the conveyor belt being shipped within `days` days.

Example 1:

```
Input: weights = [1,2,3,4,5,6,7,8,9,10], days = 5
Output: 15
Explanation: A ship capacity of 15 is the minimum to ship all the packages in 5 days like this:
1st day: 1, 2, 3, 4, 5
2nd day: 6, 7
3rd day: 8
4th day: 9
5th day: 10

Note that the cargo must be shipped in the order given, so using a ship of capacity 14 and splitting
the packages into parts like (2, 3, 4, 5), (1, 6, 7), (8), (9), (10) is not allowed.
```

Example 2:

```
Input: weights = [3,2,2,4,1,4], days = 3
Output: 6
Explanation: A ship capacity of 6 is the minimum to ship all the packages in 3 days like this:
1st day: 3, 2
2nd day: 2, 4
3rd day: 1, 4
```

Example 3:

```
Input: weights = [1,2,3,1,1], days = 4
Output: 3
Explanation:
1st day: 1
2nd day: 2
3rd day: 3
4th day: 1, 1
```

Constraints:

- `1 <= days <= weights.length <= 5 * 10^4`
- `1 <= weights[i] <= 500`

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Capacity is at least the heaviest package and at most the total weight. Testing every value in that range is too slow: $n \le 5 \times 10^4$ and the sum can be in the millions. Larger capacity never increases the number of days, so feasibility is monotonic and the least valid capacity can be found by binary search. For a candidate x we pack left to right and start a new day when x is exceeded. We bisect the first true value of this check on $[\max w_i, \sum w_i]$.

Python 3

```
class Solution:
    def shipWithinDays(self, weights: List[int], days: int) -> int:
        def check(mx):
            ws, cnt = 0, 1
            for w in weights:
                ws += w
                if ws > mx:
                    cnt += 1
                    ws = w
            return cnt <= days

        left, right = max(weights), sum(weights) + 1
        return left + bisect_left(range(left, right), True, key=check)
```

Complexity. Time: O(n * log(sum(weights))). Space: O(1).

```

PATTERN 4 · BINARY SEARCH · PROBLEM 11 OF 20

162. Find Peak Element

Medium · Array, Binary Search

leetcode.com/problems/find-peak-element

★ **TOP 10 PROBLEM** in Binary Search: master this one first

PROBLEM

A peak element is an element that is strictly greater than its neighbors.

Given a **0-indexed** integer array `nums`, find a peak element, and return its index. If the array contains multiple peaks, return the index to **any of the peaks**.

You may imagine that `nums[-1] = nums[n] = -∞`. In other words, an element is always considered to be strictly greater than a neighbor that is outside the array.

You must write an algorithm that runs in `O(log n)` time.

Example 1:

```
Input: nums = [1,2,3,1]
Output: 2
Explanation: 3 is a peak element and your function should return the index number 2.
```

Example 2:

```
Input: nums = [1,2,1,3,5,6,4]
Output: 5
Explanation: Your function can return either index number 1 where the peak element is 2, or index
number 5 where the peak element is 6.
```

Constraints:

- `1 <= nums.length <= 1000`
- -2^{31} `<= nums[i] <=` $2^{31} - 1$
- `nums[i] != nums[i + 1]` for all valid `i`.

SOLUTION (PYTHON 3)

Solution 1: Binary Search

How to think about it

Neighbors differ and the sentinels are -∞, so a peak exists. A linear scan works for n≤ 1000; the problem wants O(log n). Compare mid to its right neighbor: a smaller right side means a peak in the left half (including mid), otherwise in the right half. Shrink until the two ends meet.

We define the left boundary of binary search as left=0 and the right boundary as right=n-1, where n is the length of the array. In each step of binary search, we find the middle element mid of the current interval, and compare the values of mid and its right neighbor mid+1:

- If the value of mid is greater than the value of mid+1, there exists a peak element on the left side, and we update the right boundary right to mid.
- Otherwise, there exists a peak element on the right side, and we update the left boundary left to mid+1.
- Finally, when the left boundary left is equal to the right boundary right, we have found the peak element of the array.

The time complexity is O(log n), where n is the length of the array nums. Each step of binary search can reduce the search interval by half, so the time complexity is O(log n). The space complexity is O(1).

Python 3

```python
class Solution:
    def findPeakElement(self, nums: List[int]) -> int:
        left, right = 0, len(nums) - 1
        while left < right:
            mid = (left + right) >> 1
            if nums[mid] > nums[mid + 1]:
                right = mid
            else:
                left = mid + 1
        return left
```

    return [-1, -1]
```

PATTERN 4 · BINARY SEARCH · PROBLEM 12 OF 20

1283. Find the Smallest Divisor Given a Threshold

Medium · Array, Binary Search

leetcode.com/problems/find-the-smallest-divisor-given-a-threshold

PROBLEM

Given an array of integers `nums` and an integer `threshold`, we will choose a positive integer `divisor`, divide all the array by it, and sum the division's result. Find the **smallest** `divisor` such that the result mentioned above is less than or equal to `threshold`.

Each result of the division is rounded to the nearest integer greater than or equal to that element. (For example: `7/3 = 3` and `10/2 = 5`).

The test cases are generated so that there will be an answer.

Example 1:

```
Input: nums = [1,2,5,9], threshold = 6
Output: 5
Explanation: We can get a sum to 17 (1+2+5+9) if the divisor is 1.
If the divisor is 4 we can get a sum of 7 (1+1+2+3) and if the divisor is 5 the sum will be 5
(1+1+1+2).
```

Example 2:

```
Input: nums = [44,22,33,11,1], threshold = 5
Output: 44
```

Constraints:

- `1 <= nums.length <= 5 * 10^4`
- `1 <= nums[i] <= 10^6`
- `nums.length <= threshold <= 10^6`

SOLUTION (PYTHON 3)

Solution 1: Binary Search

How to think about it

A larger divisor only decreases the sum of ceilings, so the predicate is monotone. $n \le 5\times 10^4$ forbids trying every divisor. We binary-search the smallest v in [1,max nums] such that $\sum \text{ceil}(\text{nums}_i/v) \le \text{threshold}$. Each check is one linear scan.

Notice that for number v, if the sum of results of dividing each number in nums by v is less than or equal to threshold, then all values greater than v satisfy the condition. There is a monotonicity, so we can use binary search to find the smallest v that satisfies the condition.

We define the left boundary of the binary search l=1, r=max(nums). Each time we take mid=(l+r)/2, calculate the sum of the results of dividing each number in nums by mid s, if s is less than or equal to threshold, then it means that mid satisfies the condition, we will update r to mid, otherwise we will update l to mid+1.

Finally, return l.

The time complexity is O(n × log M), where n is the length of the array nums and M is the maximum value in the array nums. The space complexity is O(1).

Python 3

```
class Solution:
    def smallestDivisor(self, nums: List[int], threshold: int) -> int:
        def f(v: int) -> bool:
            v += 1
            return sum((x + v - 1) // v for x in nums) <= threshold

        return bisect_left(range(max(nums)), True, key=f) + 1
```

```

PATTERN 4 · BINARY SEARCH · PROBLEM 13 OF 20

378. Kth Smallest Element in a Sorted Matrix

Medium · Array, Binary Search, Matrix, Sorting, Heap (Priority Queue)

leetcode.com/problems/kth-smallest-element-in-a-sorted-matrix

★ **TOP 10 PROBLEM** in K-way Merge: master this one first

Also appears in pattern 38 K-way Merge

PROBLEM

Given an `n x n matrix` where each of the rows and columns is sorted in ascending order, return *the* k^{th} *smallest element in the matrix*.

Note that it is the k^{th} smallest element **in the sorted order**, not the k^{th} **distinct** element.

You must find a solution with a memory complexity better than $O(n^2)$.

Example 1:

```
Input: matrix = [[1,5,9],[10,11,13],[12,13,15]], k = 8
Output: 13
Explanation: The elements in the matrix are [1,5,9,10,11,12,13,13,15], and the 8th smallest number is 13
```

Example 2:

```
Input: matrix = [[-5]], k = 1
Output: -5
```

Constraints:

- `n == matrix.length == matrix[i].length`
- `1 <= n <= 300`
- -10^9 `<= matrix[i][j] <=` 10^9
- All the rows and columns of `matrix` are **guaranteed** to be sorted in **non-decreasing order**.
- `1 <= k <=` n^2

Follow up:

- Could you solve the problem with a constant memory (i.e., $O(1)$ memory complexity)?
- Could you solve the problem in $O(n)$ time complexity? The solution may be too advanced for an interview but you may find reading this paper fun.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Rows and columns increase; find the k-th smallest. Flattening and sorting is $O(n^2 \log n)$. The answer lies in [matrix[0][0], matrix[n-1][n-1]], so binary-search the value. `check(mid)` counts entries ≤ mid from the bottom-left in O(n) by monotonicity. If the count is ≥ k, shrink the right bound. The smallest feasible mid is the answer.

Python 3

```python
class Solution:
    def kthSmallest(self, matrix: List[List[int]], k: int) -> int:
        def check(matrix, mid, k, n):
            count = 0
            i, j = n - 1, 0
            while i >= 0 and j < n:
                if matrix[i][j] <= mid:
                    count += i + 1
                    j += 1
                else:
                    i -= 1
            return count >= k

        n = len(matrix)
        left, right = matrix[0][0], matrix[n - 1][n - 1]
        while left < right:
            mid = (left + right) >> 1
            if check(matrix, mid, k, n):
                right = mid
            else:
                left = mid + 1
        return left
```

    return total
```

PATTERN 4 · BINARY SEARCH · PROBLEM 14 OF 20

540. Single Element in a Sorted Array

Medium · Array, Binary Search

leetcode.com/problems/single-element-in-a-sorted-array

PROBLEM

You are given a sorted array consisting of only integers where every element appears exactly twice, except for one element which appears exactly once.

Return *the single element that appears only once*.

Your solution must run in `O(log n)` time and `O(1)` space.

Example 1:

```
Input: nums = [1,1,2,3,3,4,4,8,8]
Output: 2
```

Example 2:

```
Input: nums = [3,3,7,7,10,11,11]
Output: 10
```

Constraints:

- `1 <= nums.length <= 10^5`
- `0 <= nums[i] <= 10^5`

SOLUTION (PYTHON 3)

Solution 1: Binary Search

> **How to think about it**
>
> All elements appear in adjacent pairs except one singleton, and we must find it in O(log n). Pairs occupy even-odd indices. If `mid` still matches `mid xor 1`, the singleton is to the right; otherwise it lies on the left (including `mid`). XOR avoids separate even/odd cases.

The given array nums is sorted, and we need to find the element that appears only once in O(log n) time. Therefore, we consider using binary search to solve this problem.

We define the left boundary of the binary search as l = 0 and the right boundary as r = n - 1, where n is the length of the array.

In each step, we take the middle position mid = (l + r) / 2. If the index mid is even, we should compare nums[mid] with nums[mid + 1]. If the index mid is odd, we should compare nums[mid] with nums[mid - 1]. Therefore, we can uniformly compare nums[mid] with nums[mid xor 1], where xor denotes the XOR operation.

If nums[mid] ≠ nums[mid xor 1], then the answer is in [l, mid], so we set r = mid. If nums[mid] = nums[mid xor 1], then the answer is in [mid + 1, r], so we set l = mid + 1. We continue the binary search until l = r, at which point nums[l] is the element that appears only once.

The time complexity is O(log n), where n is the length of the array nums. The space complexity is O(1).

Python 3

```
class Solution:
    def singleNonDuplicate(self, nums: List[int]) -> int:
        l, r = 0, len(nums) - 1
        while l < r:
            mid = (l + r) >> 1
            if nums[mid] != nums[mid ^ 1]:
                r = mid
            else:
                l = mid + 1
        return nums[l]
```

PATTERN 4 · BINARY SEARCH · PROBLEM 15 OF 20

981. Time Based Key-Value Store

Medium · Design, Hash Table, String, Binary Search

leetcode.com/problems/time-based-key-value-store

★ **TOP 10 PROBLEM** in Design Problems: master this one first

Also appears in pattern 29 Design Problems

PROBLEM

Design a time-based key-value data structure that can store multiple values for the same key at different time stamps and retrieve the key's value at a certain timestamp.

Implement the `TimeMap` class:

- `TimeMap()` Initializes the object of the data structure.
- `void set(String key, String value, int timestamp)` Stores the key `key` with the value `value` at the given time `timestamp`.
- `String get(String key, int timestamp)` Returns a value such that `set` was called previously, with `timestamp_prev <= timestamp`. If there are multiple such values, it returns the value associated with the largest `timestamp_prev`. If there are no values, it returns `""`.

Example 1:

```
Input
["TimeMap", "set", "get", "get", "set", "get", "get"]
[[], ["foo", "bar", 1], ["foo", 1], ["foo", 3], ["foo", "bar2", 4], ["foo", 4], ["foo", 5]]
Output
[null, null, "bar", "bar", null, "bar2", "bar2"]

Explanation
TimeMap timeMap = new TimeMap();
timeMap.set("foo", "bar", 1); // store the key "foo" and value "bar" along with timestamp = 1.
timeMap.get("foo", 1); // return "bar"
timeMap.get("foo", 3); // return "bar", since there is no value corresponding to foo at timestamp 3
and timestamp 2, then the only value is at timestamp 1 is "bar".
timeMap.set("foo", "bar2", 4); // store the key "foo" and value "bar2" along with timestamp = 4.
timeMap.get("foo", 4); // return "bar2"
timeMap.get("foo", 5); // return "bar2"
```

Constraints:

- `1 <= key.length, value.length <= 100`
- `key` and `value` consist of lowercase English letters and digits.
- `1 <= timestamp <= 10^7`
- All the timestamps `timestamp` of `set` are strictly increasing.
- At most `2 * 10^5` calls will be made to `set` and `get`.

SOLUTION (PYTHON 3)

Solution 1: Hash Table + Ordered Set (or Binary Search)

How to think about it

`set` timestamps are strictly increasing, so each key's history is already sorted. `get` wants the latest value at a time ≤ the query. A linear scan is too slow over 2× 10^5 calls. Store (timestamp,value) lists per key and binary-search the upper bound.

We can use a hash table kvt to record key-value pairs, where the key is the string key and the value is an ordered set. Each element in the set is a tuple (timestamp, value), representing the value value corresponding to the key key at the timestamp timestamp.

When we need to query the value corresponding to the key key at the timestamp timestamp, we can use the ordered set to find the largest timestamp timestamp' such that timestamp' ≤ timestamp, and then return the corresponding value.

In terms of time complexity, for the set operation, since the insertion operation of the hash table has a time complexity of O(1), the time complexity is O(1). For the get operation, since the lookup operation of the hash table has a time complexity of O(1) and the lookup operation of the ordered set has a time complexity of O(log n), the time complexity is O(log n). The space complexity is O(n), where n is the number of set operations.

Python 3

```
class TimeMap:
    def __init__(self):
        self.ktv = defaultdict(list)

    def set(self, key: str, value: str, timestamp: int) -> None:
        self.ktv[key].append((timestamp, value))

    def get(self, key: str, timestamp: int) -> str:
        if key not in self.ktv:
            return ''
        tv = self.ktv[key]
        i = bisect_right(tv, (timestamp, chr(127)))

1482. Minimum Number of Days to Make m Bouquets

Medium · Array, Binary Search

leetcode.com/problems/minimum-number-of-days-to-make-m-bouquets

PROBLEM

You are given an integer array `bloomDay`, an integer `m` and an integer `k`.

You want to make `m` bouquets. To make a bouquet, you need to use `k` **adjacent flowers** from the garden.

The garden consists of `n` flowers, the i^{th} flower will bloom in the `bloomDay[i]` and then can be used in **exactly one** bouquet.

Return the **minimum** number of days you need to wait to be able to make m bouquets from the garden. If it is impossible to make m bouquets return -1.

Example 1:

```
Input: bloomDay = [1,10,3,10,2], m = 3, k = 1
Output: 3
Explanation: Let us see what happened in the first three days. x means flower bloomed and _ means
flower did not bloom in the garden.
We need 3 bouquets each should contain 1 flower.
After day 1: [x, _, _, _, _] // we can only make one bouquet.
After day 2: [x, _, _, _, x] // we can only make two bouquets.
After day 3: [x, _, x, _, x] // we can make 3 bouquets. The answer is 3.
```

Example 2:

```
Input: bloomDay = [1,10,3,10,2], m = 3, k = 2
Output: -1
Explanation: We need 3 bouquets each has 2 flowers, that means we need 6 flowers. We only have 5
flowers so it is impossible to get the needed bouquets and we return -1.
```

Example 3:

```
Input: bloomDay = [7,7,7,7,12,7,7], m = 2, k = 3
Output: 12
Explanation: We need 2 bouquets each should have 3 flowers.
Here is the garden after the 7 and 12 days:
After day 7: [x, x, x, x, _, x, x]
We can make one bouquet of the first three flowers that bloomed. We cannot make another bouquet from
the last three flowers that bloomed because they are not adjacent.
After day 12: [x, x, x, x, x, x, x]
It is obvious that we can make two bouquets in different ways.
```

Constraints:

- `bloomDay.length == n`
- `1 <= n <= 10^5`
- `1 <= bloomDay[i] <= 10^9`
- `1 <= m <= 10^6`
- `1 <= k <= n`

SOLUTION (PYTHON 3)

Solution 1: Binary Search

> **How to think about it**
>
> More days only make it easier to form m bouquets. n≤ 10^5 and bloom days reach 10^9, so binary-search the day. The check counts adjacent blooms of length k. If no day works, return -1.

According to the problem description, if a day t can satisfy making m bouquets, then for any t' > t, it can also satisfy making m bouquets. Therefore, we can use binary search to find the minimum day that satisfies making m bouquets.

Let mx be the maximum blooming day in the garden. Next, we define the left boundary of the binary search as l = 1 and the right boundary as r = mx + 1.

Then, we perform binary search. For each middle value mid = (l + r)/2, we check if it is possible to make m bouquets. If it is possible, we update the right boundary r to mid; otherwise, we update the left boundary l to mid + 1.

Finally, when l = r, the binary search ends. At this point, if l > mx, it means it is not possible to make m bouquets, and we return -1; otherwise, we return l.

Therefore, the problem is reduced to checking if a day days can make m bouquets.

We can use a function check(days) to determine if it is possible to make m bouquets. Specifically, we traverse each flower in the garden from left to right. If the blooming day of the current flower is less than or equal to days, we add the current flower to the current bouquet; otherwise, we clear the current bouquet. When the number of flowers in the current bouquet equals k, we increment the bouquet count and clear the current bouquet. Finally, we check if the bouquet count is greater than or equal to m. If it is, it means it is possible to make m bouquets; otherwise, it is not possible.

The time complexity is O(n × log M), where n and M are the number of flowers in the garden and the maximum blooming day, respectively. In this problem, M ≤ 10^9. The space complexity is O(1).

Python 3

```python
class Solution:
    def minDays(self, bloomDay: List[int], m: int, k: int) -> int:
        def check(days: int) -> int:
            cnt = cur = 0
            for x in bloomDay:
                cur = cur + 1 if x <= days else 0
                if cur == k:
                    cnt += 1
                    cur = 0
            return cnt >= m

        mx = max(bloomDay)
        l = bisect_left(range(mx + 2), True, key=check)
        return -1 if l > mx else l
```

PATTERN 4 · BINARY SEARCH · PROBLEM 17 OF 20

658. Find K Closest Elements

Medium · Array, Two Pointers, Binary Search, Sorting, Sliding Window, Heap (Priority Queue)

leetcode.com/problems/find-k-closest-elements

Also appears in pattern 38 K-way Merge

PROBLEM

Given a **sorted** integer array `arr`, two integers `k` and `x`, return the `k` closest integers to `x` in the array. The result should also be sorted in ascending order.

An integer `a` is closer to `x` than an integer `b` if:

- `|a - x| < |b - x|`, or
- `|a - x| == |b - x|` and `a < b`

Example 1:

Input: arr = [1,2,3,4,5], k = 4, x = 3

Output: [1,2,3,4]

Example 2:

Input: arr = [1,1,2,3,4,5], k = 4, x = -1

Output: [1,1,2,3]

Constraints:

- `1 <= k <= arr.length`
- `1 <= arr.length <= 10^4`
- `arr` is sorted in **ascending** order.
- `-10^4 <= arr[i], x <= 10^4`

SOLUTIONS (PYTHON 3)

Solution 1: Sort

How to think about it

We need the k closest values to x, reported in sorted order. Sorting by distance then taking k is O(nlog n). Sort by |v-x|, keep k elements, and sort those by value.

Python 3

```python
class Solution:
    def findClosestElements(self, arr: List[int], k: int, x: int) -> List[int]:
        arr.sort(key=lambda v: abs(v - x))
        return sorted(arr[:k])
```

Solution 2: Two Pointers

How to think about it

The answer is a contiguous slice. Shrink the farther endpoint until the window has length k; the slice is already sorted.

The k elements closest to x in a sorted array form one contiguous subarray.

Set pointers l and r at the two ends. Compare x - arr[l] with arr[r - 1] - x and drop the farther end until r - l = k.

The time complexity is O(n).

Python 3

```python
class Solution:
    def findClosestElements(self, arr: List[int], k: int, x: int) -> List[int]:
        l, r = 0, len(arr)
        while r - l > k:
            if x - arr[l] <= arr[r - 1] - x:
                r -= 1
            else:
                l += 1
        return arr[l:r]
```

Solution 3: Binary Search

> **How to think about it**
>
> Two pointers are linear. The best left bound in [0,n-k] is monotone: compare x-arr[mid] with arr[mid+k]-x and binary-search it.

On top of method 2, binary-search the left boundary of the window of length k over [0, n - k]. At mid, move the window left when x - arr[mid] ≤ arr[mid + k] - x, and right otherwise.

The time complexity is O(log n).

Python 3

```python
class Solution:
    def findClosestElements(self, arr: List[int], k: int, x: int) -> List[int]:
        left, right = 0, len(arr) - k
        while left < right:
            mid = (left + right) >> 1
            if x - arr[mid] <= arr[mid + k] - x:
                right = mid
            else:
                left = mid + 1
        return arr[left : left + k]
```

            right += 1
    return nums[left + 1:right]
```

PATTERN 4 · BINARY SEARCH · PROBLEM 18 OF 20

852. Peak Index in a Mountain Array

Medium · Array, Binary Search, Ternary Search

leetcode.com/problems/peak-index-in-a-mountain-array

PROBLEM

You are given an integer **mountain** array `arr` of length `n` where the values increase to a **peak element** and then decrease.

Return the index of the peak element.

Your task is to solve it in `O(log(n))` time complexity.

Example 1:

Input: arr = [0,1,0]

Output: 1

Example 2:

Input: arr = [0,2,1,0]

Output: 1

Example 3:

Input: arr = [0,10,5,2]

Output: 1

Constraints:

- `3 <= arr.length <= 10^5`
- `0 <= arr[i] <= 10^6`
- `arr` is **guaranteed** to be a mountain array.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

The array rises strictly then falls strictly; we need the peak index. A linear scan works, but n≤ 10^5 and the peak test is monotone: left of the peak arr[i]<arr[i+1], right of it the opposite. Binary search [1,n-2]: if arr[mid]>arr[mid+1] the peak is in the left half (including mid), otherwise in the right. The left endpoint is the peak.

Python 3

```python
class Solution:
    def peakIndexInMountainArray(self, arr: List[int]) -> int:
        left, right = 1, len(arr) - 2
        while left < right:
            mid = (left + right) >> 1
            if arr[mid] > arr[mid + 1]:
                right = mid
            else:
                left = mid + 1
        return left
```

Complexity. Time: O(log n). Space: O(1).

PATTERN 4 · BINARY SEARCH · PROBLEM 19 OF 20

4. Median of Two Sorted Arrays

Hard · Array, Binary Search, Divide and Conquer

leetcode.com/problems/median-of-two-sorted-arrays

★ **TOP 10 PROBLEM** in Binary Search: master this one first

Also appears in pattern 14 Recursion / Divide and Conquer

PROBLEM

Given two sorted arrays `nums1` and `nums2` of size `m` and `n` respectively, return **the median** of the two sorted arrays.

The overall run time complexity should be `O(log (m+n))`.

Example 1:

```
Input: nums1 = [1,3], nums2 = [2]
Output: 2.00000
Explanation: merged array = [1,2,3] and median is 2.
```

Example 2:

```
Input: nums1 = [1,2], nums2 = [3,4]
Output: 2.50000
Explanation: merged array = [1,2,3,4] and median is (2 + 3) / 2 = 2.5.
```

Constraints:

- `nums1.length == m`
- `nums2.length == n`
- `0 <= m <= 1000`
- `0 <= n <= 1000`
- `1 <= m + n <= 2000`
- -10^6 `<= nums1[i], nums2[i] <=` 10^6

SOLUTION (PYTHON 3)

Solution 1: Divide and Conquer

How to think about it

Merging the two sorted arrays and then reading the median is the direct approach, in O(m+n). m,n ≤ 10^3 would pass, but the problem asks for O(log(m+n)), so a linear scan is out. The bottleneck: the median only cares about the one or two middle positions after a merge. Smaller values need only be counted, not listed. Both arrays are sorted, so comparing each side's floor(k/2)-th element tells us which side's first half cannot contain the k-th smallest, and we can drop that half at once. So we never build a merged array; we search for the k-th remaining element. The median is the average of the floor((m+n+1)/2)-th and the floor((m+n+2)/2)-th, covering odd and even length with the same code. If one side has fewer than floor(k/2) elements, treat it as +∞ and discard from the other side.

The problem requires the time complexity of the algorithm to be O(log (m + n)), so we cannot directly traverse the two arrays, but need to use the binary search method.

If m + n is odd, then the median is the floor((m + n + 1)/2)-th number; if m + n is even, then the median is the average of the floor((m + n + 1)/2)-th and the floor((m + n + 2)/2)-th numbers. In fact, we can unify it as the average of the floor((m + n + 1)/2)-th and the floor((m + n + 2)/2)-th numbers.

Therefore, we can design a function f(i, j, k), which represents the k-th smallest number in the interval [i, m) of array nums1 and the interval [j, n) of array nums2. The median is the average of f(0, 0, floor((m + n + 1)/2)) and f(0, 0, floor((m + n + 2)/2)).

The implementation idea of the function f(i, j, k) is as follows:

- If i ≥ m, it means that the interval [i, m) of array nums1 is empty, so directly return nums2[j + k - 1];
- If j ≥ n, it means that the interval [j, n) of array nums2 is empty, so directly return nums1[i + k - 1];
- If k = 1, it means to find the first number, so just return the minimum of nums1[i] and nums2[j];
- Otherwise, we find the floor(k/2)-th number in the two arrays, denoted as x and y. (Note, if a certain array does not have the floor(k/2)-th number, then we regard the floor(k/2)-th number as +∞.) Compare the size of x and y:
  - If x ≤ y, it means that the floor(k/2)-th number of array nums1 cannot be the k-th smallest number, so we can exclude the interval [i, i + floor(k/2)) of array nums1, and recursively call f(i + floor(k/2), j, k - floor(k/2)).
  - If x > y, it means that the floor(k/2)-th number of array nums2 cannot be the k-th smallest number, so we can exclude the interval [j, j + floor(k/2)) of array nums2, and recursively call f(i, j + floor(k/2), k - floor(k/2)).

The time complexity is O(log(m + n)), and the space complexity is O(log(m + n)). Here, m and n are the lengths of arrays nums1 and nums2 respectively.

Python 3

```python
class Solution:
    def findMedianSortedArrays(self, nums1: List[int], nums2: List[int]) -> float:
        def f(i: int, j: int, k: int) -> int:
            if i >= m:
                return nums2[j + k - 1]
            if j >= n:
                return nums1[i + k - 1]
            if k == 1:
                return min(nums1[i], nums2[j])
            p = k // 2
            x = nums1[i + p - 1] if i + p - 1 < m else inf
            y = nums2[j + p - 1] if j + p - 1 < n else inf
            return f(i + p, j, k - p) if x < y else f(i, j + p, k - p)

        m, n = len(nums1), len(nums2)
        a = f(0, 0, (m + n + 1) // 2)
        b = f(0, 0, (m + n + 2) // 2)
        return (a + b) / 2
```

PATTERN 4 · BINARY SEARCH · PROBLEM 20 OF 20

410. Split Array Largest Sum

Hard · Greedy, Array, Binary Search, Dynamic Programming, Prefix Sum

leetcode.com/problems/split-array-largest-sum

★ **TOP 10 PROBLEM** in Binary Search: master this one first

PROBLEM

Given an integer array `nums` and an integer `k`, split `nums` into `k` non-empty subarrays such that the largest sum of any subarray is **minimized**.

Return *the minimized largest sum of the split*.

A **subarray** is a contiguous part of the array.

Example 1:

```
Input: nums = [7,2,5,10,8], k = 2
Output: 18
Explanation: There are four ways to split nums into two subarrays.
The best way is to split it into [7,2,5] and [10,8], where the largest sum among the two subarrays is
only 18.
```

Example 2:

```
Input: nums = [1,2,3,4,5], k = 2
Output: 9
Explanation: There are four ways to split nums into two subarrays.
The best way is to split it into [1,2,3] and [4,5], where the largest sum among the two subarrays is
only 9.
```

Constraints:

- `1 <= nums.length <= 1000`
- `0 <= nums[i] <= 10^6`
- `1 <= k <= min(50, nums.length)`

SOLUTION (PYTHON 3)

Solution 1: Binary Search

How to think about it

Enumerating every way to place k-1 cuts is too large. A larger cap on a subarray sum only makes a feasible split easier, so feasibility is monotone in the cap. Binary-search the cap mid. A greedy left-to-right accumulation starts a new piece whenever adding the next value would exceed mid, and we ask whether at most k pieces suffice. The search range is [max(nums),∑ nums]. The minimum feasible cap is the answer; combinatorial search becomes a linear check.

We notice that the larger the maximum sum of the subarrays, the fewer the number of subarrays. When there is a maximum sum of the subarrays that meets the condition, then a larger maximum sum of the subarrays will definitely meet the condition. This means that we can perform a binary search for the maximum sum of the subarrays to find the smallest value that meets the condition.

We define the left boundary of the binary search as left = max(nums), and the right boundary as right = sum(nums). Then for each step of the binary search, we take the middle value mid = floor((left + right)/2), and then determine whether there is a way to split the array so that the maximum sum of the subarrays does not exceed mid. If there is, it means that mid might be the smallest value that meets the condition, so we adjust the right boundary to mid. Otherwise, we adjust the left boundary to mid + 1.

How do we determine whether there is a way to split the array so that the maximum sum of the subarrays does not exceed mid? We can use a greedy method, traverse the array from left to right, and add the elements of the array to the subarray one by one. If the current sum of the subarray is greater than mid, then we add the current element to the next subarray. If we can split the array into no more than k subarrays, and the maximum sum of each subarray does not exceed mid, then mid is the smallest value that meets the condition. Otherwise, mid does not meet the condition.

The time complexity is O(n × log m), and the space complexity is O(1). Here, n and m are the length of the array and the sum of all elements in the array, respectively.

Python 3

```python
class Solution:
    def splitArray(self, nums: List[int], k: int) -> int:
        def check(mx):
            s, cnt = inf, 0
            for x in nums:
                s += x
                if s > mx:
                    s = x
                    cnt += 1
            return cnt <= k

        left, right = max(nums), sum(nums)
        return left + bisect_left(range(left, right + 1), True, key=check)
```

PATTERN 5 · PREFIX SUM · PROBLEM 1 OF 20

303. Range Sum Query - Immutable

Easy · Design, Array, Prefix Sum

leetcode.com/problems/range-sum-query-immutable

★ **TOP 10 PROBLEM** in Prefix Sum: master this one first

PROBLEM

Given an integer array `nums`, handle multiple queries of the following type:

1. Calculate the **sum** of the elements of `nums` between indices `left` and `right` **inclusive** where `left <= right`.

Implement the `NumArray` class:

- `NumArray(int[] nums)` Initializes the object with the integer array `nums`.
- `int sumRange(int left, int right)` Returns the **sum** of the elements of `nums` between indices `left` and `right` **inclusive** (i.e. `nums[left] + nums[left + 1] + ... + nums[right]`).

Example 1:

```
Input
["NumArray", "sumRange", "sumRange", "sumRange"]
[[[-2, 0, 3, -5, 2, -1]], [0, 2], [2, 5], [0, 5]]
Output
[null, 1, -1, -3]

Explanation
NumArray numArray = new NumArray([-2, 0, 3, -5, 2, -1]);
numArray.sumRange(0, 2); // return (-2) + 0 + 3 = 1
numArray.sumRange(2, 5); // return 3 + (-5) + 2 + (-1) = -1
numArray.sumRange(0, 5); // return (-2) + 0 + 3 + (-5) + 2 + (-1) = -3
```

Constraints:

- $1 \le nums.length \le 10^4$
- $-10^5 \le nums[i] \le 10^5$
- $0 \le left \le right < nums.length$
- At most 10^4 calls will be made to `sumRange`.

SOLUTION (PYTHON 3)

Solution 1: Prefix Sum

How to think about it

The array never changes, yet many range sums are requested. Summing [left,right] from scratch is O(n) per query and does not scale. A prefix array s stores the sum of the first i elements, so sum(left,right)=s[right+1]-s[left]. One linear build makes every later query O(1). Because the array is immutable, no update structure is needed.

We create a prefix sum array s of length n + 1, where s[i] represents the prefix sum of the first i elements, that is, $s[i] = \sum_{j=0}^{i-1} nums[j]$. Therefore, the sum of the elements between the indices [left, right] can be expressed as s[right + 1] - s[left].

The time complexity for initializing the prefix sum array s is O(n), and the time complexity for querying is O(1). The space complexity is O(n).

Python 3

```
class NumArray:
    def __init__(self, nums: List[int]):
        self.s = list(accumulate(nums, initial=0))

    def sumRange(self, left: int, right: int) -> int:
        return self.s[right + 1] - self.s[left]

# Your NumArray object will be instantiated and called as such:
# obj = NumArray(nums)
# param_1 = obj.sumRange(left,right)
```

# works exactly like prefix sums: the XOR of nums[l..r] is
# prefix[r + 1] ^ prefix[l].
# Time: build O(n), query O(1).  Space: O(n).
class RangeXor:
    def __init__(self, nums):
        self.prefix = [0]
```

```
        for x in nums:
            self.prefix.append(self.prefix[-1] ^ x)

    def query(self, left, right):
        return self.prefix[right + 1] ^ self.prefix[left]
```

PATTERN 5 · PREFIX SUM · PROBLEM 2 OF 20

724. Find Pivot Index

Easy · Array, Prefix Sum

leetcode.com/problems/find-pivot-index

★ **TOP 10 PROBLEM** in Prefix Sum: master this one first

PROBLEM

Given an array of integers `nums`, calculate the **pivot index** of this array.

The **pivot index** is the index where the sum of all the numbers **strictly** to the left of the index is equal to the sum of all the numbers **strictly** to the index's right.

If the index is on the left edge of the array, then the left sum is `0` because there are no elements to the left. This also applies to the right edge of the array.

Return *the **leftmost pivot index***. If no such index exists, return `-1`.

Example 1:

```
Input: nums = [1,7,3,6,5,6]
Output: 3
Explanation:
The pivot index is 3.
Left sum = nums[0] + nums[1] + nums[2] = 1 + 7 + 3 = 11
Right sum = nums[4] + nums[5] = 5 + 6 = 11
```

Example 2:

```
Input: nums = [1,2,3]
Output: -1
Explanation:
There is no index that satisfies the conditions in the problem statement.
```

Example 3:

```
Input: nums = [2,1,-1]
Output: 0
Explanation:
The pivot index is 0.
Left sum = 0 (no elements to the left of index 0)
Right sum = nums[1] + nums[2] = 1 + -1 = 0
```

Constraints:

- `1 <= nums.length <= 10^4`
- `-1000 <= nums[i] <= 1000`

Note: This question is the same as 1991: https://leetcode.com/problems/find-the-middle-index-in-array/

SOLUTION (PYTHON 3)

Solution 1: Prefix Sum

How to think about it

Find an index whose left sum equals its right sum. Recomputing both sides at every i is $O(n^2)$ for $n \le 10^4$. The two sides plus nums[i] make the total S, so 2·left+nums[i]=S. One left-to-right pass suffices. Start right at the total, subtract x before comparing with left, then add x to the left. Extra space O(1).

We define a variable left to represent the sum of elements to the left of index i in the array nums, and a variable right to represent the sum of elements to the right of index i in the array nums. Initially, left = 0, right = $\sum_{i=0}^{n-1}$ nums[i].

We traverse the array nums. For the current number x being traversed, we update right = right - x. At this point, if left = right, it indicates that the current index i is the middle position, and we can return it directly. Otherwise, we update left = left + x and continue to traverse the next number.

If the middle position is not found by the end of the traversal, return -1.

The time complexity is O(n), and the space complexity is O(1). Here, n is the length of the array nums.

Similar Problems:

- 1991. Find the Middle Index in Array
- 2574. Left and Right Sum Differences

Python 3

```
class Solution:
    def pivotIndex(self, nums: List[int]) -> int:
        left, right = 0, sum(nums)
        for i, x in enumerate(nums):
            right -= x
            if left == right:
                return i
            left += x
        return -1
```

1732. Find the Highest Altitude

Easy · Array, Prefix Sum

leetcode.com/problems/find-the-highest-altitude

★ **TOP 10 PROBLEM** in Prefix Sum: master this one first

PROBLEM

There is a biker going on a road trip. The road trip consists of `n + 1` points at various altitudes. The biker starts his trip on point `0` with altitude equal `0`.

You are given an integer array `gain` of length `n` where `gain[i]` is the **net gain in altitude** between points `i` and `i + 1` for all (`0 <= i < n`). Return *the **highest altitude** of a point.*

Example 1:

```
Input: gain = [-5,1,5,0,-7]
Output: 1
Explanation: The altitudes are [0,-5,-4,1,1,-6]. The highest is 1.
```

Example 2:

```
Input: gain = [-4,-3,-2,-1,4,3,2]
Output: 0
Explanation: The altitudes are [0,-4,-7,-9,-10,-6,-3,-1]. The highest is 0.
```

Constraints:

- `n == gain.length`
- `1 <= n <= 100`
- `-100 <= gain[i] <= 100`

SOLUTION (PYTHON 3)

Solution 1: Prefix Sum (Difference Array)

How to think about it

gain stores consecutive altitude differences from a start of 0. The highest point is the maximum prefix sum of that difference array. Accumulate gain from 0 and keep the running maximum.

We assume the altitude of each point is h_i. Since gain[i] represents the altitude difference between the ith point and the (i + 1)th point, we have gain[i] = $h_{i+1} - h_i$. Therefore:

$$\sum_{i=0}^{n-1} gain[i] = h_1 - h_0 + h_2 - h_1 + \ldots + h_n - h_{n-1} = h_n - h_0 = h_n$$

which implies:

$$h_{i+1} = \sum_{j=0}^{i} gain[j]$$

We can see that the altitude of each point can be calculated through the prefix sum. Therefore, we only need to traverse the array once, find the maximum value of the prefix sum, which is the highest altitude.

In fact, the gain array in the problem is a difference array. The prefix sum of the difference array gives the original altitude array. Then find the maximum value of the original altitude array.

The time complexity is O(n), and the space complexity is O(1). Here, n is the length of the array `gain`.

Python 3

```python
class Solution:
    def largestAltitude(self, gain: List[int]) -> int:
        return max(accumulate(gain, initial=0))
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

PATTERN 5 · PREFIX SUM · PROBLEM 4 OF 20

304. Range Sum Query 2D - Immutable

Medium · Design, Array, Matrix, Prefix Sum

leetcode.com/problems/range-sum-query-2d-immutable

★ **TOP 10 PROBLEM** in Prefix Sum, Binary Indexed Tree (Fenwick Tree): master this one first

Also appears in pattern 41 Binary Indexed Tree (Fenwick Tree)

PROBLEM

Given a 2D matrix `matrix`, handle multiple queries of the following type:

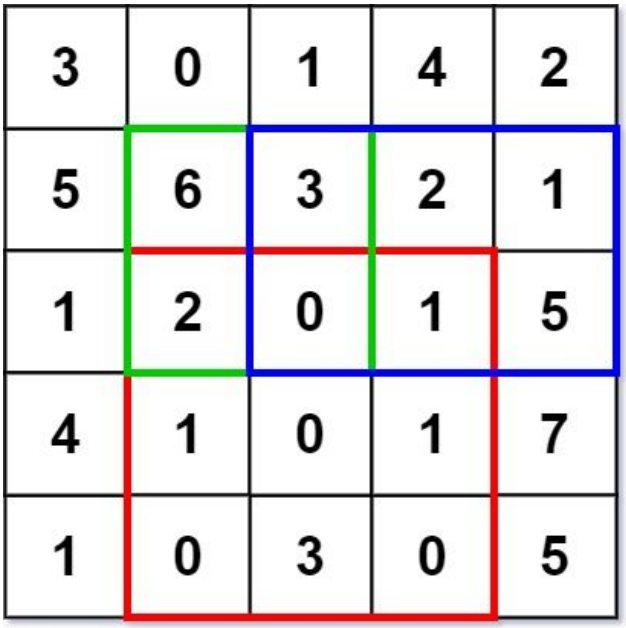
- Calculate the **sum** of the elements of `matrix` inside the rectangle defined by its **upper left corner** `(row1, col1)` and **lower right corner** `(row2, col2)`.

Implement the `NumMatrix` class:

- `NumMatrix(int[][] matrix)` Initializes the object with the integer matrix `matrix`.
- `int sumRegion(int row1, int col1, int row2, int col2)` Returns the **sum** of the elements of `matrix` inside the rectangle defined by its **upper left corner** `(row1, col1)` and **lower right corner** `(row2, col2)`.

You must design an algorithm where `sumRegion` works on `O(1)` time complexity.

Example 1:



```
Input
["NumMatrix", "sumRegion", "sumRegion", "sumRegion"]
[[[[3, 0, 1, 4, 2], [5, 6, 3, 2, 1], [1, 2, 0, 1, 5], [4, 1, 0, 1, 7], [1, 0, 3, 0, 5]]], [2, 1, 4, 3],
[1, 1, 2, 2], [1, 2, 2, 4]]
Output
[null, 8, 11, 12]

Explanation
NumMatrix numMatrix = new NumMatrix([[3, 0, 1, 4, 2], [5, 6, 3, 2, 1], [1, 2, 0, 1, 5], [4, 1, 0, 1,
7], [1, 0, 3, 0, 5]]);
numMatrix.sumRegion(2, 1, 4, 3); // return 8 (i.e sum of the red rectangle)
numMatrix.sumRegion(1, 1, 2, 2); // return 11 (i.e sum of the green rectangle)
numMatrix.sumRegion(1, 2, 2, 4); // return 12 (i.e sum of the blue rectangle)
```

Constraints:

- `m == matrix.length`
- `n == matrix[i].length`
- `1 <= m, n <= 200`
- -10^4 `<= matrix[i][j] <=` 10^4
- `0 <= row1 <= row2 < m`
- `0 <= col1 <= col2 < n`
- At most 10^4 calls will be made to `sumRegion`.

SOLUTION (PYTHON 3)

Solution 1: Two-dimensional Prefix Sum

> **How to think about it**
>
> The matrix is immutable and many sub-rectangle sums are requested. Adding cells on the fly per query does not scale. A 2D prefix s[i+1][j+1] stores the sum of the rectangle from the origin to (i,j). Inclusion-exclusion then yields any target in four lookups: add the bottom-right prefix, subtract the top and left strips, and add back the overlapping corner. After an O(mn) build each query is O(1).

We use s[i + 1][j + 1] to represent the sum of all elements in the upper left part of the ith row and jth column, where indices i and j both start from 0. We can get the following prefix sum formula:

$$s[i + 1][j + 1] = s[i + 1][j] + s[i][j + 1] - s[i][j] + nums[i][j]$$

Then, the sum of the elements of the rectangle with (x_1, y_1) and (x_2, y_2) as the upper left corner and lower right corner respectively is:

$$s[x_2 + 1][y_2 + 1] - s[x_2 + 1][y_1] - s[x_1][y_2 + 1] + s[x_1][y_1]$$

In the initialization method, we preprocess the prefix sum array s, and in the query method, we directly return the result of the above formula.

The time complexity for initializing is O(m × n), and the time complexity for querying is O(1). The space complexity is O(m × n).

Python 3

```
class NumMatrix:
    def __init__(self, matrix: List[List[int]]):
        m, n = len(matrix), len(matrix[0])
        self.s = [[0] * (n + 1) for _ in range(m + 1)]
        for i, row in enumerate(matrix):
            for j, v in enumerate(row):
                self.s[i + 1][j + 1] = (
                    self.s[i][j + 1] + self.s[i + 1][j] - self.s[i][j] + v
                )

    def sumRegion(self, row1: int, col1: int, row2: int, col2: int) -> int:
        return (
            self.s[row2 + 1][col2 + 1]
            - self.s[row2 + 1][col1]
            - self.s[row1][col2 + 1]
            + self.s[row1][col1]
        )

# Your NumMatrix object will be instantiated and called as such:
# obj = NumMatrix(matrix)
# param_1 = obj.sumRegion(row1,col1,row2,col2)
```

525. Contiguous Array

Medium · Array, Hash Table, Prefix Sum

leetcode.com/problems/contiguous-array

★ **TOP 10 PROBLEM** in Prefix Sum: master this one first

PROBLEM

Given a binary array `nums`, return *the maximum length of a contiguous subarray with an equal number of* `0` *and* `1`.

Example 1:

```
Input: nums = [0,1]
Output: 2
Explanation: [0, 1] is the longest contiguous subarray with an equal number of 0 and 1.
```

Example 2:

```
Input: nums = [0,1,0]
Output: 2
Explanation: [0, 1] (or [1, 0]) is a longest contiguous subarray with equal number of 0 and 1.
```

Example 3:

```
Input: nums = [0,1,1,1,1,1,0,0,0]
Output: 6
Explanation: [1,1,1,0,0,0] is the longest contiguous subarray with equal number of 0 and 1.
```

Constraints:

- `1 <= nums.length <= 10^5`
- `nums[i]` is either `0` or `1`.

SOLUTION (PYTHON 3)

Solution 1: Prefix Sum + Hash Table

How to think about it

We want the longest subarray with equally many 0s and 1s. Checking all pairs is $O(n^2)$ and too slow for $n \le 10^5$. Treat 0 as -1; a zero-sum subarray is balanced. Equal prefix sums bound such a segment. Store the first index of each prefix; a later repeat updates the length. Seed 0 at -1 so prefixes from the start are covered.

According to the problem description, we can treat 0s in the array as -1. In this way, when encountering a 0, the prefix sum s will decrease by one, and when encountering a 1, the prefix sum s will increase by one. Therefore, suppose the prefix sum s is equal at indices j and i, where j < i, then the subarray from index j + 1 to i has an equal number of 0s and 1s.

We use a hash table to store all prefix sums and their first occurrence indices. Initially, we map the prefix sum of 0 to -1.

As we iterate through the array, we calculate the prefix sum s. If s is already in the hash table, then we have found a subarray with a sum of 0, and its length is i - d[s], where d[s] is the index where s first appeared in the hash table. If s is not in the hash table, we store s and its index i in the hash table.

The time complexity is O(n), and the space complexity is O(n), where n is the length of the array.

Python 3

```python
class Solution:
    def findMaxLength(self, nums: List[int]) -> int:
        d = {0: -1}
        ans = s = 0
        for i, x in enumerate(nums):
            s += 1 if x else -1
            if s in d:
                ans = max(ans, i - d[s])
            else:
                d[s] = i
        return ans
```

PATTERN 5 · PREFIX SUM · PROBLEM 7 OF 20

238. Product of Array Except Self

Medium · Array, Prefix Sum

leetcode.com/problems/product-of-array-except-self

★ **TOP 10 PROBLEM** in Prefix Sum: master this one first

PROBLEM

Given an integer array `nums`, return *an array* `answer` *such that* `answer[i]` *is equal to the product of all the elements of* `nums` *except* `nums[i]`.

The product of any prefix or suffix of `nums` is **guaranteed** to fit in a **32-bit** integer.

You must write an algorithm that runs in `O(n)` time and without using the division operation.

Example 1:

```
Input: nums = [1,2,3,4]
Output: [24,12,8,6]
```

Example 2:

```
Input: nums = [-1,1,0,-3,3]
Output: [0,0,9,0,0]
```

Constraints:

- `2 <= nums.length <= 10^5`
- `-30 <= nums[i] <= 30`
- The input is generated such that `answer[i]` is **guaranteed** to fit in a **32-bit** integer.

Follow up: Can you solve the problem in `O(1)` extra space complexity? (The output array **does not** count as extra space for space complexity analysis.)

SOLUTION (PYTHON 3)

Solution 1: Two Passes

How to think about it

The product except nums[i] is the left product times the right product. Two extra arrays for prefixes and suffixes use more than constant space. Write prefix products into the answer left to right, then multiply a running suffix from the right, using only the output array.

We define two variables left and right to represent the product of all elements to the left and right of the current element, respectively. Initially, left = 1 and right = 1. We define an answer array ans of length n.

First, we traverse the array from left to right. For the i-th element, we update ans[i] with left, then multiply left by nums[i].

Next, we traverse the array from right to left. For the i-th element, we update ans[i] to ans[i] × right, then multiply right by nums[i].

After the traversal, we return the answer array ans.

The time complexity is O(n), where n is the length of the array nums. Ignoring the space consumption of the answer array, the space complexity is O(1).

Python 3

```python
class Solution:
    def productExceptSelf(self, nums: List[int]) -> List[int]:
        n = len(nums)
        ans = [0] * n
        left = right = 1
        for i, x in enumerate(nums):
            ans[i] = left
            left *= x
        for i in range(n - 1, -1, -1):
            ans[i] *= right
            right *= nums[i]
        return ans
```

```
Input: nums = [-2,1,-3,4,-1,2,1,-5,4]
Output: 6
Explanation: The subarray [4,-1,2,1] has the largest sum 6.
```

Example 2:

```
Input: nums = [1]
Output: 1
Explanation: The subarray [1] has the largest sum 1.
```

Example 3:

```
Input: nums = [5,4,-1,7,8]
Output: 23
Explanation: The subarray [5,4,-1,7,8] has the largest sum 23.
```

Constraints:

- `1 <= nums.length <= 10^5`
- `-10^4 <= nums[i] <= 10^4`

Follow up: If you have figured out the `O(n)` solution, try coding another solution using the **divide and conquer** approach, which is more subtle.

SOLUTIONS (PYTHON 3)

Solution 1: Dynamic Programming

How to think about it

The first idea is to enumerate every pair of endpoints and sum, in $O(n^2)$ or $O(n^3)$. $n \le 10^5$ will time out. The waste is recomputing overlapping subarrays. With the right endpoint fixed at i, the best left end either continues the previous segment (if its sum is positive) or starts over at i. So let f[i] be the best sum ending at i. It depends only on f[i-1], so one rolling variable suffices; the answer is the max along the way.

We define f[i] to represent the maximum sum of a contiguous subarray ending at element nums[i]. Initially, f[0] = nums[0]. The final answer we seek is $\max_{0 \le i < n} f[i]$.

Consider f[i] for $i \ge 1$. Its state transition equation is:

$$f[i] = \max(f[i - 1] + nums[i], nums[i])$$

That is:

$$f[i] = \max(f[i - 1], 0) + nums[i]$$

Since f[i] is only related to f[i - 1], we can use a single variable f to maintain the current value of f[i] and perform the state transition. The answer is $\max_{0 \le i < n} f$.

The time complexity is O(n), where n is the length of the array nums. The space complexity is O(1).

Python 3

```python
class Solution:
    def maxSubArray(self, nums: List[int]) -> int:
        ans = f = nums[0]
        for x in nums[1:]:
            f = max(f, 0) + x
            ans = max(ans, f)
        return ans
```

Solution 2: Divide and Conquer

> **How to think about it**
>
> Solution 1 is already O(n) time and O(1) space. The follow-up asks for divide and conquer, but DP's recurrence is linear in the right endpoint and does not split into disjoint halves. What it lacks is another observation: the best subarray lies entirely on the left, entirely on the right, or crosses the midpoint. Crossing means a max suffix on the left plus a max prefix on the right. Time becomes O(n log n); we use it for the follow-up, not for speed.

Split the array at the midpoint. The answer is the max of the left half, the right half, and the best subarray that crosses the midpoint (max suffix of the left plus max prefix of the right).

The time complexity is O(n log n) and the space complexity is O(log n), where n is the length of the array.

Python 3

```python
class Solution:
    def maxSubArray(self, nums: List[int]) -> int:
        def crossMaxSub(nums, left, mid, right):
            lsum = rsum = 0
            lmx = rmx = -inf
            for i in range(mid, left - 1, -1):
                lsum += nums[i]
                lmx = max(lmx, lsum)
            for i in range(mid + 1, right + 1):
                rsum += nums[i]
                rmx = max(rmx, rsum)
            return lmx + rmx

        def maxSub(nums, left, right):
            if left == right:
                return nums[left]
            mid = (left + right) >> 1
            lsum = maxSub(nums, left, mid)
            rsum = maxSub(nums, mid + 1, right)
            csum = crossMaxSub(nums, left, mid, right)
            return max(lsum, rsum, csum)

        left, right = 0, len(nums) - 1
        return maxSub(nums, left, right)
```

PATTERN 5 · PREFIX SUM · PROBLEM 10 OF 20

437. Path Sum III

Medium · Tree, Depth-First Search, Binary Tree

leetcode.com/problems/path-sum-iii

★ **TOP 10 PROBLEM** in Prefix Sum, Tree DFS (Preorder / Inorder / Postorder): master this one first

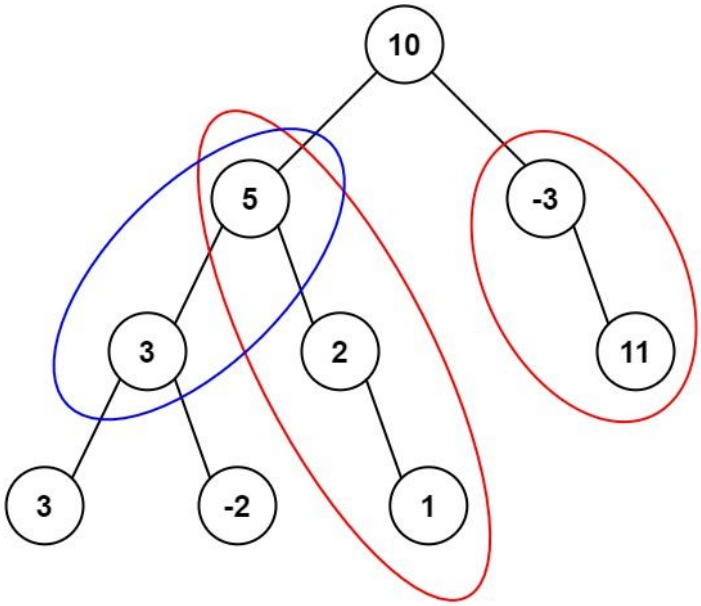
Also appears in pattern 11 Tree DFS (Preorder / Inorder / Postorder)

PROBLEM

Given the `root` of a binary tree and an integer `targetSum`, return *the number of paths where the sum of the values along the path equals* `targetSum`.

The path does not need to start or end at the root or a leaf, but it must go downwards (i.e., traveling only from parent nodes to child nodes).

Example 1:



```
Input: root = [10,5,-3,3,2,null,11,3,-2,null,1], targetSum = 8
Output: 3
Explanation: The paths that sum to 8 are shown.
```

Example 2:

```
Input: root = [5,4,8,11,null,13,4,7,2,null,null,5,1], targetSum = 22
Output: 3
```

Constraints:

- The number of nodes in the tree is in the range `[0, 1000]`.
- -10^9 `<= Node.val <=` 10^9
- `-1000 <= targetSum <= 1000`

SOLUTION (PYTHON 3)

Solution 1: Hash Table + Prefix Sum + Recursion

How to think about it

Paths must go downward. Trying every ancestor then walking down is O(n^2). A path summing to targetSum is a current prefix minus some ancestor prefix. Accumulate the prefix s in preorder and store prefix frequencies on the root-to-node path. cnt[s-targetSum] counts valid paths ending here. Undo s on the way back so another branch does not see it. cnt[0]=1 accounts for a path that starts at the root. Lookup before insert so the current node is not used twice.

We can use the idea of prefix sums to recursively traverse the binary tree while using a hash table cnt to count the occurrences of each prefix sum along the path from the root to the current node.

We design a recursive function dfs(node, s), where node represents the current node being traversed, and s represents the prefix sum along the path from the root to the current node. The return value of the function is the number of paths ending at node or its subtree nodes with a sum equal to targetSum. The final answer is dfs(root, 0).

The recursive process of dfs(node, s) is as follows:

- If the current node node is null, return 0.
- Calculate the prefix sum s along the path from the root to the current node.
- Use cnt[s - targetSum] to represent the number of paths ending at the current node with a sum equal to targetSum. Here, cnt[s - targetSum] is the count of prefix sums equal to s - targetSum in cnt.
- Increment the count of the prefix sum s by 1, i.e., cnt[s] = cnt[s] + 1.
- Recursively traverse the left and right child nodes of the current node by calling dfs(node.left, s) and dfs(node.right, s), and add their return values.
- After the return value is calculated, decrement the count of the prefix sum s by 1, i.e., cnt[s] = cnt[s] - 1.
- Finally, return the result.

The time complexity is O(n), and the space complexity is O(n), where n is the number of nodes in the binary tree.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def pathSum(self, root: Optional[TreeNode], targetSum: int) -> int:
        def dfs(node, s):
            if node is None:
                return 0
            s += node.val
            ans = cnt[s - targetSum]
            cnt[s] += 1
            ans += dfs(node.left, s)
            ans += dfs(node.right, s)
            cnt[s] -= 1
            return ans

        cnt = Counter({0: 1})
        return dfs(root, 0)
```

PATTERN 5 · PREFIX SUM · PROBLEM 13 OF 20

1524. Number of Sub-arrays With Odd Sum

Medium · Array, Math, Dynamic Programming, Prefix Sum

leetcode.com/problems/number-of-sub-arrays-with-odd-sum

PROBLEM

Given an array of integers `arr`, return *the number of subarrays with an **odd** sum*.

Since the answer can be very large, return it modulo $10^9 + 7$.

Example 1:

```
Input: arr = [1,3,5]
Output: 4
Explanation: All subarrays are [[1],[1,3],[1,3,5],[3],[3,5],[5]]
All sub-arrays sum are [1,4,9,3,8,5].
Odd sums are [1,9,3,5] so the answer is 4.
```

Example 2:

```
Input: arr = [2,4,6]
Output: 0
Explanation: All subarrays are [[2],[2,4],[2,4,6],[4],[4,6],[6]]
All sub-arrays sum are [2,6,12,4,10,6].
All sub-arrays have even sum and the answer is 0.
```

Example 3:

```
Input: arr = [1,2,3,4,5,6,7]
Output: 16
```

Constraints:

- $1 <= arr.length <= 10^5$
- $1 <= arr[i] <= 100$

SOLUTION (PYTHON 3)

Solution 1: Prefix Sum + Counter

How to think about it

Count subarrays whose sum is odd. There are $O(n^2)$ of them and $n \le 10^5$, so explicit sums fail. The parity of a subarray sum is the parity of the difference of two prefix sums. An odd prefix pairs with every previous even prefix; an even prefix pairs with every previous odd one. While scanning we keep those two counters, add the matching count for the current prefix, then update. Reduce the answer modulo 10^9+7.

We define an array cnt of length 2 as a counter, where cnt[0] and cnt[1] represent the number of subarrays with even and odd prefix sums, respectively. Initially, cnt[0] = 1 and cnt[1] = 0.

Next, we maintain the current prefix sum s, initially s = 0.

Traverse the array arr, for each element x encountered, add the value of x to s, then based on the parity of s, add the value of cnt[s mod 2 xor 1] to the answer, and then increment the value of cnt[s mod 2] by 1.

After the traversal, we get the answer. Note the modulo operation for the answer.

Time complexity is O(n), where n is the length of the array arr. Space complexity is O(1).

Python 3

```python
class Solution:
    def numOfSubarrays(self, arr: List[int]) -> int:
        mod = 10**9 + 7
        cnt = [1, 0]
        ans = s = 0
        for x in arr:
            s += x
            ans = (ans + cnt[s & 1 ^ 1]) % mod
            cnt[s & 1] += 1
        return ans
```

    remainder = 0
    count = 0
    for x in nums:
        remainder = (remainder + x) % m
        count += seen.get((remainder - r) % m, 0)
        seen[remainder] = seen.get(remainder, 0) + 1
    return count
```

PATTERN 5 · PREFIX SUM · PROBLEM 14 OF 20

1413. Minimum Value to Get Positive Step by Step Sum

Easy · Array, Prefix Sum

leetcode.com/problems/minimum-value-to-get-positive-step-by-step-sum

PROBLEM

Given an array of integers `nums`, you start with an initial **positive** value *startValue*.

In each iteration, you calculate the step by step sum of *startValue* plus elements in `nums` (from left to right).

Return the minimum **positive** value of *startValue* such that the step by step sum is never less than 1.

Example 1:

```
Input: nums = [-3,2,-3,4,2]
Output: 5
Explanation: If you choose startValue = 4, in the third iteration your step by step sum is less than 1.
step by step sum
startValue = 4 | startValue = 5 | nums
  (4 -3 ) = 1 | (5 -3 ) = 2 | -3
  (1 +2 ) = 3 | (2 +2 ) = 4 | 2
  (3 -3 ) = 0 | (4 -3 ) = 1 | -3
  (0 +4 ) = 4 | (1 +4 ) = 5 | 4
  (4 +2 ) = 6 | (5 +2 ) = 7 | 2
```

Example 2:

```
Input: nums = [1,2]
Output: 1
Explanation: Minimum start value should be positive.
```

Example 3:

```
Input: nums = [1,-2,-3]
Output: 5
```

Constraints:

- `1 <= nums.length <= 100`
- `-100 <= nums[i] <= 100`

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

Every running sum must stay at least 1. If the start value is x, then x plus every prefix is ≥ 1, so x≥ 1-minprefix. Also x≥ 1. n≤ 100. One pass tracks the prefix and its minimum t; the answer is max(1,1-t).

Python 3

```python
class Solution:
    def minStartValue(self, nums: List[int]) -> int:
        s, t = 0, inf
        for num in nums:
            s += num
            t = min(t, s)
        return max(1, 1 - t)
```

Complexity. Time: O(n). Space: O(1).

Solution 2

> **How to think about it**
>
> Method 1 tracks the minimum on the fly. Building all prefixes with `accumulate` and then taking min uses the same formula, only with an explicit prefix array.

Python 3

```python
class Solution:
    def minStartValue(self, nums: List[int]) -> int:
        s = list(accumulate(nums))
        return 1 if min(s) >= 0 else abs(min(s)) + 1
```

Complexity. Time: O(n). Space: O(n).

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

PROBLEM

Given an integer array `nums` and two integers `firstLen` and `secondLen`, return *the maximum sum of elements in two non-overlapping **subarrays** with lengths* `firstLen` *and* `secondLen`.

The array with length `firstLen` could occur before or after the array with length `secondLen`, but they have to be non-overlapping.

A **subarray** is a **contiguous** part of an array.

Example 1:

```
Input: nums = [0,6,5,2,2,5,1,9,4], firstLen = 1, secondLen = 2
Output: 20
Explanation: One choice of subarrays is [9] with length 1, and [6,5] with length 2.
```

Example 2:

```
Input: nums = [3,8,1,3,2,1,8,9,0], firstLen = 3, secondLen = 2
Output: 29
Explanation: One choice of subarrays is [3,8,1] with length 3, and [8,9] with length 2.
```

Example 3:

```
Input: nums = [2,1,5,6,0,9,5,0,3,8], firstLen = 4, secondLen = 3
Output: 31
Explanation: One choice of subarrays is [5,6,0,9] with length 4, and [0,3,8] with length 3.
```

Constraints:

- `1 <= firstLen, secondLen <= 1000`
- `2 <= firstLen + secondLen <= 1000`
- `firstLen + secondLen <= nums.length <= 1000`
- `0 <= nums[i] <= 1000`

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Enumerating both segments is O(n^2) and tight at n≤ 1000. After one segment is fixed, the other only needs the best fixed-length window on the remaining side. Prefix sums give any window sum in O(1). We handle “ firstLen on the left” and “ secondLen on the left” separately, keeping the best left window in t as the right window slides. The answer is the larger of the two scans.

Python 3

```
class Solution:
    def maxSumTwoNoOverlap(self, nums: List[int], firstLen: int, secondLen: int) -> int:
        n = len(nums)
        s = list(accumulate(nums, initial=0))
        ans = t = 0
        i = firstLen
        while i + secondLen - 1 < n:
            t = max(t, s[i] - s[i - firstLen])
            ans = max(ans, t + s[i + secondLen] - s[i])
            i += 1
        t = 0
        i = secondLen
        while i + firstLen - 1 < n:
            t = max(t, s[i] - s[i - secondLen])
            ans = max(ans, t + s[i + firstLen] - s[i])
            i += 1
        return ans
```

        if total > best_total:
            best_total = total
```

```
            answer = [left, middle, right]
    return answer
```

PATTERN 5 · PREFIX SUM · PROBLEM 16 OF 20

307. Range Sum Query - Mutable

Medium · Design, Binary Indexed Tree, Segment Tree, Array, Divide and Conquer, Sqrt Decomposition

leetcode.com/problems/range-sum-query-mutable

★ **TOP 10 PROBLEM** in Segment Tree, Binary Indexed Tree (Fenwick Tree): master this one first

Also appears in pattern 40 Segment Tree, 41 Binary Indexed Tree (Fenwick Tree)

PROBLEM

Given an integer array `nums`, handle multiple queries of the following types:

1. **Update** the value of an element in `nums`.
2. Calculate the **sum** of the elements of `nums` between indices `left` and `right` **inclusive** where `left <= right`.

Implement the `NumArray` class:

- `NumArray(int[] nums)` Initializes the object with the integer array `nums`.
- `void update(int index, int val)` **Updates** the value of `nums[index]` to be `val`.
- `int sumRange(int left, int right)` Returns the **sum** of the elements of `nums` between indices `left` and `right` **inclusive** (i.e. `nums[left] + nums[left + 1] + ... + nums[right]`).

Example 1:

```
Input
["NumArray", "sumRange", "update", "sumRange"]
[[[1, 3, 5]], [0, 2], [1, 2], [0, 2]]
Output
[null, 9, null, 8]

Explanation
NumArray numArray = new NumArray([1, 3, 5]);
numArray.sumRange(0, 2); // return 1 + 3 + 5 = 9
numArray.update(1, 2); // nums = [1, 2, 5]
numArray.sumRange(0, 2); // return 1 + 2 + 5 = 8
```

Constraints:

- `1 <= nums.length <= 3 * 10^4`
- `-100 <= nums[i] <= 100`
- `0 <= index < nums.length`
- `-100 <= val <= 100`
- `0 <= left <= right < nums.length`
- At most `3 * 10^4` calls will be made to `update` and `sumRange`.

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

Unlike problem 303, a point update must stay cheap together with range sums. Rebuilding a prefix array after every write, or scanning on each query, cannot keep both operations logarithmic. A Fenwick tree stores prefix sums via lowbit: update walks x+=x&-x, query walks x-=x&-x. A range is the difference of two prefixes; an update reads the old value and writes the delta. The constructor inserts each index once.

Python 3

```python
class BinaryIndexedTree:
    __slots__ = ["n", "c"]

    def __init__(self, n):
        self.n = n
        self.c = [0] * (n + 1)

    def update(self, x: int, delta: int):
        while x <= self.n:
            self.c[x] += delta
            x += x & -x

    def query(self, x: int) -> int:
        s = 0
        while x > 0:
            s += self.c[x]
            x -= x & -x
        return s

class NumArray:
    __slots__ = ["tree"]

    def __init__(self, nums: List[int]):
        self.tree = BinaryIndexedTree(len(nums))
        for i, v in enumerate(nums, 1):
            self.tree.update(i, v)

    def update(self, index: int, val: int) -> None:
        prev = self.sumRange(index, index)
        self.tree.update(index + 1, val - prev)

    def sumRange(self, left: int, right: int) -> int:
        return self.tree.query(right + 1) - self.tree.query(left)

# Your NumArray object will be instantiated and called as such:
# obj = NumArray(nums)
# obj.update(index,val)
# param_2 = obj.sumRange(left,right)
```

Complexity. Time: build O(n log n), update and sumRange O(log n) each. Space: O(n).

Solution 2

How to think about it

A Fenwick tree is tailored to prefix sums and is less natural for arbitrary segment aggregates. A segment tree splits [l,r] at the midpoint; each internal node stores its interval sum, and a point update touches only the O(log n) nodes on the root-to-leaf path. A query decomposes [left,right] into O(log n) node intervals. The asymptotics match Method 1; the explicit children make later extensions (e.g. range extrema) straightforward.

Python 3

```python
class Node:
    __slots__ = ["l", "r", "v"]

    def __init__(self):
        self.l = self.r = self.v = 0

class SegmentTree:
    __slots__ = ["nums", "tr"]

    def __init__(self, nums):
        self.nums = nums
        n = len(nums)
        self.tr = [Node() for _ in range(n << 2)]
        self.build(1, 1, n)

    def build(self, u, l, r):
        self.tr[u].l, self.tr[u].r = l, r
        if l == r:
            self.tr[u].v = self.nums[l - 1]
            return
        mid = (l + r) >> 1
        self.build(u << 1, l, mid)
        self.build(u << 1 | 1, mid + 1, r)
        self.pushup(u)

    def modify(self, u, x, v):
        if self.tr[u].l == x and self.tr[u].r == x:
            self.tr[u].v = v
            return
        mid = (self.tr[u].l + self.tr[u].r) >> 1
        if x <= mid:
            self.modify(u << 1, x, v)
        else:
            self.modify(u << 1 | 1, x, v)
        self.pushup(u)

    def query(self, u, l, r):
        if self.tr[u].l >= l and self.tr[u].r <= r:
            return self.tr[u].v
        mid = (self.tr[u].l + self.tr[u].r) >> 1
        result = 0
        if l <= mid:
            result += self.query(u << 1, l, r)
        if r > mid:
            result += self.query(u << 1 | 1, l, r)
        return result

    def pushup(self, u):
        self.tr[u].v = self.tr[u << 1].v + self.tr[u << 1 | 1].v

class NumArray:
    __slots__ = ["tree"]

    def __init__(self, nums: List[int]):
        self.tree = SegmentTree(nums)

    def update(self, index: int, val: int) -> None:
        self.tree.modify(1, index + 1, val)
```

```python
    def sumRange(self, left: int, right: int) -> int:
        return self.tree.query(1, left + 1, right + 1)

# Your NumArray object will be instantiated and called as such:
```

```
# obj = NumArray(nums)
# obj.update(index,val)
# param_2 = obj.sumRange(left,right)
```

PATTERN 5 · PREFIX SUM · PROBLEM 17 OF 20

1590. Make Sum Divisible by P

Medium · Array, Hash Table, Prefix Sum

leetcode.com/problems/make-sum-divisible-by-p

★ **TOP 10 PROBLEM** in Prefix Sum: master this one first

PROBLEM

Given an array of positive integers `nums`, remove the **smallest** subarray (possibly **empty**) such that the **sum** of the remaining elements is divisible by `p`. It is **not** allowed to remove the whole array.

Return *the length of the smallest subarray that you need to remove, or* `-1` *if it's impossible*.

A **subarray** is defined as a contiguous block of elements in the array.

Example 1:

```
Input: nums = [3,1,4,2], p = 6
Output: 1
Explanation: The sum of the elements in nums is 10, which is not divisible by 6. We can remove the
subarray [4], and the sum of the remaining elements is 6, which is divisible by 6.
```

Example 2:

```
Input: nums = [6,3,5,2], p = 9
Output: 2
Explanation: We cannot remove a single element to get a sum divisible by 9. The best way is to remove
the subarray [5,2], leaving us with [6,3] with sum 9.
```

Example 3:

```
Input: nums = [1,2,3], p = 3
Output: 0
Explanation: Here the sum is 6. which is already divisible by 3. Thus we do not need to remove
anything.
```

Constraints:

- `1 <= nums.length <= 10^5`
- `1 <= nums[i] <= 10^9`
- `1 <= p <= 10^9`

SOLUTION (PYTHON 3)

Solution 1: Prefix Sum + Hash Table

How to think about it

Delete the shortest subarray so the remaining sum is divisible by p. n≤ 10^5 rules out enumerating intervals. If the total is k modulo p, the deleted piece must be k modulo p as well. Scan prefix sums modulo p and remember the last index of each residue. At residue cur, look up (cur-k) mod p; the gap is a candidate deletion. Deleting the entire array is forbidden.

First, we calculate the sum of all elements in the array nums modulo p, denoted as k. If k is 0, it means the sum of all elements in the array nums is a multiple of p, so we directly return 0.

If k is not 0, we need to find the shortest subarray such that removing this subarray makes the sum of the remaining elements modulo p equal to 0.

We can traverse the array nums, maintaining the current prefix sum modulo p, denoted as cur. We use a hash table last to record the last occurrence of each prefix sum modulo p.

If there exists a subarray ending at nums[i] such that removing this subarray makes the sum of the remaining elements modulo p equal to 0, we need to find a previous prefix sum modulo p equal to target at position j such that (target + k - cur) mod p = 0. If found, we can remove the subarray nums[j+1,..i] to make the sum of the remaining elements modulo p equal to 0.

Therefore, if there exists a target = (cur - k + p) mod p, we can update the answer to min(ans, i - j). Then, we update last[cur] to i. We continue traversing the array nums until the end to get the answer.

The time complexity is O(n), and the space complexity is O(n). Here, n is the length of the array nums.

Python 3

```python
class Solution:
    def minSubarray(self, nums: List[int], p: int) -> int:
        k = sum(nums) % p
        if k == 0:
            return 0
        last = {0: -1}
        cur = 0
        ans = len(nums)
        for i, x in enumerate(nums):
            cur = (cur + x) % p
            target = (cur - k + p) % p
            if target in last:
                ans = min(ans, i - last[target])
            last[cur] = i
        return -1 if ans == len(nums) else ans
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

```

PATTERN 5 · PREFIX SUM · PROBLEM 18 OF 20

1314. Matrix Block Sum

Medium · Array, Matrix, Prefix Sum

leetcode.com/problems/matrix-block-sum

PROBLEM

Given a `m x n` matrix `mat` and an integer `k`, return *a matrix* `answer` *where each* `answer[i][j]` *is the sum of all elements* `mat[r][c]` *for*:

- `i - k <= r <= i + k`,
- `j - k <= c <= j + k`, and
- `(r, c)` is a valid position in the matrix.

Example 1:

```
Input: mat = [[1,2,3],[4,5,6],[7,8,9]], k = 1
Output: [[12,21,16],[27,45,33],[24,39,28]]
```

Example 2:

```
Input: mat = [[1,2,3],[4,5,6],[7,8,9]], k = 2
Output: [[45,45,45],[45,45,45],[45,45,45]]
```

Constraints:

- `m == mat.length`
- `n == mat[i].length`
- `1 <= m, n, k <= 100`
- `1 <= mat[i][j] <= 100`

SOLUTION (PYTHON 3)

Solution 1: Two-Dimensional Prefix Sum

How to think about it

Each cell asks for the sum of a square neighborhood. Summing on the fly is $O(mnk^2)$ when k is large. The same rectangles are requested many times; a 2D prefix reduces any rectangle to four corners. Build s[i][j] as the sum of the top-left i × j block, clamp each window to the matrix, and evaluate $s[x_2+1][y_2+1]-s[x_1][y_2+1]-s[x_2+1][y_1]+s[x_1][y_1]$.

This problem is a template for two-dimensional prefix sum.

We define s[i][j] as the sum of the elements in the first i rows and the first j columns of the matrix mat. The calculation formula for s[i][j] is:

$$s[i][j] = s[i-1][j] + s[i][j-1] - s[i-1][j-1] + mat[i-1][j-1]$$

In this way, we can quickly calculate the sum of elements in any rectangular area through the s array.

For a rectangular area with the upper left coordinate (x_1, y_1) and the lower right coordinate (x_2, y_2), we can calculate the sum of its elements through the s array:

$$s[x_2+1][y_2+1] - s[x_1][y_2+1] - s[x_2+1][y_1] + s[x_1][y_1]$$

The time complexity is O(m × n), and the space complexity is O(m × n). Where m and n are the number of rows and columns in the matrix, respectively.

Python 3

```python
class Solution:
    def matrixBlockSum(self, mat: List[List[int]], k: int) -> List[List[int]]:
        m, n = len(mat), len(mat[0])
        s = [[0] * (n + 1) for _ in range(m + 1)]
        for i, row in enumerate(mat, 1):
            for j, x in enumerate(row, 1):
                s[i][j] = s[i - 1][j] + s[i][j - 1] - s[i - 1][j - 1] + x
        ans = [[0] * n for _ in range(m)]
        for i in range(m):
            for j in range(n):
                x1, y1 = max(i - k, 0), max(j - k, 0)
                x2, y2 = min(m - 1, i + k), min(n - 1, j + k)
                ans[i][j] = (
                    s[x2 + 1][y2 + 1] - s[x1][y2 + 1] - s[x2 + 1][y1] + s[x1][y1]
                )
        return ans
```

PATTERN 5 · PREFIX SUM · PROBLEM 19 OF 20

1277. Count Square Submatrices with All Ones

Medium · Array, Dynamic Programming, Matrix

leetcode.com/problems/count-square-submatrices-with-all-ones

Also appears in pattern 22 Dynamic Programming - 2D / Grid, 28 Dynamic Programming - Knapsack Style

PROBLEM

Given a `m * n` matrix of ones and zeros, return how many **square** submatrices have all ones.

Example 1:

```
Input: matrix =
[
  [0,1,1,1],
  [1,1,1,1],
  [0,1,1,1]
]
Output: 15
Explanation:
There are 10 squares of side 1.
There are 4 squares of side 2.
There is 1 square of side 3.
Total number of squares = 10 + 4 + 1 = 15.
```

Example 2:

```
Input: matrix =
[
  [1,0,1],
  [1,1,0],
  [1,1,0]
]
Output: 7
Explanation:
There are 6 squares of side 1.
There is 1 square of side 2.
Total number of squares = 6 + 1 = 7.
```

Constraints:

- `1 <= arr.length <= 300`
- `1 <= arr[0].length <= 300`
- `0 <= arr[i][j] <= 1`

SOLUTION (PYTHON 3)

Solution 1: Dynamic Programming

> **How to think about it**
>
> We count all-1 squares. m,n ≤ 300, so enumerating squares is O(n^3). The largest square cornered at (i,j) is limited by the squares at the top, left, and top-left cells. f[i][j] is that side length: if the cell is 1, take the min of those three plus one. Each such square contributes f[i][j] squares (sides 1… f). DP turns counting into one fill.

We define f[i][j] as the side length of the square submatrix with (i,j) as the bottom-right corner. Initially f[i][j] = 0, and the answer is $\sum_{i,j}$ f[i][j].

Consider how to perform state transition for f[i][j].

- When matrix[i][j] = 0, we have f[i][j] = 0.

- When matrix[i][j] = 1, the value of state f[i][j] depends on the values of the three positions above, left, and top-left:
  - If i = 0 or j = 0, then f[i][j] = 1.
  - Otherwise f[i][j] = min(f[i-1][j-1], f[i-1][j], f[i][j-1]) + 1.

The answer is $\sum_{i,j} f[i][j]$.

Time complexity O(m × n), space complexity O(m × n). Where m and n are the number of rows and columns of the matrix respectively.

Python 3

```
class Solution:
    def countSquares(self, matrix: List[List[int]]) -> int:
        m, n = len(matrix), len(matrix[0])
        f = [[0] * n for _ in range(m)]
        ans = 0
        for i, row in enumerate(matrix):
            for j, v in enumerate(row):
                if v == 0:
                    continue
                if i == 0 or j == 0:
                    f[i][j] = 1
                else:
                    f[i][j] = min(f[i - 1][j - 1], f[i - 1][j], f[i][j - 1]) + 1
                ans += f[i][j]
        return ans
```

2270. Number of Ways to Split Array

Medium · Array, Prefix Sum

leetcode.com/problems/number-of-ways-to-split-array

PROBLEM

You are given a **0-indexed** integer array `nums` of length `n`.

`nums` contains a **valid split** at index `i` if the following are true:

- The sum of the first `i + 1` elements is **greater than or equal to** the sum of the last `n - i - 1` elements.
- There is **at least one** element to the right of `i`. That is, `0 <= i < n - 1`.

Return *the number of **valid splits** in* `nums`.

Example 1:

```
Input: nums = [10,4,-8,7]
Output: 2
Explanation:
There are three ways of splitting nums into two non-empty parts:
- Split nums at index 0. Then, the first part is [10], and its sum is 10. The second part is [4,-8,7],
and its sum is 3. Since 10 >= 3, i = 0 is a valid split.
- Split nums at index 1. Then, the first part is [10,4], and its sum is 14. The second part is [-8,7],
and its sum is -1. Since 14 >= -1, i = 1 is a valid split.
- Split nums at index 2. Then, the first part is [10,4,-8], and its sum is 6. The second part is [7],
and its sum is 7. Since 6 < 7, i = 2 is not a valid split.
Thus, the number of valid splits in nums is 2.
```

Example 2:

```
Input: nums = [2,3,1,0]
Output: 2
Explanation:
There are two valid splits in nums:
- Split nums at index 1. Then, the first part is [2,3], and its sum is 5. The second part is [1,0], and
its sum is 1. Since 5 >= 1, i = 1 is a valid split.
- Split nums at index 2. Then, the first part is [2,3,1], and its sum is 6. The second part is [0], and
its sum is 0. Since 6 >= 0, i = 2 is a valid split.
```

Constraints:

- `2 <= nums.length <= 10^5`
- `-10^5 <= nums[i] <= 10^5`

SOLUTION (PYTHON 3)

Solution 1: Prefix Sum

> **How to think about it**
>
> A valid split needs the left sum at least the right sum, and a non-empty right part. n ≤ 10^5 forbids summing from scratch. The two sides add to the total s, so the test is prefix t ≥ s-t. Compute s, then scan the first n-1 elements, accumulating t and counting.

First, we calculate the total sum s of the array nums. Then, we traverse the first n-1 elements of the array nums, using the variable t to record the prefix sum. If t ≥ s - t, we increment the answer by one.

After the traversal, we return the answer.

The time complexity is O(n), where n is the length of the array nums. The space complexity is O(1).

Python 3

```
class Solution:
    def waysToSplitArray(self, nums: List[int]) -> int:
        s = sum(nums)
        ans = t = 0
        for x in nums[:-1]:
            t += x
            ans += t >= s - t
        return ans
```

    return positions
```

PATTERN 6 OF 41

String Manipulation / Parsing

20 problems · 4 Easy · 13 Medium · 3 Hard

THE IDEA

Walk the string once with an index (or a stack) and handle each kind of character. Most bugs are edge cases: signs, spaces, overflow, empty input.

Signals: convert or validate text (atoi, roman numerals), reverse words, compress, add or multiply numbers stored as strings, simplify a path.

A TEMPLATE TO KEEP IN YOUR HANDS (PYTHON)

```
i, n = 0, len(s)
while i < n and s[i] == " ":        # skip leading spaces
    i += 1
sign = 1
if i < n and s[i] in "+-":
    sign = -1 if s[i] == "-" else 1
    i += 1
value = 0
while i < n and s[i].isdigit():
    value = value * 10 + int(s[i])
    i += 1
```

PATTERN 6 · STRING MANIPULATION / PARSING · PROBLEM 1 OF 20

20. Valid Parentheses

Easy · Stack, String, Parentheses

leetcode.com/problems/valid-parentheses

★ **TOP 10 PROBLEM** in String Manipulation / Parsing, Stack: master this one first

Also appears in pattern 8 Stack

PROBLEM

Given a string `s` containing just the characters `'('`, `')'`, `'{'`, `'}'`, `'['` and `']'`, determine if the input string is valid.

An input string is valid if:

1. Open brackets must be closed by the same type of brackets.
2. Open brackets must be closed in the correct order.
3. Every close bracket has a corresponding open bracket of the same type.

Example 1:

Input: s = "()"

Output: true

Example 2:

Input: s = "()[]{}"

Output: true

Example 3:

Input: s = "(]"

Output: false

Example 4:

Input: s = "([])"

Output: true

Example 5:

Input: s = "([)]"

Output: false

Constraints:

- `1 <= s.length <= 10^4`
- `s` consists of parentheses only `'()[]{}'`.

SOLUTION (PYTHON 3)

Solution 1: Stack

How to think about it

Repeatedly deleting adjacent pairs (), [], and {} until nothing is left is correct, but each pass rescans the string. With n ≤ 10^4, deeply nested input falls to O(n^2) and can easily time out. The bottleneck is that a match is more than two neighboring characters. A later opener must close first, while an earlier one stays open. Once the brackets cross, as in ([)], deleting neighbors cannot reduce the string to empty. Matching is therefore last-in, first-out: the only legal partner of the current closer is the most recent unmatched opener. A stack keeps those unfinished matches. An opener pushes its closer, so the closer allowed next sits on top, and a closer is compared only with that top. A mismatch means the type or the order is already wrong, and a non-empty stack at the end means some opener never closed.

We use a hash table d to map each opening bracket to its closing bracket, and a stack stk to store closers that have not been matched yet. Scan s from left to right. When the current character is an opening bracket, push the corresponding closer from d onto stk. When it is a closing bracket, return `false` if stk is empty or the popped top is different from that character.

After the scan, return `true` if stk is empty: every pair has been closed in the right type and order. If the stack still holds a closer, some opening bracket was never matched, so return `false`.

The time complexity is O(n), and the space complexity is O(n), where n is the length of s.

Python 3

```python
class Solution:
    def isValid(self, s: str) -> bool:
        stk = []
        d = {'(': ')', '[': ']', '{': '}'}
        for c in s:
            if c in d:
                stk.append(d[c])
            elif not stk or stk.pop() != c:
                return False
        return not stk
```

```

PATTERN 6 · STRING MANIPULATION / PARSING · PROBLEM 2 OF 20

14. Longest Common Prefix

Easy · Trie, Array, String

leetcode.com/problems/longest-common-prefix

★ **TOP 10 PROBLEM** in String Manipulation / Parsing: master this one first

PROBLEM

Write a function to find the longest common prefix string amongst an array of strings.

If there is no common prefix, return an empty string `""`.

Example 1:

```
Input: strs = ["flower","flow","flight"]
Output: "fl"
```

Example 2:

```
Input: strs = ["dog","racecar","car"]
Output: ""
Explanation: There is no common prefix among the input strings.
```

Constraints:

- `1 <= strs.length <= 200`
- `0 <= strs[i].length <= 200`
- `strs[i]` consists of only lowercase English letters if it is non-empty.

SOLUTION (PYTHON 3)

Solution 1: Character Comparison

How to think about it

The first idea is to take the first string as the prefix and shrink it against each later string. n,m≤ 200, so even a triple loop would pass. A trie works too, but it is heavier than this problem needs. The prefix only ever shrinks: once a column disagrees, a longer prefix cannot exist. Align the strings vertically; position i can extend the prefix only if every string matches there. So we compare column by column against strs[0] and return as soon as a string is too short or a character differs. No trie.

We use the first string strs[0] as a benchmark, and compare whether the i-th character of the subsequent strings is the same as the i-th character of strs[0]. If they are the same, we continue to compare the next character. Otherwise, we return the first i characters of strs[0].

If the traversal ends, it means that the first i characters of all strings are the same, and we return strs[0].

The time complexity is O(n × m), where n and m are the length of the string array and the minimum length of the strings, respectively. The space complexity is O(1).

Python 3

```python
class Solution:
    def longestCommonPrefix(self, strs: List[str]) -> str:
        for i in range(len(strs[0])):
            for s in strs[1:]:
                if len(s) <= i or s[i] != strs[0][i]:
                    return s[:i]
        return strs[0]
```

459. Repeated Substring Pattern

Easy · String, String Matching, KMP, Extended KMP

leetcode.com/problems/repeated-substring-pattern

★ **TOP 10 PROBLEM** in String Matching / Pattern Search: master this one first

Also appears in pattern 7 String Matching / Pattern Search

PROBLEM

Given a string `s`, check if it can be constructed by taking a substring of it and appending multiple copies of the substring together.

Example 1:

```
Input: s = "abab"
Output: true
Explanation: It is the substring "ab" twice.
```

Example 2:

```
Input: s = "aba"
Output: false
```

Example 3:

```
Input: s = "abcabcabcabc"
Output: true
Explanation: It is the substring "abc" four times or the substring "abcabc" twice.
```

Constraints:

- `1 <= s.length <= 10^4`
- `s` consists of lowercase English letters.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

We ask whether s is a proper prefix repeated. Trying every prefix length is $O(n^2)$. Build s+s and search for s starting at index 1. A hit before n means s lines up inside the concatenation, hence a period exists. Starting at 1 skips the trivial match at 0; a hit at n is only the middle copy, so there is no smaller period.

Python 3

```python
class Solution:
    def repeatedSubstringPattern(self, s: str) -> bool:
        return (s + s).index(s, 1) < len(s)
```

PATTERN 6 · STRING MANIPULATION / PARSING · PROBLEM 4 OF 20

28. Find the Index of the First Occurrence in a String

Easy · Two Pointers, String, String Matching, KMP, Boyer–Moore, Extended KMP

leetcode.com/problems/find-the-index-of-the-first-occurrence-in-a-string

★ **TOP 10 PROBLEM** in String Manipulation / Parsing, String Matching / Pattern Search: master this one first

Also appears in pattern 7 String Matching / Pattern Search

PROBLEM

Given two strings `needle` and `haystack`, return the index of the first occurrence of `needle` in `haystack`, or `-1` if `needle` is not part of `haystack`.

Example 1:

```
Input: haystack = "sadbutsad", needle = "sad"
Output: 0
Explanation: "sad" occurs at index 0 and 6.
The first occurrence is at index 0, so we return 0.
```

Example 2:

```
Input: haystack = "leetcode", needle = "leeto"
Output: -1
Explanation: "leeto" did not occur in "leetcode", so we return -1.
```

Constraints:

- `1 <= haystack.length, needle.length <= 10^4`
- `haystack` and `needle` consist of only lowercase English characters.

SOLUTIONS (PYTHON 3)

Solution 1: Traversal

How to think about it

The first idea is to try every start i in haystack and test whether the length-m slice equals needle. With n,m ≤ 10^4, the worst case O((n-m)m) is about 10^8 and usually passes. The bottleneck is paying m character comparisons at many near-matches. Smarter matchers amortize toward linear time, but this size does not force them yet. We only need the first hit; a mismatch just moves on to the next i. So scan i from 0 to n-m, return i on equality, else -1. Extra space is O(1).

We compare the string `needle` with each character of the string `haystack` as the starting point. If we find a matching index, we return it directly.

Assuming the length of the string `haystack` is n and the length of the string `needle` is m, the time complexity is O((n-m) × m), and the space complexity is O(1).

Python 3

```python
class Solution:
    def strStr(self, haystack: str, needle: str) -> int:
        n, m = len(haystack), len(needle)
        for i in range(n - m + 1):
            if haystack[i : i + m] == needle:
                return i
        return -1
```

Solution 2: Rabin-Karp String Matching Algorithm

> **How to think about it**
>
> Solution 1 may compare all m characters at every start, approaching O(nm). We want the next window to reuse work from the last one. A fixed-length substring can be rolling-hashed: add the incoming character, drop the outgoing one, update in O(1). When the window hash equals needle's hash, compare the raw strings to rule out a collision. One scan of haystack then costs expected O(n+m).

The Rabin-Karp algorithm essentially uses a sliding window combined with a hash function to compare the hashes of fixed-length strings, which can reduce the time complexity of comparing whether two strings are the same to O(1).

Assuming the length of the string `haystack` is n and the length of the string `needle` is m, the time complexity is O(n+m), and the space complexity is O(1).

Python 3

```python
class Solution:
    def strStr(self, haystack: str, needle: str) -> int:
        n, m = len(haystack), len(needle)
        mod = (1 << 31) - 1
        target = sha = 0
        multi = 1
        for i in range(m):
            target = (target * 256 + ord(needle[i])) % mod
        for _ in range(1, m):
            multi = multi * 256 % mod
        left = 0
        for right in range(n):
            sha = (sha * 256 + ord(haystack[right])) % mod
            if right - left + 1 < m:
                continue
            if sha == target and haystack[left : right + 1] == needle:
                return left
            sha = (sha - ord(haystack[left]) * multi % mod + mod) % mod
            left += 1
        return -1
```

Solution 3: KMP

> **How to think about it**
>
> Solution 2 makes a window comparison expected O(1), but it still hashes modulo a prime and must verify the raw strings on a collision. We want a worst-case linear scan without hashing. After a mismatch we need not rewind haystack to the start of the window. The prefix function of needle stores the longest proper border of the matched prefix, so we know where in the pattern to resume. Build next for needle, then scan haystack once, falling back only along next. Time O(n+m) and extra space O(m).

Compute the prefix function next of needle, where next[i] is the longest proper border of needle[0..i]. Scan haystack: equal characters grow the match length, and a mismatch jumps it to next[j-1]. When the match length reaches m, return the start index i-m+1.

The time complexity is O(n+m) and the space complexity is O(m), where n and m are the lengths of haystack and needle.

Python 3

```python
class Solution:
    def strStr(self, haystack: str, needle: str) -> int:
        n, m = len(haystack), len(needle)
        nxt = [0] * m
        j = 0
        for i in range(1, m):
            while j and needle[i] != needle[j]:
                j = nxt[j - 1]
            if needle[i] == needle[j]:
                j += 1
            nxt[i] = j
        j = 0
        for i, ch in enumerate(haystack):
            while j and ch != needle[j]:
                j = nxt[j - 1]
            if ch == needle[j]:
                j += 1
            if j == m:
                return i - m + 1
        return -1
```

```

PATTERN 6 · STRING MANIPULATION / PARSING · PROBLEM 5 OF 20

8. String to Integer (atoi)

Medium · String

leetcode.com/problems/string-to-integer-atoi

★ **TOP 10 PROBLEM** in String Manipulation / Parsing: master this one first

PROBLEM

Implement the `myAtoi(string s)` function, which converts a string to a 32-bit signed integer.

The algorithm for `myAtoi(string s)` is as follows:

1. **Whitespace**: Ignore any leading whitespace (`" "`).
2. **Signedness**: Determine the sign by checking if the next character is `'-'` or `'+'`, assuming positivity if neither present.
3. **Conversion**: Read the integer by skipping leading zeros until a non-digit character is encountered or the end of the string is reached. If no digits were read, then the result is 0.
4. **Rounding**: If the integer is out of the 32-bit signed integer range $[-2^{31}, 2^{31} - 1]$, then round the integer to remain in the range. Specifically, integers less than -2^{31} should be rounded to -2^{31}, and integers greater than $2^{31} - 1$ should be rounded to $2^{31} - 1$.

Return the integer as the final result.

Note: You must not use any built-in library function that converts a string to a number (for example, `atoi`, `stoi`, `Integer.parseInt`, `int()`, `parseInt`, `Number()`). Perform the conversion manually.

Example 1:

Input: s = "42"

Output: 42

Explanation:

```
The underlined characters are what is read in and the caret is the current reader position.
Step 1: "42" (no characters read because there is no leading whitespace)
         ^
Step 2: "42" (no characters read because there is neither a '-' nor '+')
         ^
Step 3: "42" ("42" is read in)
           ^
```

Example 2:

Input: s = " -042"

Output: -42

Explanation:

```
Step 1: " -042" (leading whitespace is read and ignored)
            ^
Step 2: " -042" ('-' is read, so the result should be negative)
             ^
Step 3: " -042" ("042" is read in, leading zeros ignored in the result)
               ^
```

Example 3:

Input: s = "1337c0d3"

Output: 1337

Explanation:

```
Step 1: "1337c0d3" (no characters read because there is no leading whitespace)
         ^
Step 2: "1337c0d3" (no characters read because there is neither a '-' nor '+')
         ^
Step 3: "1337c0d3" ("1337" is read in; reading stops because the next character is a non-digit)
            ^
```

Example 4:

Input: s = "0-1"

Output: 0

Explanation:

```
Step 1: "0-1" (no characters read because there is no leading whitespace)
         ^
Step 2: "0-1" (no characters read because there is neither a '-' nor '+')
         ^
Step 3: "0-1" ("0" is read in; reading stops because the next character is a non-digit)
          ^
```

Example 5:

Input: s = "words and 987"

Output: 0

Explanation:

Reading stops at the first non-digit character 'w'.

Constraints:

- `0 <= s.length <= 200`
- `s` consists of English letters (lower-case and upper-case), digits (`0 - 9`), `' '`, `'+'`, `'-'`, and `'.'`.

SOLUTION (PYTHON 3)

Solution 1: Traverse the String

How to think about it

A single left-to-right scan is enough; n ≤ 200 is not a complexity issue. The easy mistakes are the order of rules: skip leading spaces, consume at most one sign, then take consecutive digits, stop at the first non-digit, and clamp to 32 bits. Without 64-bit integers we cannot finish the product and clip later. We accumulate the absolute value, comparing against floor((2^{31}-1)/10) before multiplying by 10, and saturate to 2^{31}-1 or -2^{31} on overflow. Both signs share that upper bound; the sign is applied at the end. An empty string or all spaces has no digits, so we return 0.

First, we determine whether the string is empty. If it is, we directly return 0.

Otherwise, we need to traverse the string, skip the leading spaces, and determine whether the first non-space character is a positive or negative sign.

Then we traverse the following characters. If it is a digit, we judge whether adding this digit will cause integer overflow. If it does, we return the result according to the positive or negative sign. Otherwise, we add the digit to the result. We continue to traverse the following characters until we encounter a non-digit character or the traversal ends.

After the traversal ends, we return the result according to the positive or negative sign.

The time complexity is O(n), where n is the length of the string. We only need to process all characters in turn. The space complexity is O(1).

Python 3

```
class Solution:
    def myAtoi(self, s: str) -> int:
        if not s:
            return 0
        n = len(s)
        if n == 0:
            return 0
        i = 0
        while s[i] == ' ':
            i += 1
            if i == n:
                return 0
        sign = -1 if s[i] == '-' else 1
        if s[i] in ['-', '+']:
            i += 1
        res, flag = 0, (2**31 - 1) // 10
        while i < n:
            if not s[i].isdigit():
                break
            c = int(s[i])
            if res > flag or (res == flag and c > 7):
                return 2**31 - 1 if sign > 0 else -(2**31)
            res = res * 10 + c
            i += 1
        return sign * res
```

PATTERN 6 · STRING MANIPULATION / PARSING · PROBLEM 6 OF 20

6. Zigzag Conversion

Medium · String

leetcode.com/problems/zigzag-conversion

PROBLEM

The string "PAYPALISHIRING" is written in a zigzag pattern on a given number of rows like this: (you may want to display this pattern in a fixed font for better legibility)

```
P A H N
A P L S I I G
Y I R
```

And then read line by line: "PAHNAPLSIIGYIR"

Write the code that will take a string and make this conversion given a number of rows:

```
string convert(string s, int numRows);
```

Example 1:

```
Input: s = "PAYPALISHIRING", numRows = 3
Output: "PAHNAPLSIIGYIR"
```

Example 2:

```
Input: s = "PAYPALISHIRING", numRows = 4
Output: "PINALSIGYAHRPI"
Explanation:
P I N
A L S I G
Y A H R
P I
```

Example 3:

```
Input: s = "A", numRows = 1
Output: "A"
```

Constraints:

- `1 <= s.length <= 1000`
- `s` consists of English letters (lower-case and upper-case), `','` and `'.'`.
- `1 <= numRows <= 1000`

SOLUTION (PYTHON 3)

Solution 1: Simulation

How to think about it

Drawing the 2D grid and reading by row is correct, but most cells are empty. n ≤ 10^3 would pass, yet the unused "column" dimension is wasted. Only the row of each character, and order within a row, affect the answer. The row index goes 0,1,…,numRows-1 and then back, reversing at the top or bottom. So we keep numRows lists and flip a direction k at the boundaries. k starts at -1, so the first row immediately turns it downward. When numRows=1, top and bottom are the same row; we must return s as is, or the direction would bounce in place.

We use a 2D array g to simulate the process of arranging the string in a zigzag pattern, where g[i][j] represents the character at row i and column j. Initially, i = 0. We also define a direction variable k, initially k = -1, which means moving

upwards.

We traverse the string s from left to right. For each character c, we append it to g[i]. If i = 0 or i = numRows - 1, it means the current character is at a turning point in the zigzag pattern, so we reverse the value of k, i.e., k = -k. Then, we update i to i + k, which means moving up or down one row. Continue traversing the next character until the end of the string s. Finally, we return the concatenation of all rows in g as the result.

The time complexity is O(n) and the space complexity is O(n), where n is the length of the string s.

Python 3

```python
class Solution:
    def convert(self, s: str, numRows: int) -> str:
        if numRows == 1:
            return s
        g = [[] for _ in range(numRows)]
        i, k = 0, -1
        for c in s:
            g[i].append(c)
            if i == 0 or i == numRows - 1:
                k = -k
            i += k
        return ''.join(chain(*g))
```

PATTERN 6 · STRING MANIPULATION / PARSING · PROBLEM 8 OF 20

43. Multiply Strings

Medium · Math, String, Simulation

leetcode.com/problems/multiply-strings

★ **TOP 10 PROBLEM** in String Manipulation / Parsing: master this one first

PROBLEM

Given two non-negative integers `num1` and `num2` represented as strings, return the product of `num1` and `num2`, also represented as a string.

Note: You must not use any built-in BigInteger library or convert the inputs to integer directly.

Example 1:

```
Input: num1 = "2", num2 = "3"
Output: "6"
```

Example 2:

```
Input: num1 = "123", num2 = "456"
Output: "56088"
```

Constraints:

- `1 <= num1.length, num2.length <= 200`
- `num1` and `num2` consist of digits only.
- Both `num1` and `num2` do not contain any leading zero, except the number `0` itself.

SOLUTION (PYTHON 3)

Solution 1: Simulating Mathematical Multiplication

How to think about it

The first idea is convert both strings to integers and multiply. Lengths go to 200, so native integers overflow; the problem also forbids converting directly. The bottleneck is big-integer multiplication. Grade-school arithmetic says the product of digit i and digit j contributes to a fixed place; carries can wait. The product is at most m+n digits, so an array of that length is the scratch paper: accumulate, then carry. That is cheaper than a full bigint library.

Assume the lengths of num1 and num2 are m and n respectively, then the length of their product can be at most m + n.

The proof is as follows:

- If num1 and num2 both take the minimum value, then their product is $10^{m-1} \times 10^{n-1} = 10^{m+n-2}$, with a length of m + n - 1.
- If num1 and num2 both take the maximum value, then their product is $(10^m - 1) \times (10^n - 1) = 10^{m+n} - 10^m - 10^n + 1$, with a length of m + n.

Therefore, we can apply for an array of length m + n to store each digit of the product.

From the least significant digit to the most significant digit, we calculate each digit of the product in turn, and finally convert the array into a string.

Note to check whether the most significant digit is 0, if it is, remove it.

The time complexity is O(m × n), and the space complexity is O(m + n). Here, m and n are the lengths of num1 and num2 respectively.

Python 3

```
class Solution:
    def multiply(self, num1: str, num2: str) -> str:
        if num1 == "0" or num2 == "0":
            return "0"
        m, n = len(num1), len(num2)
        arr = [0] * (m + n)
        for i in range(m - 1, -1, -1):
            a = int(num1[i])
            for j in range(n - 1, -1, -1):
                b = int(num2[j])
                arr[i + j + 1] += a * b
        for i in range(m + n - 1, 0, -1):
            arr[i - 1] += arr[i] // 10
            arr[i] %= 10
        i = 0 if arr[0] else 1
        return "".join(str(x) for x in arr[i:])
```

        quotient.append(str(remainder // divisor))
        remainder %= divisor
    text = "".join(quotient).lstrip("0")
    if text == "":
        text = "0"
    return text, remainder
```

PATTERN 6 · STRING MANIPULATION / PARSING · PROBLEM 9 OF 20

165. Compare Version Numbers

Medium · Two Pointers, String

leetcode.com/problems/compare-version-numbers

PROBLEM

Given two **version strings**, `version1` and `version2`, compare them. A version string consists of **revisions** separated by dots `'.'`. The **value of the revision** is its **integer conversion** ignoring leading zeros.

To compare version strings, compare their revision values in **left-to-right order**. If one of the version strings has fewer revisions, treat the missing revision values as `0`.

Return the following:

- If `version1 < version2`, return -1.
- If `version1 > version2`, return 1.
- Otherwise, return 0.

Example 1:

Input: version1 = "1.2", version2 = "1.10"

Output: -1

Explanation:

version1's second revision is "2" and version2's second revision is "10": 2 < 10, so version1 < version2.

Example 2:

Input: version1 = "1.01", version2 = "1.001"

Output: 0

Explanation:

Ignoring leading zeroes, both "01" and "001" represent the same integer "1".

Example 3:

Input: version1 = "1.0", version2 = "1.0.0.0"

Output: 0

Explanation:

version1 has less revisions, which means every missing revision are treated as "0".

Constraints:

- `1 <= version1.length, version2.length <= 500`
- `version1` and `version2` only contain digits and `'.'`.
- `version1` and `version2` **are valid version numbers**.
- All the given revisions in `version1` and `version2` can be stored in a **32-bit integer**.

SOLUTION (PYTHON 3)

Solution 1: Two Pointers

How to think about it

Compare revision numbers; missing parts are 0 and leading zeros do not count. Splitting into integer arrays uses extra space. Lengths are at most 500. Two pointers scan together, finish a part at each dot, and treat a missing side as 0 until they differ or both end.

Traverse both strings simultaneously using two pointers i and j, which point to the current positions in each string, starting with i = j = 0.

Each time, extract the corresponding revision numbers from both strings, denoted as a and b. Compare a and b: if a < b, return -1; if a > b, return 1; if a = b, continue to compare the next pair of revision numbers.

The time complexity is O(max(m, n)), and the space complexity is O(1), where m and n are the lengths of the two strings.

Python 3

```python
class Solution:
    def compareVersion(self, version1: str, version2: str) -> int:
        m, n = len(version1), len(version2)
        i = j = 0
        while i < m or j < n:
            a = b = 0
            while i < m and version1[i] != '.':
                a = a * 10 + int(version1[i])
                i += 1
            while j < n and version2[j] != '.':
                b = b * 10 + int(version2[j])
                j += 1
            if a != b:
                return -1 if a < b else 1
            i, j = i + 1, j + 1
        return 0
```

```

91. Decode Ways

Medium · String, Dynamic Programming

leetcode.com/problems/decode-ways

★ **TOP 10 PROBLEM** in Dynamic Programming - 1D: master this one first

Also appears in pattern 13 Dynamic Programming - 1D

PROBLEM

You have intercepted a secret message encoded as a string of numbers. The message is **decoded** via the following mapping:

```
"1" -> 'A'
"2" -> 'B'
...
"25" -> 'Y'
"26" -> 'Z'
```

However, while decoding the message, you realize that there are many different ways you can decode the message because some codes are contained in other codes (`"2"` and `"5"` vs `"25"`).

For example, `"11106"` can be decoded into:

- `"AAJF"` with the grouping `(1, 1, 10, 6)`
- `"KJF"` with the grouping `(11, 10, 6)`
- The grouping `(1, 11, 06)` is invalid because `"06"` is not a valid code (only `"6"` is valid).

Note: there may be strings that are impossible to decode.

Given a string s containing only digits, return the **number of ways** to **decode** it. If the entire string cannot be decoded in any valid way, return `0`.

The test cases are generated so that the answer fits in a **32-bit** integer.

Example 1:

Input: s = "12"

Output: 2

Explanation:

"12" could be decoded as "AB" (1 2) or "L" (12).

Example 2:

Input: s = "226"

Output: 3

Explanation:

"226" could be decoded as "BZ" (2 26), "VF" (22 6), or "BBF" (2 2 6).

Example 3:

Input: s = "06"

Output: 0

Explanation:

"06" cannot be mapped to "F" because of the leading zero ("6" is different from "06"). In this case, the string is not a valid encoding, so return 0.

Constraints:

- `1 <= s.length <= 100`
- `s` contains only digits and may contain leading zero(s).

SOLUTIONS (PYTHON 3)

Solution 1: Dynamic Programming

> **How to think about it**
>
> The first idea is recursion: at index i, decode s[i] alone (if not 0), or pair it with the previous digit into 10– 26. n ≤ 100, but without memoization the tree is exponential because the same prefix is decoded again and again. The bottleneck is that the number of ways to decode the first i characters depends only on shorter prefixes, and a valid split is only “one digit / two digits”. That is climbing stairs with encoding constraints. So let f[i] be the number of ways for the first i characters. The empty string has one way; 0 cannot stand alone; only 10– 26 can be a pair. Scan once instead of enumerating every partition.

We define f[i] to represent the number of decoding methods for the first i characters of the string. Initially, f[0]=1, and the rest f[i]=0.

Consider how f[i] transitions.

- If the ith character (i.e., s[i-1]) forms a code on its own, it corresponds to one decoding method, i.e., f[i]=f[i-1]. The premise is s[i-1] ≠ 0.
- If the string formed by the i-1th character and the ith character is within the range [1,26], then they can be treated as a whole, corresponding to one decoding method, i.e., f[i] = f[i] + f[i-2]. The premise is s[i-2] ≠ 0, and s[i-2]s[i-1] is within the range [1,26].

The time complexity is O(n), and the space complexity is O(n). Here, n is the length of the string.

Python 3

```python
class Solution:
    def numDecodings(self, s: str) -> int:
        n = len(s)
        f = [1] + [0] * n
        for i, c in enumerate(s, 1):
            if c != "0":
                f[i] = f[i - 1]
            if i > 1 and s[i - 2] != "0" and int(s[i - 2 : i]) <= 26:
                f[i] += f[i - 2]
        return f[n]
```

Solution 2: Optimized Dynamic Programming

> **How to think about it**
>
> Solution 1 is already correct. Each f[i] only needs f[i-1] and f[i-2], so the full array is unnecessary. Two rolling variables cut space to O(1); time is still a single pass.

We notice that the state f[i] is only related to f[i-1] and f[i-2]. Therefore, we can use two variables to replace these states, reducing the space complexity from O(n) to O(1). The time complexity remains O(n).

Python 3

```python
class Solution:
    def numDecodings(self, s: str) -> int:
        f, g = 0, 1
        for i, c in enumerate(s, 1):
            h = g if c != "0" else 0
            if i > 1 and s[i - 2] != "0" and int(s[i - 2 : i]) <= 26:
                h += f
            f, g = g, h
        return g
```

    return ways[n]
```

71. Simplify Path

Medium · Stack, String

leetcode.com/problems/simplify-path

★ **TOP 10 PROBLEM** in String Manipulation / Parsing: master this one first

Also appears in pattern 8 Stack

PROBLEM

You are given an *absolute* path for a Unix-style file system, which always begins with a slash `'/'`. Your task is to transform this absolute path into its **simplified canonical path**.

The *rules* of a Unix-style file system are as follows:

- A single period `'.'` represents the current directory.
- A double period `'..'` represents the previous/parent directory.
- Multiple consecutive slashes such as `'//'` and `'///'` are treated as a single slash `'/'`.
- Any sequence of periods that does **not match** the rules above should be treated as a **valid directory or file name**. For example, `'...'` and `'....'` are valid directory or file names.

The simplified canonical path should follow these *rules*:

- The path must start with a single slash `'/'`.
- Directories within the path must be separated by exactly one slash `'/'`.
- The path must not end with a slash `'/'`, unless it is the root directory.
- The path must not have any single or double periods (`'.'` and `'..'`) used to denote current or parent directories.

Return the **simplified canonical path**.

Example 1:

Input: path = "/home/"

Output: "/home"

Explanation:

The trailing slash should be removed.

Example 2:

Input: path = "/home//foo/"

Output: "/home/foo"

Explanation:

Multiple consecutive slashes are replaced by a single one.

Example 3:

Input: path = "/home/user/Documents/../Pictures"

Output: "/home/user/Pictures"

Explanation:

A double period `".."` refers to the directory up a level (the parent directory).

Example 4:

Input: path = "/../"

Output: "/"

Explanation:

Going one level up from the root directory is not possible.

Example 5:

Input: path = "/.../a/../b/c/../d/./"

Output: "/.../b/d"

Explanation:

`"..."` is a valid name for a directory in this problem.

Constraints:

- `1 <= path.length <= 3000`
- `path` consists of English letters, digits, period `'.'`, slash `'/'` or `'_'`.
- `path` is a valid absolute Unix path.

SOLUTION (PYTHON 3)

Solution 1: Stack

> **How to think about it**
>
> The first idea is repeated string replace of `'//'`, `'/./'`, and `'/../'`. n ≤ 3000 might pass, but stacked slashes and `'..'` interact, so the replace order is hard to get right. What we need is undo: a valid name must be erasable by `'..'`, while empty segments and `'.'` do not move us. That is last-in, first-out, so a stack holds the directories from the root to here. Split on `'/'`, process each piece, then join into the canonical path. We must not pop above the root, so the stack is checked before popping.

We first split the path into a number of substrings split by `'/'`. Then, we traverse each substring and perform the following operations based on the content of the substring:

- If the substring is empty or `'.'`, no operation is performed because `'.'` represents the current directory.
- If the substring is `'..'`, the top element of the stack is popped, because `'..'` represents the parent directory.
- If the substring is other strings, the substring is pushed into the stack, because the substring represents the subdirectory of the current directory.

Finally, we concatenate all the elements in the stack from the bottom to the top of the stack to form a string, which is the simplified canonical path.

The time complexity is O(n) and the space complexity is O(n), where n is the length of the path.

Python 3

```python
class Solution:
    def simplifyPath(self, path: str) -> str:
        stk = []
        for s in path.split('/'):
            if not s or s == '.':
                continue
            if s == '..':
                if stk:
                    stk.pop()
            else:
                stk.append(s)
        return '/' + '/'.join(stk)
```

PATTERN 6 · STRING MANIPULATION / PARSING · PROBLEM 12 OF 20

139. Word Break

Medium · Trie, Memoization, Array, Hash Table, String, Dynamic Programming, Brute-Force Search

leetcode.com/problems/word-break

★ **TOP 10 PROBLEM** in Dynamic Programming - 1D: master this one first

Also appears in pattern 13 Dynamic Programming - 1D, 32 Trie (Prefix Tree)

PROBLEM

Given a string `s` and a dictionary of strings `wordDict`, return `true` if `s` can be segmented into a space-separated sequence of one or more dictionary words.

Note that the same word in the dictionary may be reused multiple times in the segmentation.

Example 1:

```
Input: s = "leetcode", wordDict = ["leet","code"]
Output: true
Explanation: Return true because "leetcode" can be segmented as "leet code".
```

Example 2:

```
Input: s = "applepenapple", wordDict = ["apple","pen"]
Output: true
Explanation: Return true because "applepenapple" can be segmented as "apple pen apple".
Note that you are allowed to reuse a dictionary word.
```

Example 3:

```
Input: s = "catsandog", wordDict = ["cats","dog","sand","and","cat"]
Output: false
```

Constraints:

- `1 <= s.length <= 300`
- `1 <= wordDict.length <= 1000`
- `1 <= wordDict[i].length <= 20`
- `s` and `wordDict[i]` consist of only lowercase English letters.
- All the strings of `wordDict` are **unique**.

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

Can s be segmented into dictionary words? |s|≤ 300; backtracking repeats the same suffixes. f[i] means the prefix s[0..i) can be split: try a cut j where f[j] is true and s[j..i) is in the dictionary. A hash set makes the membership test expected O(1).

Python 3

```python
class Solution:
    def wordBreak(self, s: str, wordDict: List[str]) -> bool:
        words = set(wordDict)
        n = len(s)
        f = [True] + [False] * n
        for i in range(1, n + 1):
            f[i] = any(f[j] and s[j:i] in words for j in range(i))
        return f[n]
```

Solution 2

> **How to think about it**
>
> Solution 1 slices a substring and hashes it at every cut, which is O(n) per test. A trie lets us walk from index i along existing edges only, so useless slices disappear and the time becomes $O(n^2)$.

Python 3

```python
class Trie:
    def __init__(self):
        self.children: List[Trie | None] = [None] * 26
        self.isEnd = False

    def insert(self, w: str):
        node = self
        for c in w:
            idx = ord(c) - ord('a')
            if not node.children[idx]:
                node.children[idx] = Trie()
            node = node.children[idx]
        node.isEnd = True

class Solution:
    def wordBreak(self, s: str, wordDict: List[str]) -> bool:
        trie = Trie()
        for w in wordDict:
            trie.insert(w)
        n = len(s)
        f = [False] * (n + 1)
        f[n] = True
        for i in range(n - 1, -1, -1):
            node = trie
            for j in range(i, n):
                idx = ord(s[j]) - ord('a')
                if not node.children[idx]:
                    break
                node = node.children[idx]
                if node.isEnd and f[j + 1]:
                    f[i] = True
                    break
        return f[0]
```

leetcode.com/problems/longest-palindromic-substring

★ **TOP 10 PROBLEM** in String Manipulation / Parsing, String Matching / Pattern Search: master this one first

Also appears in pattern 7 String Matching / Pattern Search

PROBLEM

Given a string `s`, return *the longest palindromic substring* in `s`.

Example 1:

```
Input: s = "babad"
Output: "bab"
Explanation: "aba" is also a valid answer.
```

Example 2:

```
Input: s = "cbbd"
Output: "bb"
```

Constraints:

- `1 <= s.length <= 1000`
- `s` consist of only digits and English letters.

SOLUTIONS (PYTHON 3)

Solution 1: Dynamic Programming

How to think about it

Checking every s[i..j] from the ends is O(n^3). n ≤ 10^3 is tight and often times out. The waste is rescanning each substring. A palindrome has optimal substructure: s[i..j] is a palindrome iff the two ends match and the inner s[i+1..j-1] already is one. Single characters are palindromes for free. So we fill an interval table in dependency order instead of scanning repeatedly. f[i][j] reads a shorter inner cell, so that cell must already be known; while filling, k and mx remember the start and length of the best palindrome so far.

We define f[i][j] to represent whether the string s[i..j] is a palindrome, initially f[i][j] = true.

Next, we define variables k and mx, where k represents the starting position of the longest palindrome, and mx represents the length of the longest palindrome. Initially, k = 0, mx = 1.

Considering f[i][j], if s[i] = s[j], then f[i][j] = f[i + 1][j - 1]; otherwise, f[i][j] = false. If f[i][j] = true and mx < j - i + 1, then we update k = i, mx = j - i + 1.

Since f[i][j] depends on f[i + 1][j - 1], we need to ensure that i + 1 is before j - 1, so we need to enumerate i from large to small, and enumerate j from small to large.

The time complexity is O(n^2), and the space complexity is O(n^2). Here, n is the length of the string s.

Python 3

```python
class Solution:
    def longestPalindrome(self, s: str) -> str:
        n = len(s)
        f = [[True] * n for _ in range(n)]
        k, mx = 0, 1
        for i in range(n - 2, -1, -1):
            for j in range(i + 1, n):
                f[i][j] = False
                if s[i] == s[j]:
                    f[i][j] = f[i + 1][j - 1]
                    if f[i][j] and mx < j - i + 1:
                        k, mx = i, j - i + 1
        return s[k : k + mx]
```

Solution 2: Enumerate Palindrome Midpoint

How to think about it

Solution 1 is already $O(n^2)$ time, but it still pays $O(n^2)$ space. Each check only needs the inner layer, not the whole table. A palindrome expands symmetrically from a center: grow while the two ends match. We must try both odd centers (i,i) and even centers (i,i+1), or we miss strings like `"bb"`. After expanding, recover the start from center i and length t. Extra space drops to O(1).

We can enumerate the midpoint of the palindrome, spread to both sides, and find the longest palindrome.

The time complexity is $O(n^2)$, and the space complexity is $O(1)$. Here, n is the length of the string s.

Python 3

```python
class Solution:
    def longestPalindrome(self, s: str) -> str:
        def f(l, r):
            while l >= 0 and r < n and s[l] == s[r]:
                l, r = l - 1, r + 1
            return r - l - 1

        n = len(s)
        start, mx = 0, 1
        for i in range(n):
            a = f(i, i)
            b = f(i, i + 1)
            t = max(a, b)
            if mx < t:
                mx = t
                start = i - ((t - 1) >> 1)
        return s[start : start + mx]
```

38. Count and Say

Medium · String

leetcode.com/problems/count-and-say

PROBLEM

The **count-and-say** sequence is a sequence of digit strings defined by the recursive formula:

- `countAndSay(1) = "1"`
- `countAndSay(n)` is the run-length encoding of `countAndSay(n - 1)`.

Run-length encoding (RLE) is a string compression method that works by replacing each maximal group of consecutive identical characters with the concatenation of the length of the group followed by the character itself. For example, to compress the string `"3322251"` we replace `"33"` with `"23"`, replace `"222"` with `"32"`, replace `"5"` with `"15"`, and replace `"1"` with `"11"`. Thus the compressed string becomes `"23321511"`.

Given a positive integer `n`, return *the* n^{th} *element of the* ***count-and-say*** *sequence*.

Example 1:

Input: n = 4

Output: "1211"

Explanation:

```
countAndSay(1) = "1"
countAndSay(2) = RLE of "1" = "11"
countAndSay(3) = RLE of "11" = "21"
countAndSay(4) = RLE of "21" = "1211"
```

Example 2:

Input: n = 1

Output: "1"

Explanation:

This is the base case.

Constraints:

- `1 <= n <= 30`

Follow up:

Could you solve it iteratively?

SOLUTION (PYTHON 3)

Solution 1: Simulation

> **How to think about it**
>
> The definition itself is “the n-th term describes the (n-1)-th”, so there is no cheaper closed form. n ≤ 30, so we can start from `"1"` and iterate n-1 times. Each term is a run-length encoding of the previous one: a streak of the same character becomes “count + character”. Two pointers walk the current string s and append each run’s length and character to a new string. The follow-up asks for an iterative solution, which also avoids a recursion stack.

The task requires outputting the appearance sequence of the n-th item, where the n-th item is the description of the n-1-th item in the sequence. Therefore, we iterate n-1 times. In each iteration, we use fast and slow pointers, denoted as j and i respectively, to record the current character's position and the position of the next character that is not equal to the current character. We then update the sequence of the previous item to be j-i occurrences of the current character.

Time Complexity:

1. The outer loop runs `n - 1` times, iterating to generate the "Count and Say" sequence up to the nth term.
2. The inner while loop iterates through each character in the current string s and counts the consecutive occurrences of the same character.
3. The inner while loop runs in O(m) time, where m is the length of the current string s.

Overall, the time complexity is O(n × m), where n is the input parameter representing the term to generate, and m is the maximum length of the string in the sequence.

Space Complexity: O(m).

Python 3

```python
class Solution:
    def countAndSay(self, n: int) -> str:
        s = '1'
        for _ in range(n - 1):
            i = 0
            t = []
            while i < len(s):
                j = i
                while j < len(s) and s[j] == s[i]:
                    j += 1
                t.append(str(j - i))
                t.append(str(s[i]))
                i = j
            s = ''.join(t)
        return s
```

    return "".join(result)
```

249. Group Shifted Strings

Medium · Array, Hash Table, String

leetcode.com/problems/group-shifted-strings

Also appears in pattern 7 String Matching / Pattern Search

PROBLEM

Perform the following shift operations on a string:

- **Right shift**: Replace every letter with the **successive** letter of the English alphabet, where 'z' is replaced by 'a'. For example, `"abc"` can be right-shifted to `"bcd"` or `"xyz"` can be right-shifted to `"yza"`.
- **Left shift**: Replace every letter with the **preceding** letter of the English alphabet, where 'a' is replaced by 'z'. For example, `"bcd"` can be left-shifted to `"abc"` or `"yza"` can be left-shifted to `"xyz"`.

We can keep shifting the string in both directions to form an **endless shifting sequence**.

- For example, shift `"abc"` to form the sequence: `... <-> "abc" <-> "bcd" <-> ... <-> "xyz" <-> "yza" <-> .... <-> "zab" <-> "abc" <-> ...`

You are given an array of strings `strings`, group together all `strings[i]` that belong to the same shifting sequence. You may return the answer in **any order**.

Example 1:

Input: strings = ["abc","bcd","acef","xyz","az","ba","a","z"]

Output: [["acef"],["a","z"],["abc","bcd","xyz"],["az","ba"]]

Example 2:

Input: strings = ["a"]

Output: [["a"]]

Constraints:

- `1 <= strings.length <= 200`
- `1 <= strings[i].length <= 50`
- `strings[i]` consists of lowercase English letters.

SOLUTION (PYTHON 3)

Solution 1: Hash Table

> **How to think about it**
>
> Strings in one shift group share the same sequence of letter gaps. Translating each string so that it starts with a yields a grouping key. A hash map buckets by that canonical form, and the buckets are the answer.

We use a hash table g to store each string after shifting and with the first character as 'a'. That is, g[t] represents the set of all strings that become t after shifting.

We iterate through each string. For each string, we calculate its shifted string t, and then add it to g[t].

Finally, we take out all the values in g, which is the answer.

The time complexity is O(L) and the space complexity is O(L), where L is the sum of the lengths of all strings.

Python 3

```
class Solution:
    def groupStrings(self, strings: List[str]) -> List[List[str]]:
        g = defaultdict(list)
        for s in strings:
            diff = ord(s[0]) - ord("a")
            t = []
            for c in s:
                c = ord(c) - diff
                if c < ord("a"):
                    c += 26
                t.append(chr(c))
            g["".join(t)].append(s)
        return list(g.values())
```

```

PATTERN 6 · STRING MANIPULATION / PARSING · PROBLEM 16 OF 20

767. Reorganize String

Medium · Greedy, Hash Table, String, Counting, Sorting, Heap (Priority Queue)

leetcode.com/problems/reorganize-string

★ **TOP 10 PROBLEM** in Heap / Priority Queue: master this one first

Also appears in pattern 19 Heap / Priority Queue, 37 Two Heaps

PROBLEM

Given a string `s`, rearrange the characters of `s` so that any two adjacent characters are not the same.

Return *any possible rearrangement of* `s` *or return* `""` *if not possible*.

Example 1:

```
Input: s = "aab"
Output: "aba"
```

Example 2:

```
Input: s = "aaab"
Output: ""
```

Constraints:

- `1 <= s.length <= 500`
- `s` consists of lowercase English letters.

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

Rearrange so no two adjacent characters match. If one letter exceeds ceil(n/2), it is impossible. Place the most frequent letters on even indices first, then restart at index 1, which separates copies. Fill from `most_common` into a buffer, wrapping i to 1 when it passes n.

Python 3

```python
class Solution:
    def reorganizeString(self, s: str) -> str:
        n = len(s)
        cnt = Counter(s)
        mx = max(cnt.values())
        if mx > (n + 1) // 2:
            return ''
        i = 0
        ans = [None] * n
        for k, v in cnt.most_common():
            while v:
                ans[i] = k
                v -= 1
                i += 2
                if i >= n:
                    i = 1
        return ''.join(ans)
```

Complexity. Time: O(n + C log C), C = number of distinct letters. Space: O(n).

Solution 2

How to think about it

Even-index placement is specific to distance 1. The same greedy as “rearrange k apart” uses a max-heap plus a cooldown queue of length k=2. Pop the current most frequent letter, enqueue it, and return it to the heap after k steps. If the built string is short, fail.

Python 3

```python
class Solution:
    def reorganizeString(self, s: str) -> str:
        return self.rearrangeString(s, 2)

    def rearrangeString(self, s: str, k: int) -> str:
        h = [(-v, c) for c, v in Counter(s).items()]
        heapify(h)
        q = deque()
        ans = []
        while h:
            v, c = heappop(h)
            v *= -1
            ans.append(c)
            q.append((v - 1, c))
            if len(q) >= k:
                w, c = q.popleft()
                if w:
                    heappush(h, (-w, c))
        return "" if len(ans) != len(s) else "".join(ans)
```

Complexity. Time: O(n log C), C = number of distinct letters. Space: O(n).

            most = count[ch]
```

```
    return most <= (len(s) + 1) // 2
```

PATTERN 6 · STRING MANIPULATION / PARSING · PROBLEM 17 OF 20

394. Decode String

Medium · Stack, Recursion, String

leetcode.com/problems/decode-string

★ **TOP 10 PROBLEM** in String Manipulation / Parsing, Stack: master this one first

Also appears in pattern 8 Stack

PROBLEM

Given an encoded string, return its decoded string.

The encoding rule is: `k[encoded_string]`, where the `encoded_string` inside the square brackets is being repeated exactly `k` times. Note that `k` is guaranteed to be a positive integer.

You may assume that the input string is always valid; there are no extra white spaces, square brackets are well-formed, etc. Furthermore, you may assume that the original data does not contain any digits and that digits are only for those repeat numbers, `k`. For example, there will not be input like `3a` or `2[4]`.

The test cases are generated so that the length of the output will never exceed 10^5.

Example 1:

```
Input: s = "3[a]2[bc]"
Output: "aaabcbc"
```

Example 2:

```
Input: s = "3[a2[c]]"
Output: "accaccacc"
```

Example 3:

```
Input: s = "2[abc]3[cd]ef"
Output: "abcabccdcdcdef"
```

Constraints:

- `1 <= s.length <= 30`
- `s` consists of lowercase English letters, digits, and square brackets `'[]'`.
- `s` is guaranteed to be **a valid** input.
- All the integers in `s` are in the range `[1, 300]`.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Decode nested k[encoded] repeats. Recursion works; a stack can store the multiplier and the outer string together. Digits build `num`; `[` pushes the count and the current result; `]` pops and concatenates the repeated segment; letters append. The stack expands inside-out.

Python 3

```python
class Solution:
    def decodeString(self, s: str) -> str:
        s1, s2 = [], []
        num, res = 0, ''
        for c in s:
            if c.isdigit():
                num = num * 10 + int(c)
            elif c == '[':
                s1.append(num)
                s2.append(res)
                num, res = 0, ''
            elif c == ']':
                res = s2.pop() + res * s1.pop()
            else:
                res += c
        return res
```

Complexity. Time: O(L), L = length of the decoded string (each character is copied once per nesting level). Space: O(L).

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

68. Text Justification

Hard · Array, String, Simulation

leetcode.com/problems/text-justification

★ **TOP 10 PROBLEM** in String Manipulation / Parsing: master this one first

PROBLEM

Given an array of strings `words` and a width `maxWidth`, format the text such that each line has exactly `maxWidth` characters and is fully (left and right) justified.

You should pack your words in a greedy approach; that is, pack as many words as you can in each line. Pad extra spaces `' '` when necessary so that each line has exactly `maxWidth` characters.

Extra spaces between words should be distributed as evenly as possible. If the number of spaces on a line does not divide evenly between words, the empty slots on the left will be assigned more spaces than the slots on the right.

For the last line of text, it should be left-justified, and no extra space is inserted between words.

Note:

- A word is defined as a character sequence consisting of non-space characters only.
- Each word's length is guaranteed to be greater than `0` and not exceed `maxWidth`.
- The input array `words` contains at least one word.

Example 1:

```
Input: words = ["This", "is", "an", "example", "of", "text", "justification."], maxWidth = 16
Output:
[
   "This is an",
   "example of text",
   "justification. "
]
```

Example 2:

```
Input: words = ["What","must","be","acknowledgment","shall","be"], maxWidth = 16
Output:
[
  "What must be",
  "acknowledgment ",
  "shall be "
]
Explanation: Note that the last line is "shall be " instead of "shall be", because the last line must
be left-justified instead of fully-justified.
Note that the second line is also left-justified because it contains only one word.
```

Example 3:

```
Input: words = ["Science","is","what","we","understand","well","enough","to","explain","to","a","compu
ter.","Art","is","everything","else","we","do"], maxWidth = 20
Output:
[
  "Science is what we",
  "understand well",
  "enough to explain to",
  "a computer. Art is",
  "everything else we",
  "do "
]
```

Constraints:

- `1 <= words.length <= 300`
- `1 <= words[i].length <= 20`
- `words[i]` consists of only English letters and symbols.
- `1 <= maxWidth <= 100`
- `words[i].length <= maxWidth`

SOLUTION (PYTHON 3)

Solution 1: Simulation

How to think about it

The first idea is to pack as many words as possible into a line, then pad with spaces. There are at most 300 words and the width is at most 100, so a linear scan is enough; no backtracking. The bottleneck is not runtime but the spacing rules: the last line and a one-word line must be left-aligned; every other line must spread extra spaces as evenly as possible, leftover spaces going to the left gaps first. So we greedily take the words that fit, then branch on “last line / single word” versus even distribution. Process lines from left to right.

We can simulate the process according to the problem's requirements. Note that if it is the last line, or if there is only one word in the line, then we should align to the left. Otherwise, we should distribute the spaces evenly.

The time complexity is O(L), and the space complexity is O(L). Here, L is the sum of the lengths of all words.

Python 3

```python
class Solution:
    def fullJustify(self, words: List[str], maxWidth: int) -> List[str]:
        ans = []
        i, n = 0, len(words)
        while i < n:
            t = []
            cnt = len(words[i])
            t.append(words[i])
            i += 1
            while i < n and cnt + 1 + len(words[i]) <= maxWidth:
                cnt += 1 + len(words[i])
                t.append(words[i])
                i += 1
            if i == n or len(t) == 1:
                left = ' '.join(t)
                right = ' ' * (maxWidth - len(left))
                ans.append(left + right)

PATTERN 6 · STRING MANIPULATION / PARSING · PROBLEM 19 OF 20

224. Basic Calculator

Hard · Stack, Recursion, Math, String

leetcode.com/problems/basic-calculator

★ **TOP 10 PROBLEM** in String Manipulation / Parsing, Stack: master this one first

Also appears in pattern 8 Stack

PROBLEM

Given a string `s` representing a valid expression, implement a basic calculator to evaluate it, and return *the result of the evaluation*.

Note: You are **not** allowed to use any built-in function which evaluates strings as mathematical expressions, such as `eval()`.

Example 1:

```
Input: s = "1 + 1"
Output: 2
```

Example 2:

```
Input: s = " 2-1 + 2 "
Output: 3
```

Example 3:

```
Input: s = "(1+(4+5+2)-3)+(6+8)"
Output: 23
```

Constraints:

- `1 <= s.length <= 3 * 10^5`
- `s` consists of digits, `'+'`, `'-'`, `'('`, `')'`, and `' '`.
- `s` represents a valid expression.
- `'+'` is **not** used as a unary operation (i.e., `"+1"` and `"+(2 + 3)"` is invalid).
- `'-'` could be used as a unary operation (i.e., `"-1"` and `"-(2 + 3)"` is valid).
- There will be no two consecutive operators in the input.
- Every number and running calculation will fit in a signed 32-bit integer.

SOLUTION (PYTHON 3)

Solution 1: Stack

How to think about it

Plus, minus, and parentheses prevent a single left-to-right sum. A parenthesized fragment is its own accumulation, so the outer total and sign must be saved on entry. A stack stores ans and sign at (and resets them; at) we pop and add the inner result times the outer sign. Digits join ans with the current sign.

We use a stack stk to save the current calculation result and operator, a variable sign to save the current sign, and a variable ans to save the final calculation result.

Next, we traverse each character of the string s:

- If the current character is a number, we use a loop to read the following consecutive numbers, and then add or subtract it to ans according to the current sign.
- If the current character is `'+'`, we change the variable sign to positive.

- If the current character is `'-'`, we change the variable sign to negative.
- If the current character is `'('`, we push the current ans and sign into the stack, and reset them to empty and 1, and start to calculate the new ans and sign.
- If the current character is `')'`, we pop the top two elements of the stack, one is the operator, and the other is the number calculated before the bracket. We multiply the current number by the operator, and add the previous number to get the new ans.

After traversing the string s, we return ans.

The time complexity is O(n), and the space complexity is O(n), where n is the length of the string s.

Python 3

```python
class Solution:
    def calculate(self, s: str) -> int:
        stk = []
        ans, sign = 0, 1
        i, n = 0, len(s)
        while i < n:
            if s[i].isdigit():
                x = 0
                j = i
                while j < n and s[j].isdigit():
                    x = x * 10 + int(s[j])
                    j += 1
                ans += sign * x
                i = j - 1
            elif s[i] == "+":
                sign = 1
            elif s[i] == "-":
                sign = -1
            elif s[i] == "(":
                stk.append(ans)
                stk.append(sign)
                ans, sign = 0, 1
            elif s[i] == ")":
                ans = stk.pop() * ans + stk.pop()
            i += 1
        return ans
```

821. Shortest Distance to a Character

Easy · Array, Two Pointers, String

leetcode.com/problems/shortest-distance-to-a-character

PROBLEM

Given a string `s` and a character `c` that occurs in `s`, return *an array of integers* `answer` *where* `answer.length == s.length` *and* `answer[i]` *is the* ***distance*** *from index* `i` *to the* ***closest*** *occurrence of character* `c` *in* `s`.

The **distance** between two indices `i` and `j` is `abs(i - j)`, where `abs` is the absolute value function.

Example 1:

```
Input: s = "loveleetcode", c = "e"
Output: [3,2,1,0,1,0,0,1,2,2,1,0]
Explanation: The character 'e' appears at indices 3, 5, 6, and 11 (0-indexed).
The closest occurrence of 'e' for index 0 is at index 3, so the distance is abs(0 - 3) = 3.
The closest occurrence of 'e' for index 1 is at index 3, so the distance is abs(1 - 3) = 2.
For index 4, there is a tie between the 'e' at index 3 and the 'e' at index 5, but the distance is
still the same: abs(4 - 3) == abs(4 - 5) = 1.
The closest occurrence of 'e' for index 8 is at index 6, so the distance is abs(8 - 6) = 2.
```

Example 2:

```
Input: s = "aaab", c = "b"
Output: [3,2,1,0]
```

Constraints:

- `1 <= s.length <= 10^4`
- `s[i]` and `c` are lowercase English letters.
- It is guaranteed that `c` occurs at least once in `s`.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Each index needs its distance to the nearest c. Scanning both sides from every position is quadratic and unnecessary for n≤ 10^4. The nearest c is either to the left or to the right. A left-to-right pass records the latest c; a right-to-left pass keeps the closer of the two. Two linear sweeps fill the answer.

Python 3

```python
class Solution:
    def shortestToChar(self, s: str, c: str) -> List[int]:
        n = len(s)
        ans = [n] * n
        pre = -inf
        for i, ch in enumerate(s):
            if ch == c:
                pre = i
            ans[i] = min(ans[i], i - pre)
        suf = inf
        for i in range(n - 1, -1, -1):
            if s[i] == c:
                suf = i
            ans[i] = min(ans[i], suf - i)
        return ans
```

Complexity. Time: O(n). Space: O(1) extra (the answer itself is O(n)).

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

            distance[i] = last - i
    return distance
```

1065. Index Pairs of a String

Easy · Trie, Array, String, Sorting, Aho-Corasick

leetcode.com/problems/index-pairs-of-a-string

★ **TOP 10 PROBLEM** in Trie (Prefix Tree): master this one first

Also appears in pattern 32 Trie (Prefix Tree)

PROBLEM

Given a string `text` and an array of strings `words`, return *an array of all index pairs* `[i, j]` *so that the substring* `text[i...j]` *is in* `words`.

Return the pairs `[i, j]` in sorted order (i.e., sort them by their first coordinate, and in case of ties sort them by their second coordinate).

Example 1:

```
Input: text = "thestoryofleetcodeandme", words = ["story","fleet","leetcode"]
Output: [[3,7],[9,13],[10,17]]
```

Example 2:

```
Input: text = "ababa", words = ["aba","ab"]
Output: [[0,1],[0,2],[2,3],[2,4]]
Explanation: Notice that matches can overlap, see "aba" is found in [0,2] and [2,4].
```

Constraints:

- `1 <= text.length <= 100`
- `1 <= words.length <= 20`
- `1 <= words[i].length <= 50`
- `text` and `words[i]` consist of lowercase English letters.
- All the strings of `words` are **unique**.

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

Every substring of text can be tested against the word list. Both sides are short, so a set of words plus all slices [i,j] is enough. The set answers in expected constant time, and enumerating indices already yields sorted pairs.

Python 3

```python
class Solution:
    def indexPairs(self, text: str, words: List[str]) -> List[List[int]]:
        words = set(words)
        n = len(text)
        return [
            [i, j] for i in range(n) for j in range(i, n) if text[i : j + 1] in words
        ]
```

Complexity. Time: O(n^3) in the worst case (n^2 slices of length up to n). Space: O(W), W = total length of the words.

Solution 2

How to think about it

Trying every slice wastes failed lookups on long text. Shared prefixes let us walk a trie from each start and stop at the first mismatch. Insert the words, then from each i extend the node to the right and record [i,j] at end marks.

Python 3

```python
class Trie:
    def __init__(self):
        self.children = [None] * 26
        self.is_end = False

    def insert(self, word):
        node = self
        for c in word:
            idx = ord(c) - ord('a')
            if node.children[idx] is None:
                node.children[idx] = Trie()
            node = node.children[idx]
        node.is_end = True

class Solution:
    def indexPairs(self, text: str, words: List[str]) -> List[List[int]]:
        trie = Trie()
        for w in words:
            trie.insert(w)
        n = len(text)
        ans = []
        for i in range(n):
            node = trie
            for j in range(i, n):
                idx = ord(text[j]) - ord('a')
                if node.children[idx] is None:
                    break
                node = node.children[idx]
                if node.is_end:

```

1023. Camelcase Matching

Medium · Trie, Array, Two Pointers, String, String Matching

leetcode.com/problems/camelcase-matching

Also appears in pattern 32 Trie (Prefix Tree)

PROBLEM

Given an array of strings `queries` and a string `pattern`, return a boolean array `answer` where `answer[i]` is `true` if `queries[i]` matches `pattern`, and `false` otherwise.

A query word `queries[i]` matches `pattern` if you can insert lowercase English letters into the pattern so that it equals the query. You may insert a character at any position in pattern or you may choose not to insert any characters **at all**.

Example 1:

```
Input: queries = ["FooBar","FooBarTest","FootBall","FrameBuffer","ForceFeedBack"], pattern = "FB"
Output: [true,false,true,true,false]
Explanation: "FooBar" can be generated like this "F" + "oo" + "B" + "ar".
"FootBall" can be generated like this "F" + "oot" + "B" + "all".
"FrameBuffer" can be generated like this "F" + "rame" + "B" + "uffer".
```

Example 2:

```
Input: queries = ["FooBar","FooBarTest","FootBall","FrameBuffer","ForceFeedBack"], pattern = "FoBa"
Output: [true,false,true,false,false]
Explanation: "FooBar" can be generated like this "Fo" + "o" + "Ba" + "r".
"FootBall" can be generated like this "Fo" + "ot" + "Ba" + "ll".
```

Example 3:

```
Input: queries = ["FooBar","FooBarTest","FootBall","FrameBuffer","ForceFeedBack"], pattern = "FoBaT"
Output: [false,true,false,false,false]
Explanation: "FooBarTest" can be generated like this "Fo" + "o" + "Ba" + "r" + "T" + "est".
```

Constraints:

- `1 <= pattern.length, queries.length <= 100`
- `1 <= queries[i].length <= 100`
- `queries[i]` and `pattern` consist of English letters.

SOLUTION (PYTHON 3)

Solution 1: Two Pointers

> **How to think about it**
>
> Each query can be matched against the pattern in linear time; both the number of queries and the lengths are at most 100. Extra letters in a query may only be lowercase insertions, and every pattern character must appear in order. Two pointers walk the query and the pattern. The query pointer skips lowercase mismatches; running off the end or hitting a conflicting letter fails. After the pattern is consumed, the query suffix must be all lowercase. The check is applied to every query.

We can traverse every string in `queries` and check whether it matches `pattern` or not. If it matches, we add `true` to the answer array, otherwise we add `false`.

Next, we implement a function check(s, t) to check whether the string s matches the string t.

We can use two pointers i and j to traverse the two strings. If the characters pointed to by i and j are not the same and s[i] is a lowercase letter, then we move the pointer i to the next position.

If the pointer i has reached the end of the string s or the characters pointed to by i and j are not the same, we return `false`. Otherwise, we move both pointers i and j to the next position. When the pointer j reaches the end of the string t, we need to check if the remaining characters in the string s are all lowercase letters. If so, we return `true`, otherwise we return `false`.

Time complexity O(n × m), where n and m are the length of the array `queries` and the string `pattern` respectively.

Python 3

```python
class Solution:
    def camelMatch(self, queries: List[str], pattern: str) -> List[bool]:
        def check(s, t):
            m, n = len(s), len(t)
            i = j = 0
            while j < n:
                while i < m and s[i] != t[j] and s[i].islower():
                    i += 1
                if i == m or s[i] != t[j]:
                    return False
                i, j = i + 1, j + 1
            while i < m and s[i].islower():
                i += 1
            return i == m

        return [check(q, pattern) for q in queries]
```

    initials = ""
    for i in range(len(query)):
        if i == 0 or query[i].isupper():
            initials += query[i]
    return initials == pattern
```

792. Number of Matching Subsequences

Medium · Trie, Array, Hash Table, String, Binary Search, Dynamic Programming, Sorting

leetcode.com/problems/number-of-matching-subsequences

Also appears in pattern 32 Trie (Prefix Tree)

PROBLEM

Given a string `s` and an array of strings `words`, return *the number of* `words[i]` *that is a subsequence of* `s`.

A **subsequence** of a string is a new string generated from the original string with some characters (can be none) deleted without changing the relative order of the remaining characters.

- For example, `"ace"` is a subsequence of `"abcde"`.

Example 1:

```
Input: s = "abcde", words = ["a","bb","acd","ace"]
Output: 3
Explanation: There are three strings in words that are a subsequence of s: "a", "acd", "ace".
```

Example 2:

```
Input: s = "dsahjpjauf", words = ["ahjpjau","ja","ahbwzgqnuk","tnmlanowax"]
Output: 2
```

Constraints:

- `1 <= s.length <= 5 * 10^4`
- `1 <= words.length <= 5000`
- `1 <= words[i].length <= 50`
- `s` and `words[i]` consist of only lowercase English letters.

SOLUTIONS (PYTHON 3)

Solution 1: Bucketing

How to think about it

$|s| \le 5 \times 10^4$; a pointer scan per word rereads s. Bucket words by their next needed letter and, while scanning s, advance only that bucket. A finished word counts; otherwise the remainder goes to the bucket of its new head. Each character of each word is handled once.

Python 3

```python
class Solution:
    def numMatchingSubseq(self, s: str, words: List[str]) -> int:
        d = defaultdict(deque)
        for w in words:
            d[w[0]].append(w)
        ans = 0
        for c in s:
            for _ in range(len(d[c])):
                t = d[c].popleft()
                if len(t) == 1:
                    ans += 1
                else:
                    d[t[1]].append(t[1:])
        return ans
```

Complexity. Time: O(n + L), L = total length of the words. Space: O(k), k = number of words.

Solution 2: Bucketing (Index Pointers)

How to think about it

Solution 1 slices leftover strings. Store (word_index, matched_len) instead; same buckets, less allocation.

Python 3

```python
class Solution:
    def numMatchingSubseq(self, s: str, words: List[str]) -> int:
        d = defaultdict(deque)
        for i, w in enumerate(words):
            d[w[0]].append((i, 0))
        ans = 0
        for c in s:
            for _ in range(len(d[c])):
                i, j = d[c].popleft()
                j += 1
                if j == len(words[i]):
                    ans += 1
                else:
                    d[words[i][j]].append((i, j))
        return ans
```

Complexity. Time: O(n + L), L = total length of the words. Space: O(k), k = number of words.

Solution 3: Binary Search

How to think about it

Bucketing keeps all words live. Alternatively, store every index of each letter in s and binary-search the next position for each character of w. A test is O(|w|log n) and needs no queues.

Python 3

```python
class Solution:
    def numMatchingSubseq(self, s: str, words: List[str]) -> int:
        def check(w):
            i = -1
            for c in w:
                j = bisect_right(d[c], i)
                if j == len(d[c]):
                    return False
                i = d[c][j]
            return True

        d = defaultdict(list)
        for i, c in enumerate(s):
            d[c].append(i)
        return sum(check(w) for w in words)
```

PATTERN 7 · STRING MATCHING / PATTERN SEARCH · PROBLEM 12 OF 20

214. Shortest Palindrome

Hard · String, String Matching, Manacher, Hash Function, Rolling Hash, KMP, Extended KMP

leetcode.com/problems/shortest-palindrome

★ **TOP 10 PROBLEM** in String Matching / Pattern Search: master this one first

PROBLEM

You are given a string `s`. You can convert `s` to a palindrome by adding characters in front of it.

Return *the shortest palindrome you can find by performing this transformation*.

Example 1:

```
Input: s = "aacecaaa"
Output: "aaacecaaa"
```

Example 2:

```
Input: s = "abcd"
Output: "dcbabcd"
```

Constraints:

- `0 <= s.length <= 5 * 10^4`
- `s` consists of lowercase English letters only.

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

The fewest characters to prepend so that s becomes a palindrome are the reverse of the suffix after the longest palindromic prefix. Testing every prefix is slow. We roll a prefix hash and its reverse; equality updates the longest palindromic prefix. The leftover suffix is reversed and prepended.

Python 3

```python
class Solution:
    def shortestPalindrome(self, s: str) -> str:
        base = 131
        mod = 10**9 + 7
        n = len(s)
        prefix = suffix = 0
        mul = 1
        idx = 0
        for i, c in enumerate(s):
            prefix = (prefix * base + (ord(c) - ord('a') + 1)) % mod
            suffix = (suffix + (ord(c) - ord('a') + 1) * mul) % mod
            mul = (mul * base) % mod
            if prefix == suffix:
                idx = i + 1
        return s if idx == n else s[idx:][::-1] + s
```

Complexity. Time: O(n). Space: O(1) extra (the answer is O(n)).

Solution 2: KMP Algorithm

> **How to think about it**
> Polynomial hashes may collide. Concatenating s with its reverse and computing KMP next makes the last next value the longest palindromic prefix length. The same construction then runs in linear time without modular hashing.

According to the problem description, we need to reverse the string s to obtain the string rev, and then find the longest common part of the suffix of the string rev and the prefix of the string s. We can use the KMP algorithm to concatenate the string s and the string rev and find the longest common part of the longest prefix and the longest suffix.

The time complexity is O(n), and the space complexity is O(n). Here, n is the length of the string s.

Python 3

```python
class Solution:
    def shortestPalindrome(self, s: str) -> str:
        t = s + "#" + s[::-1] + "$"
        n = len(t)
        next = [0] * n
        next[0] = -1
        i, j = 2, 0
        while i < n:
            if t[i - 1] == t[j]:
                j += 1
                next[i] = j
                i += 1
            elif j:
                j = next[j]
            else:
                next[i] = 0
                i += 1
        return s[::-1][: -next[-1]] + s
```

        k = border[k - 1]
    return sorted(lengths)
```

44. Wildcard Matching

Hard · Greedy, Recursion, String, Dynamic Programming

leetcode.com/problems/wildcard-matching

★ **TOP 10 PROBLEM** in String Matching / Pattern Search: master this one first

PROBLEM

Given an input string (`s`) and a pattern (`p`), implement wildcard pattern matching with support for `'?'` and `'*'` where:

- `'?'` Matches any single character.
- `'*'` Matches any sequence of characters (including the empty sequence).

The matching should cover the **entire** input string (not partial).

Example 1:

```
Input: s = "aa", p = "a"
Output: false
Explanation: "a" does not match the entire string "aa".
```

Example 2:

```
Input: s = "aa", p = "*"
Output: true
Explanation: '*' matches any sequence.
```

Example 3:

```
Input: s = "cb", p = "?a"
Output: false
Explanation: '?' matches 'c', but the second letter is 'a', which does not match 'b'.
```

Constraints:

- `0 <= s.length, p.length <= 2000`
- `s` contains only lowercase English letters.
- `p` contains only lowercase English letters, `'?'` or `'*'`.

SOLUTIONS (PYTHON 3)

Solution 1: Memoization Search

How to think about it

The first idea is recurse character by character: literals and `?` match one, `*` eats empty or more. Correct, but without memo the `*` branches explode. |s|, |p| ≤ 2000 will time out. The bottleneck is asking the same suffix pair (i, j) over and over. The state is only “does s[i:] match p[j:]”; subproblems overlap heavily. Cache dfs(i, j). The three `*` moves (consume one, advance both, skip `*`) are transitions on that state. Memoization turns exponential search into O(mn).

We design a function dfs(i, j), which represents whether the string s starting from the i-th character matches the string p starting from the j-th character. The answer is dfs(0, 0).

The execution process of the function dfs(i, j) is as follows:

- If i ≥ len(s), then dfs(i, j) is true only when j ≥ len(p) or p[j] = '*' and dfs(i, j + 1) is true.
- If j ≥ len(p), then dfs(i, j) is false.
- If p[j] = '*', then dfs(i, j) is true if and only if dfs(i + 1, j) or dfs(i + 1, j + 1) or dfs(i, j + 1) is true.
- Otherwise, dfs(i, j) is true if and only if p[j] = '?' or s[i] = p[j] and dfs(i + 1, j + 1) is true.

To avoid repeated calculations, we use the method of memoization search and store the result of dfs(i, j) in a hash table.

The time complexity is O(m × n), and the space complexity is O(m × n). Where m and n are the lengths of the strings s and p, respectively.

Python 3

```python
class Solution:
    def isMatch(self, s: str, p: str) -> bool:
        @cache
        def dfs(i: int, j: int) -> bool:
            if i >= len(s):
                return j >= len(p) or (p[j] == "*" and dfs(i, j + 1))
            if j >= len(p):
                return False
            if p[j] == "*":
                return dfs(i + 1, j) or dfs(i + 1, j + 1) or dfs(i, j + 1)
            return (p[j] == "?" or s[i] == p[j]) and dfs(i + 1, j + 1)

        return dfs(0, 0)
```

Solution 2: Dynamic Programming

> **How to think about it**
>
> Solution 1 already fills this match table from shorter prefixes to longer ones. The f[i][j] below is that same table.

Solution 1 already fills this table from shorter prefixes to longer ones.

Define f[i][j] to represent whether the first i characters of string s match the first j characters of string p. Initially, f[0][0] = true, indicating that two empty strings are matching. For j ∈ [1, n], if p[j-1] = '*', then f[0][j] = f[0][j-1].

Next, we consider the case of i ∈ [1, m] and j ∈ [1, n]:

- If p[j-1] = '*', then f[i][j] = f[i-1][j] ∨ f[i][j-1] ∨ f[i-1][j-1].
- Otherwise, f[i][j] = (p[j-1] = '?' ∨ s[i-1] = p[j-1]) ∧ f[i-1][j-1].

The final answer is f[m][n].

The time complexity is O(m × n), and the space complexity is O(m × n). Where m and n are the lengths of the strings s and p, respectively.

Python 3

```python
class Solution:
    def isMatch(self, s: str, p: str) -> bool:
        m, n = len(s), len(p)
        f = [[False] * (n + 1) for _ in range(m + 1)]
        f[0][0] = True
        for j in range(1, n + 1):
            if p[j - 1] == "*":
                f[0][j] = f[0][j - 1]
        for i in range(1, m + 1):
            for j in range(1, n + 1):
                if p[j - 1] == "*":
                    f[i][j] = f[i - 1][j] or f[i][j - 1] or f[i - 1][j - 1]
                else:
                    f[i][j] = f[i - 1][j - 1] and (
                        p[j - 1] == "?" or s[i - 1] == p[j - 1]
                    )
        return f[m][n]
```

Solution 3: Dynamic Programming

How to think about it

Matching one character at a time is the natural first idea: a literal or `?` consumes one character, and `*` consumes the empty string or any run. Both strings can have length 2000, and the first move on `*` is always dfs(i+1, j), so that chain is as deep as |s| and exceeds the default recursion limit. The same index pair is asked repeatedly, and whether two prefixes match depends only on shorter prefixes. Let f[i][j] mean the first i characters of s match the first j characters of p. The empty pair is true, and a run of `*` on the pattern inherits along j. Filling i and j from small to large works because a `*` reads the cell above, the cell to the left, and the diagonal, while a literal or `?` reads only the diagonal.

Define f[i][j] to represent whether the first i characters of string s match the first j characters of string p. Initially, f[0][0] = true, indicating that two empty strings are matching. For $j \in [1, n]$, if p[j-1] = '*', then f[0][j] = f[0][j-1].

Next, we consider the case of $i \in [1, m]$ and $j \in [1, n]$:

- If p[j-1] = '*', then f[i][j] = f[i-1][j] ∨ f[i][j-1] ∨ f[i-1][j-1].
- Otherwise, f[i][j] = (p[j-1] = '?' ∨ s[i-1] = p[j-1]) ∧ f[i-1][j-1].

The final answer is f[m][n].

The time complexity is O(m × n), and the space complexity is O(m × n). Where m and n are the lengths of the strings s and p, respectively.

Python 3

```python
class Solution:
    def isMatch(self, s: str, p: str) -> bool:
        m, n = len(s), len(p)
        f = [[False] * (n + 1) for _ in range(m + 1)]
        f[0][0] = True
        for j in range(1, n + 1):
            if p[j - 1] == "*":
                f[0][j] = f[0][j - 1]
        for i in range(1, m + 1):
            for j in range(1, n + 1):
                if p[j - 1] == "*":
                    f[i][j] = f[i - 1][j] or f[i][j - 1] or f[i - 1][j - 1]
                else:
                    f[i][j] = f[i - 1][j - 1] and (
                        p[j - 1] == "?" or s[i - 1] == p[j - 1]
                    )
        return f[m][n]
```

10. Regular Expression Matching

Hard · Recursion, String, Dynamic Programming

leetcode.com/problems/regular-expression-matching

★ **TOP 10 PROBLEM** in String Matching / Pattern Search: master this one first

PROBLEM

Given an input string `s` and a pattern `p`, implement regular expression matching with support for `'.'` and `'*'` where:

- `'.'` Matches any single character.
- `'*'` Matches zero or more of the preceding element.

Return a boolean indicating whether the matching covers the entire input string (not partial).

Example 1:

```
Input: s = "aa", p = "a"
Output: false
Explanation: "a" does not match the entire string "aa".
```

Example 2:

```
Input: s = "aa", p = "a*"
Output: true
Explanation: '*' means zero or more of the preceding element, 'a'. Therefore, by repeating 'a' once,
it becomes "aa".
```

Example 3:

```
Input: s = "ab", p = ".*"
Output: true
Explanation: ".*" means "zero or more (*) of any character (.)".
```

Constraints:

- `1 <= s.length <= 20`
- `1 <= p.length <= 20`
- `s` contains only lowercase English letters.
- `p` contains only lowercase English letters, `'.'`, and `'*'`.
- It is guaranteed for each appearance of the character `'*'`, there will be a previous valid character to match.

SOLUTIONS (PYTHON 3)

Solution 1: Memoization Search

How to think about it

Matching left to right and, at each `*`, trying 0,1,2,… repetitions is the natural search. s and p are at most length 20, so exponential time sometimes passes, but the same pair of positions is recomputed over and over. A `*` applies only to the preceding token: either match it 0 times (skip two pattern indices), or the current character fits that token (including `.`) and the same `*` consumes the next character of s. A plain character must be consumed one-for-one. The state is therefore “can suffix i of s match suffix j of p”. Search with memoization so exponential branches collapse to O(mn) pairs (i,j).

We design a function dfs(i, j), which indicates whether the i-th character of s matches the j-th character of p. The answer is dfs(0, 0).

The calculation process of the function dfs(i, j) is as follows:

- If j has reached the end of p, then if i has also reached the end of s, the match is successful, otherwise, the match fails.
- If the next character of j is `'*'`, we can choose to match 0 s[i] characters, which is dfs(i, j + 2). If i < m and s[i] matches p[j], we can choose to match 1 s[i] character, which is dfs(i + 1, j).
- If the next character of j is not `'*'`, then if i < m and s[i] matches p[j], it is dfs(i + 1, j + 1). Otherwise, the match fails.

During the process, we can use memoization search to avoid repeated calculations.

The time complexity is O(m × n), and the space complexity is O(m × n). Here, m and n are the lengths of s and p respectively.

Python 3

```
class Solution:
    def isMatch(self, s: str, p: str) -> bool:
        @cache
        def dfs(i, j):
            if j >= n:
                return i == m
            if j + 1 < n and p[j + 1] == '*':
                return dfs(i, j + 2) or (
                    i < m and (s[i] == p[j] or p[j] == '.') and dfs(i + 1, j)
                )
            return i < m and (s[i] == p[j] or p[j] == '.') and dfs(i + 1, j + 1)

        m, n = len(s), len(p)
        return dfs(0, 0)
```

Solution 2: Dynamic Programming

> **How to think about it**
>
> Memoized Solution 1 is already O(mn), but it is still recursion: implicit stack depth and larger constants. The transitions have no aftereffect, so we can fill i,j in increasing order. f[i][j] is whether the first i characters of s match the first j of p. Empty matches empty. We also need i=0 so patterns like `a*` can match the empty string, which is why the outer loop starts from the empty prefix. The `*` cases are the same as Solution 1: skip two pattern characters, or consume one more character of s when it fits. After filling the table we read f[m][n].

We can convert the memoization search in Solution 1 into dynamic programming.

Define f[i][j] to represent whether the first i characters of string s match the first j characters of string p. The answer is f[m][n]. Initialize f[0][0] = true, indicating that the empty string and the empty regular expression match.

Similar to Solution 1, we can discuss different cases.

- If p[j - 1] is `'*'`, we can choose to match 0 s[i - 1] characters, which is f[i][j] = f[i][j - 2]. If s[i - 1] matches p[j - 2], we can choose to match 1 s[i - 1] character, which is f[i][j] = f[i][j] ∨ f[i - 1][j].
- If p[j - 1] is not `'*'`, then if s[i - 1] matches p[j - 1], it is f[i][j] = f[i - 1][j - 1]. Otherwise, the match fails.

The time complexity is O(m × n), and the space complexity is O(m × n). Here, m and n are the lengths of s and p respectively.

Python 3

```
class Solution:
    def isMatch(self, s: str, p: str) -> bool:
        m, n = len(s), len(p)
        f = [[False] * (n + 1) for _ in range(m + 1)]
        f[0][0] = True
        for i in range(m + 1):
            for j in range(1, n + 1):
                if p[j - 1] == "*":
                    f[i][j] = f[i][j - 2]
                    if i > 0 and (p[j - 2] == "." or s[i - 1] == p[j - 2]):
                        f[i][j] |= f[i - 1][j]
                elif i > 0 and (p[j - 1] == "." or s[i - 1] == p[j - 1]):
                    f[i][j] = f[i - 1][j - 1]
        return f[m][n]
```

1392. Longest Happy Prefix

Hard · String, String Matching, Hash Function, Rolling Hash, KMP, Extended KMP

leetcode.com/problems/longest-happy-prefix

★ **TOP 10 PROBLEM** in String Matching / Pattern Search: master this one first

PROBLEM

A string is called a **happy prefix** if it is a **non-empty** prefix which is also a suffix (excluding itself).

Given a string `s`, return *the **longest happy prefix** of* `s`. Return an empty string `""` if no such prefix exists.

Example 1:

```
Input: s = "level"
Output: "l"
Explanation: s contains 4 prefix excluding itself ("l", "le", "lev", "leve"), and suffix ("l", "el", "vel", "evel"). The largest prefix which is also suffix is given by "l".
```

Example 2:

```
Input: s = "ababab"
Output: "abab"
Explanation: "abab" is the largest prefix which is also suffix. They can overlap in the original string.
```

Constraints:

- `1 <= s.length <= 10^5`
- `s` contains only lowercase English letters.

SOLUTIONS (PYTHON 3)

Solution 1: String Hashing

How to think about it

The longest proper prefix that is also a suffix. Comparing every length from short to long is quadratic for n ≤ 10^5. Starting from the longest proper prefix, s[:-i]==s[i:] yields that prefix as soon as it holds; otherwise the answer is empty.

String Hashing is a method to map a string of any length to a non-negative integer, with the probability of collision being almost zero. String hashing is used to calculate the hash value of a string, which allows for quick determination of whether two strings are equal.

We choose a fixed value BASE, and consider the string as a number in BASE radix, assigning a value greater than 0 to represent each character. Generally, the values we assign are much smaller than BASE. For example, for strings composed of lowercase letters, we can assign a=1, b=2, ..., z=26. We choose a fixed value MOD, and calculate the remainder of the BASE radix number divided by MOD, which is used as the hash value of the string.

Generally, we choose BASE=131 or BASE=13331, at which point the probability of hash value collision is extremely low. As long as the hash values of two strings are the same, we consider the two strings to be equal. Usually, MOD is chosen as 2^{64}. In C++, we can directly use the unsigned long long type to store this hash value. When calculating, we do not handle arithmetic overflow. When overflow occurs, it is equivalent to automatically taking the modulus of 2^{64}, which can avoid inefficient modulus operations.

Except for extremely specially constructed data, the above hash algorithm is unlikely to produce collisions. In general, the above hash algorithm can appear in the standard answers of the problem. We can also choose some appropriate values of BASE and MOD (such as large prime numbers), and perform several groups of hash operations. Only when the results are all the same do we consider the original strings to be equal, making it even more difficult to construct data that causes this hash to produce errors.

Python 3

```python
class Solution:
    def longestPrefix(self, s: str) -> str:
        for i in range(1, len(s)):
            if s[:-i] == s[i:]:
                return s[i:]
        return ''
```

Complexity. Time: O(n^2) (each slice comparison costs O(n)). Space: O(n).

Solution 2: KMP Algorithm

> **How to think about it**
>
> Comparing whole slices still scans Θ(n) characters per length. KMP's next table is exactly the longest proper prefix that equals a suffix. Appending a sentinel and reading next[-1] returns that length in linear time.

According to the problem description, we need to find the longest happy prefix of a string, which is the longest prefix of the string that is also a suffix of the string. We can use the KMP algorithm to solve this problem.

The time complexity is O(n), and the space complexity is O(n). Here, n is the length of the string.

Python 3

```python
class Solution:
    def longestPrefix(self, s: str) -> str:
        s += "#"
        n = len(s)
        next = [0] * n
        next[0] = -1
        i, j = 2, 0
        while i < n:
            if s[i - 1] == s[j]:
                j += 1
                next[i] = j
                i += 1
            elif j:
                j = next[j]
            else:
                next[i] = 0
                i += 1
        return s[: next[-1]]
```

    return result
```

1316. Distinct Echo Substrings

Hard · Trie, String, Suffix Array, Suffix Tree, Hash Function, Rolling Hash, Suffix Automato

leetcode.com/problems/distinct-echo-substrings

PROBLEM

Return the number of **distinct** non-empty substrings of `text` that can be written as the concatenation of some string with itself (i.e. it can be written as `a + a` where `a` is some string).

Example 1:

```
Input: text = "abcabcabc"
Output: 3
Explanation: The 3 substrings are "abcabc", "bcabca" and "cabcab".
```

Example 2:

```
Input: text = "leetcodeleetcode"
Output: 2
Explanation: The 2 substrings are "ee" and "leetcodeleetcode".
```

Constraints:

- `1 <= text.length <= 2000`
- `text` has only lowercase English letters.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Count distinct substrings of the form xx. For n ≤ 2000, comparing both halves of every even-length substring character-wise is nearly $O(n^3)$. Equality of two pieces is O(1) with string hashes. After a prefix-hash build, every even interval is tested by hashing its two halves; a set of those hashes is the number of distinct echo substrings.

Python 3

```python
class Solution:
    def distinctEchoSubstrings(self, text: str) -> int:
        def get(l, r):
            return (h[r] - h[l - 1] * p[r - l + 1]) % mod

        n = len(text)
        base = 131
        mod = int(1e9) + 7
        h = [0] * (n + 10)
        p = [1] * (n + 10)
        for i, c in enumerate(text):
            t = ord(c) - ord('a') + 1
            h[i + 1] = (h[i] * base) % mod + t
            p[i + 1] = (p[i] * base) % mod
        vis = set()
        for i in range(n - 1):
            for j in range(i + 1, n, 2):
                k = (i + j) >> 1
                a = get(i + 1, k + 1)
                b = get(k + 2, j + 1)
                if a == b:
                    vis.add(a)
        return len(vis)
```

1032. Stream of Characters

Hard · Design, Trie, Array, String, Data Stream, Aho-Corasick

leetcode.com/problems/stream-of-characters

★ **TOP 10 PROBLEM** in String Matching / Pattern Search, Trie (Prefix Tree): master this one first

Also appears in pattern 32 Trie (Prefix Tree)

PROBLEM

Design an algorithm that accepts a stream of characters and checks if a suffix of these characters is a string of a given array of strings `words`.

For example, if `words = ["abc", "xyz"]` and the stream added the four characters (one by one) `'a'`, `'x'`, `'y'`, and `'z'`, your algorithm should detect that the suffix `"xyz"` of the characters `"axyz"` matches `"xyz"` from `words`.

Implement the `StreamChecker` class:

- `StreamChecker(String[] words)` Initializes the object with the strings array `words`.
- `boolean query(char letter)` Accepts a new character from the stream and returns `true` if any non-empty suffix from the stream forms a word that is in `words`.

Example 1:

```
Input
["StreamChecker", "query", "query", "query", "query", "query", "query", "query", "query", "query",
"query", "query", "query"]
[[["cd", "f", "kl"]], ["a"], ["b"], ["c"], ["d"], ["e"], ["f"], ["g"], ["h"], ["i"], ["j"], ["k"],
["l"]]
Output
[null, false, false, false, true, false, true, false, false, false, false, false, true]

Explanation
StreamChecker streamChecker = new StreamChecker(["cd", "f", "kl"]);
streamChecker.query("a"); // return False
streamChecker.query("b"); // return False
streamChecker.query("c"); // return False
streamChecker.query("d"); // return True, because 'cd' is in the wordlist
streamChecker.query("e"); // return False
streamChecker.query("f"); // return True, because 'f' is in the wordlist
streamChecker.query("g"); // return False
streamChecker.query("h"); // return False
streamChecker.query("i"); // return False
streamChecker.query("j"); // return False
streamChecker.query("k"); // return False
streamChecker.query("l"); // return True, because 'kl' is in the wordlist
```

Constraints:

- `1 <= words.length <= 2000`
- `1 <= words[i].length <= 200`
- `words[i]` consists of lowercase English letters.
- `letter` is a lowercase English letter.
- At most $4 * 10^4$ calls will be made to query.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Matching the whole stream against every word on each query repeats work: up to 4× 10^4 queries and a large total pattern length. We only need to know whether the stream currently ends with some word. Inserting the reversed words into a trie turns suffix queries into prefix walks. Words have length at most 200, so only a bounded tail of the stream matters. The constructor builds that reverse trie; each query appends the letter and walks at most 201 steps, succeeding at an end mark.

Python 3

```python
class Trie:
    def __init__(self):
        self.children = [None] * 26
        self.is_end = False

    def insert(self, w: str):
        node = self
        for c in w[::-1]:
            idx = ord(c) - ord('a')
            if node.children[idx] is None:
                node.children[idx] = Trie()
            node = node.children[idx]
        node.is_end = True

    def search(self, w: List[str]) -> bool:
        node = self
        for c in w[::-1]:
            idx = ord(c) - ord('a')
            if node.children[idx] is None:
                return False
            node = node.children[idx]
            if node.is_end:
                return True
        return False

class StreamChecker:
    def __init__(self, words: List[str]):
        self.trie = Trie()
        self.cs = []
        self.limit = 201
        for w in words:
            self.trie.insert(w)

    def query(self, letter: str) -> bool:
        self.cs.append(letter)
        return self.trie.search(self.cs[-self.limit :])

# Your StreamChecker object will be instantiated and called as such:
# obj = StreamChecker(words)
# param_1 = obj.query(letter)
```

Complexity. Time: build O(L), L = total length of the words; each query O(m), m = length of the longest word. Space: O(L).

PATTERN 7 · STRING MATCHING / PATTERN SEARCH · PROBLEM 19 OF 20

336. Palindrome Pairs

Hard · Trie, Array, Hash Table, String, Hash Function

leetcode.com/problems/palindrome-pairs

Also appears in pattern 32 Trie (Prefix Tree)

PROBLEM

You are given a **0-indexed** array of **unique** strings `words`.

A **palindrome pair** is a pair of integers `(i, j)` such that:

- `0 <= i, j < words.length`,
- `i != j`, and
- `words[i] + words[j]` (the concatenation of the two strings) is a palindrome.

Return *an array of all the **palindrome pairs** of* `words`.

You must write an algorithm with `O(sum of words[i].length)` runtime complexity.

Example 1:

```
Input: words = ["abcd","dcba","lls","s","sssll"]
Output: [[0,1],[1,0],[3,2],[2,4]]
Explanation: The palindromes are ["abcddcba","dcbaabcd","slls","llssssll"]
```

Example 2:

```
Input: words = ["bat","tab","cat"]
Output: [[0,1],[1,0]]
Explanation: The palindromes are ["battab","tabbat"]
```

Example 3:

```
Input: words = ["a",""]
Output: [[0,1],[1,0]]
Explanation: The palindromes are ["a","a"]
```

Constraints:

- `1 <= words.length <= 5000`
- `0 <= words[i].length <= 300`
- `words[i]` consists of lowercase English letters.

SOLUTIONS (PYTHON 3)

Solution 1: Hash Map

How to think about it

Two words should concatenate to a palindrome. Testing every ordered pair is too slow. Split a word: if one side is already a palindrome, the reverse of the other side, if present, completes a pair. Index every word in a hash map. For each cut of w, a palindromic prefix looks up the reversed suffix, and a palindromic suffix looks up the reversed prefix. The empty cut is used on only one side. The code checks both sides at every cut.

Python 3

```python
class Solution:
    def palindromePairs(self, words: List[str]) -> List[List[int]]:
        d = {w: i for i, w in enumerate(words)}
        ans = []
        for i, w in enumerate(words):
            for j in range(len(w) + 1):
                a, b = w[:j], w[j:]
                ra, rb = a[::-1], b[::-1]
                if ra in d and d[ra] != i and b == rb:
                    ans.append([i, d[ra]])
                if j and rb in d and d[rb] != i and a == ra:
                    ans.append([d[rb], i])
        return ans
```

Complexity. Time: O(n * m^2), m = length of the longest word. Space: O(n * m).

Solution 2

How to think about it

Method 1 builds a reversed string for every cut. Inserting words into a trie lets us walk the other word backwards and read an index at a node, without allocating the reverse. When the remaining side is a palindrome we take the stored index; the matches are the same.

Python 3 (written for this guide: the doocs page has no Python 3 version of this solution)

```python
class Trie:
    def __init__(self):
        self.children = [None] * 26
        self.v = -1

    def insert(self, w: str, i: int) -> None:
        node = self
        for c in w:
            k = ord(c) - 97
            if node.children[k] is None:
                node.children[k] = Trie()
            node = node.children[k]
        node.v = i

    def search(self, w: str, i: int, j: int) -> int:
        # walk the letters w[j], w[j - 1], ..., w[i] (the word read backwards)
        node = self
        for k in range(j, i - 1, -1):
            idx = ord(w[k]) - 97
            if node.children[idx] is None:
                return -1
            node = node.children[idx]
        return node.v

class Solution:
    def palindromePairs(self, words: List[str]) -> List[List[int]]:
        def is_palindrome(w: str, i: int, j: int) -> bool:
            while i < j:
                if w[i] != w[j]:
                    return False
                i += 1
                j -= 1
            return True

        trie = Trie()
        for i, w in enumerate(words):
            trie.insert(w, i)
        ans = []
        for i, w in enumerate(words):
            m = len(w)
            for j in range(m + 1):
                if is_palindrome(w, j, m - 1):
                    k = trie.search(w, 0, j - 1)
                    if k != -1 and k != i:
                        ans.append([i, k])
                if j and is_palindrome(w, 0, j - 1):
                    k = trie.search(w, j, m - 1)
                    if k != -1 and k != i:
                        ans.append([k, i])
        return ans
```

Complexity. Time: O(n * m^2), m = length of the longest word. Space: O(n * m).

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

```

472. Concatenated Words

Hard · Depth-First Search, Trie, Array, String, Dynamic Programming, Sorting

leetcode.com/problems/concatenated-words

Also appears in pattern 32 Trie (Prefix Tree)

PROBLEM

Given an array of strings `words` (**without duplicates**), return *all the **concatenated words** in the given list of* `words`.

A **concatenated word** is defined as a string that is comprised entirely of at least two shorter words (not necessarily distinct) in the given array.

Example 1:

```
Input: words = ["cat","cats","catsdogcats","dog","dogcatsdog","hippopotamuses","rat","ratcatdogcat"]
Output: ["catsdogcats","dogcatsdog","ratcatdogcat"]
Explanation: "catsdogcats" can be concatenated by "cats", "dog" and "cats";
"dogcatsdog" can be concatenated by "dog", "cats" and "dog";
"ratcatdogcat" can be concatenated by "rat", "cat", "dog" and "cat".
```

Example 2:

```
Input: words = ["cat","dog","catdog"]
Output: ["catdog"]
```

Constraints:

- `1 <= words.length <= 10^4`
- `1 <= words[i].length <= 30`
- `words[i]` consists of only lowercase English letters.
- All the strings of `words` are **unique**.
- `1 <= sum(words[i].length) <= 10^5`

SOLUTION (PYTHON 3)

Solution 1

How to think about it

A concatenated word is at least two shorter dictionary words. Trying every split and a set lookup grows with both n and length. Sort by length and insert shorter words into a trie first. DFS the current word on the trie: at an end-of-word node recurse on the suffix; if the whole word splits, it is concatenated, otherwise insert it. Concatenated words stay out of the trie, since a longer word can always fall back to atomic pieces. The empty suffix is the success base case.

Python 3

```python
class Trie:
    def __init__(self):
        self.children = [None] * 26
        self.is_end = False

    def insert(self, w):
        node = self
        for c in w:
            idx = ord(c) - ord('a')
            if node.children[idx] is None:
                node.children[idx] = Trie()
            node = node.children[idx]
        node.is_end = True

class Solution:
    def findAllConcatenatedWordsInADict(self, words: List[str]) -> List[str]:
        def dfs(w):
            if not w:
                return True
            node = trie
            for i, c in enumerate(w):
                idx = ord(c) - ord('a')
                if node.children[idx] is None:
                    return False
                node = node.children[idx]
                if node.is_end and dfs(w[i + 1 :]):
                    return True
            return False

        trie = Trie()
        ans = []
        words.sort(key=lambda x: len(x))
        for w in words:
            if dfs(w):
                ans.append(w)
            else:
                trie.insert(w)
        return ans
```

Complexity. Time: O(n * m^2), m = length of the longest word. Space: O(n * m).

PATTERN 8 · STACK · PROBLEM 2 OF 20

1047. Remove All Adjacent Duplicates In String

Easy · Stack, String

leetcode.com/problems/remove-all-adjacent-duplicates-in-string

★ **TOP 10 PROBLEM** in Stack: master this one first

PROBLEM

You are given a string `s` consisting of lowercase English letters. A **duplicate removal** consists of choosing two **adjacent** and **equal** letters and removing them.

We repeatedly make **duplicate removals** on `s` until we no longer can.

Return *the final string after all such duplicate removals have been made*. It can be proven that the answer is **unique**.

Example 1:

```
Input: s = "abbaca"
Output: "ca"
Explanation:
For example, in "abbaca" we could remove "bb" since the letters are adjacent and equal, and this is the only possible move. The result of this move is that the string is "aaca", of which only "aa" is possible, so the final string is "ca".
```

Example 2:

```
Input: s = "azxxzy"
Output: "ay"
```

Constraints:

- `1 <= s.length <= 10^5`
- `s` consists of lowercase English letters.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Repeatedly deleting adjacent equal pairs may rescan a string of length 10^5. After a deletion the new adjacency is local, so a stack can keep the compressed prefix. A character equal to the top is popped; otherwise it is pushed. The stack at the end is the fully reduced string.

Python 3

```python
class Solution:
    def removeDuplicates(self, s: str) -> str:
        stk = []
        for c in s:
            if stk and stk[-1] == c:
                stk.pop()
            else:
                stk.append(c)
        return ''.join(stk)
```

Complexity. Time: O(n). Space: O(n).

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

Built on the solutions above: helper functions, then the function for each follow-up. No tests and no restating of the question.

```
# FOLLOW-UPS (answered below, in this order):
# 1. Characters arrive one at a time: always know the
# current reduced string
# 2. Count how many pairs were removed

# ============================================================
# FOLLOW-UP 1: Characters arrive one at a time: always
# know the current reduced string
# ============================================================

# ---- follow-up 1: function ----
# Answer: Keep the stack between calls: a new character
# either cancels the top one or is pushed.
# Time: O(k) per add, k = current length (the string is
# rebuilt); O(1) if you only keep the stack.  Space: O(n).
class ReducingStream:
    def __init__(self):
        self.stack = []

    def add(self, ch):
        if self.stack and self.stack[-1] == ch:
            self.stack.pop()
        else:
            self.stack.append(ch)
        return "".join(self.stack)

# ============================================================
# FOLLOW-UP 2: Count how many pairs were removed
# ============================================================

# ---- follow-up 2: function ----
# Answer: The same scan; every time the new character
# cancels the top one, count one removed pair.
# Time: O(n).  Space: O(n).
def count_removed_pairs(s):
    stack = []
    pairs = 0
    for ch in s:
        if stack and stack[-1] == ch:
            stack.pop()
            pairs += 1
        else:
            stack.append(ch)
    return pairs
```

PATTERN 8 · STACK · PROBLEM 3 OF 20

1544. Make The String Great

Easy · Stack, String

leetcode.com/problems/make-the-string-great

PROBLEM

Given a string `s` of lower and upper case English letters.

A good string is a string which doesn't have **two adjacent characters** `s[i]` and `s[i + 1]` where:

- `0 <= i <= s.length - 2`
- `s[i]` is a lower-case letter and `s[i + 1]` is the same letter but in upper-case or **vice-versa**.

To make the string good, you can choose **two adjacent** characters that make the string bad and remove them. You can keep doing this until the string becomes good.

Return *the string* after making it good. The answer is guaranteed to be unique under the given constraints.

Notice that an empty string is also good.

Example 1:

```
Input: s = "leEeetcode"
Output: "leetcode"
Explanation: In the first step, either you choose i = 1 or i = 2, both will result "leEeetcode" to be reduced to "leetcode".
```

Example 2:

```
Input: s = "abBAcC"
Output: ""
Explanation: We have many possible scenarios, and all lead to the same answer. For example:
"abBAcC" --> "aAcC" --> "cC" --> ""
"abBAcC" --> "abBA" --> "aA" --> ""
```

Example 3:

```
Input: s = "s"
Output: "s"
```

Constraints:

- `1 <= s.length <= 100`
- `s` contains only lower and upper case English letters.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

A “great” string has no adjacent letters that differ only in case. Repeated left-to-right deletions work for n≤ 100, but a deletion can create a new pair further left, forcing extra passes. A stack holds the cleaned prefix. If the new character differs from the top by 32 (exactly a case pair), pop; otherwise push. One linear scan produces the answer.

Python 3

```
class Solution:
    def makeGood(self, s: str) -> str:
        stk = []
        for c in s:
            if not stk or abs(ord(stk[-1]) - ord(c)) != 32:
                stk.append(c)
            else:
                stk.pop()
        return "".join(stk)
```

Complexity. Time: O(n). Space: O(n).

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

```

PATTERN 8 · STACK · PROBLEM 4 OF 20

496. Next Greater Element I

Easy · Stack, Array, Hash Table, Monotonic Stack

leetcode.com/problems/next-greater-element-i

★ **TOP 10 PROBLEM** in Stack, Monotonic Stack / Queue (Specific Variants): master this one first

Also appears in pattern 9 Monotonic Stack / Queue (Specific Variants)

PROBLEM

The **next greater element** of some element `x` in an array is the **first greater** element that is **to the right** of `x` in the same array.

You are given two **distinct 0-indexed** integer arrays `nums1` and `nums2`, where `nums1` is a subset of `nums2`.

For each `0 <= i < nums1.length`, find the index `j` such that `nums1[i] == nums2[j]` and determine the **next greater element** of `nums2[j]` in `nums2`. If there is no next greater element, then the answer for this query is `-1`.

Return *an array* `ans` *of length* `nums1.length` *such that* `ans[i]` *is the* ***next greater element*** *as described above.*

Example 1:

```
Input: nums1 = [4,1,2], nums2 = [1,3,4,2]
Output: [-1,3,-1]
Explanation: The next greater element for each value of nums1 is as follows:
- 4 is underlined in nums2 = [1,3,4,2]. There is no next greater element, so the answer is -1.
- 1 is underlined in nums2 = [1,3,4,2]. The next greater element is 3.
- 2 is underlined in nums2 = [1,3,4,2]. There is no next greater element, so the answer is -1.
```

Example 2:

```
Input: nums1 = [2,4], nums2 = [1,2,3,4]
Output: [3,-1]
Explanation: The next greater element for each value of nums1 is as follows:
- 2 is underlined in nums2 = [1,2,3,4]. The next greater element is 3.
- 4 is underlined in nums2 = [1,2,3,4]. There is no next greater element, so the answer is -1.
```

Constraints:

- `1 <= nums1.length <= nums2.length <= 1000`
- `0 <= nums1[i], nums2[i] <= 10^4`
- All integers in `nums1` and `nums2` are **unique**.
- All the integers of `nums1` also appear in `nums2`.

Follow up:

Could you find an

`O(nums1.length + nums2.length)`

solution?

SOLUTION (PYTHON 3)

Solution 1: Monotonic Stack

How to think about it

nums1 is a subset of nums2; we want each value's next greater element in nums2. Scanning rightward from every nums1 value is O(nm). Walk nums2 right to left with a decreasing stack: after popping smaller tops, the new top is the next greater value, stored in a map. Then look up nums1. Each value enters and leaves the stack once. Building the map on nums2 first avoids scanning it once per query.

We can traverse the array nums2 from right to left, maintaining a stack stk that is monotonically increasing from top to bottom. We use a hash table d to record the next greater element for each element.

When we encounter an element x, if the stack is not empty and the top element of the stack is less than x, we keep popping the top elements until the stack is empty or the top element is greater than or equal to x. At this point, if the stack is not empty, the top element of the stack is the next greater element for x. Otherwise, x has no next greater element.

Finally, we traverse the array nums1 and use the hash table d to get the answer.

The time complexity is O(m + n), and the space complexity is O(n). Here, m and n are the lengths of the arrays nums1 and nums2, respectively.

Python 3

```python
class Solution:
    def nextGreaterElement(self, nums1: List[int], nums2: List[int]) -> List[int]:
        stk = []
        d = {}
        for x in nums2[::-1]:
            while stk and stk[-1] < x:
                stk.pop()
            if stk:
                d[x] = stk[-1]
            stk.append(x)
        return [d.get(x, -1) for x in nums1]
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

```python
# FOLLOW-UPS (answered below, in this order):
# 1. The array is circular (Next Greater Element II)
# 2. The next SMALLER element to the right

# ============================================================
# FOLLOW-UP 1: The array is circular (Next Greater Element
# II)
# ============================================================

# ---- follow-up 1: function ----
# Answer: Go around the array twice (positions 0 to 2n -
# 1, reading the numbers modulo n) with a stack of
# positions whose next greater element is still unknown.
# Time: O(n).  Space: O(n).
def next_greater_circular(nums):
    n = len(nums)
    answer = [-1] * n
    stack = []
    for i in range(2 * n):
        value = nums[i % n]
        while stack and nums[stack[-1]] < value:
            answer[stack.pop()] = value
        if i < n:
            stack.append(i)
    return answer

# ============================================================
# FOLLOW-UP 2: The next SMALLER element to the right
# ============================================================

# ---- follow-up 2: function ----
# Answer: Same stack, but pop while the new number is
# smaller than the number on top.
# Time: O(n).  Space: O(n).
def next_smaller(nums):
    answer = [-1] * len(nums)
    stack = []
```

```
    for i in range(len(nums)):
        while stack and nums[stack[-1]] > nums[i]:
            answer[stack.pop()] = nums[i]
        stack.append(i)
    return answer
```

682. Baseball Game

Easy · Stack, Array, Simulation

leetcode.com/problems/baseball-game

PROBLEM

You are keeping the scores for a baseball game with strange rules. At the beginning of the game, you start with an empty record.

You are given a list of strings `operations`, where `operations[i]` is the i^{th} operation you must apply to the record and is one of the following:

- An integer `x`.
  - Record a new score of `x`.
- `'+'`.
  - Record a new score that is the sum of the previous two scores.
- `'D'`.
  - Record a new score that is the double of the previous score.
- `'C'`.
  - Invalidate the previous score, removing it from the record.

Return *the sum of all the scores on the record after applying all the operations*.

The test cases are generated such that the answer and all intermediate calculations fit in a **32-bit** integer and that all operations are valid.

Example 1:

```
Input: ops = ["5","2","C","D","+"]
Output: 30
Explanation:
"5" - Add 5 to the record, record is now [5].
"2" - Add 2 to the record, record is now [5, 2].
"C" - Invalidate and remove the previous score, record is now [5].
"D" - Add 2 * 5 = 10 to the record, record is now [5, 10].
"+" - Add 5 + 10 = 15 to the record, record is now [5, 10, 15].
The total sum is 5 + 10 + 15 = 30.
```

Example 2:

```
Input: ops = ["5","-2","4","C","D","9","+","+"]
Output: 27
Explanation:
"5" - Add 5 to the record, record is now [5].
"-2" - Add -2 to the record, record is now [5, -2].
"4" - Add 4 to the record, record is now [5, -2, 4].
"C" - Invalidate and remove the previous score, record is now [5, -2].
"D" - Add 2 * -2 = -4 to the record, record is now [5, -2, -4].
"9" - Add 9 to the record, record is now [5, -2, -4, 9].
"+" - Add -4 + 9 = 5 to the record, record is now [5, -2, -4, 9, 5].
"+" - Add 9 + 5 = 14 to the record, record is now [5, -2, -4, 9, 5, 14].
The total sum is 5 + -2 + -4 + 9 + 5 + 14 = 27.
```

Example 3:

```
Input: ops = ["1","C"]
Output: 0
Explanation:
"1" - Add 1 to the record, record is now [1].
"C" - Invalidate and remove the previous score, record is now [].
Since the record is empty, the total sum is 0.
```

Constraints:

- `1 <= operations.length <= 1000`
- `operations[i]` is `"C"`, `"D"`, `"+"`, or a string representing an integer in the range $[-3 * 10^4, 3 * 10^4]$.
- For operation `"+"`, there will always be at least two previous scores on the record.
- For operations `"C"` and `"D"`, there will always be at least one previous score on the record.

SOLUTION (PYTHON 3)

Solution 1: Stack + Simulation

> **How to think about it**
>
> Each operation refers to the last score, the last two, or an undo, so recent values must stay accessible. A stack stores rounds: `+` sums the top two, `D` doubles the top, `C` pops, a number pushes. Sum the stack at the end.

We can use a stack to simulate this process.

Traverse operations, for each operation:

- If it is `+`, add the top two elements of the stack and push the result onto the stack;
- If it is `D`, multiply the top element of the stack by 2 and push the result onto the stack;
- If it is `C`, pop the top element of the stack;
- If it is a number, push the number onto the stack.

Finally, sum all the elements in the stack to get the answer.

The time complexity is O(n), and the space complexity is O(n). Here, n is the length of operations.

Python 3

```python
class Solution:
    def calPoints(self, operations: List[str]) -> int:
        stk = []
        for op in operations:
            if op == "+":
                stk.append(stk[-1] + stk[-2])
            elif op == "D":
                stk.append(stk[-1] << 1)
            elif op == "C":
                stk.pop()
            else:
                stk.append(int(op))
        return sum(stk)
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

Built on the solutions above: helper functions, then the function for each follow-up. No tests and no restating of the question.

```python
# FOLLOW-UPS (answered below, in this order):
# 1. Return the total after every operation
# 2. Add an operation 'U' that undoes the previous
# operation (of any kind)

# ========================================================
# FOLLOW-UP 1: Return the total after every operation
# ========================================================
```

```
# ---- follow-up 1: function ----
# Answer: Keep the list of valid scores as before and
# append the running sum of that list after each
# operation.
# Time: O(n^2) (the total is recomputed after every
# operation).  Space: O(n).
def totals_after_each_operation(operations):
    scores = []
    totals = []
    for op in operations:
        if op == "C":
            scores.pop()

PATTERN 8 · STACK · PROBLEM 7 OF 20

155. Min Stack

Medium · Stack, Design

leetcode.com/problems/min-stack

★ **TOP 10 PROBLEM** in Stack, Design Problems: master this one first

Also appears in pattern 29 Design Problems

PROBLEM

Design a stack that supports push, pop, top, and retrieving the minimum element in constant time.

Implement the `MinStack` class:

- `MinStack()` initializes the stack object.
- `void push(int value)` pushes the element `value` onto the stack.
- `void pop()` removes the element on the top of the stack.
- `int top()` gets the top element of the stack.
- `int getMin()` retrieves the minimum element in the stack.

You must implement a solution with `O(1)` time complexity for each function.

Example 1:

```
Input
["MinStack","push","push","push","getMin","pop","top","getMin"]
[[],[-2],[0],[-3],[],[],[],[]]

Output
[null,null,null,null,-3,null,0,-2]

Explanation
MinStack minStack = new MinStack();
minStack.push(-2);
minStack.push(0);
minStack.push(-3);
minStack.getMin(); // return -3
minStack.pop();
minStack.top(); // return 0
minStack.getMin(); // return -2
```

Constraints:

- -2^{31} <= val <= $2^{31} - 1$
- Methods `pop`, `top` and `getMin` operations will always be called on **non-empty** stacks.
- At most $3 * 10^4$ calls will be made to `push`, `pop`, `top`, and `getMin`.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

getMin must be O(1) like push/pop. Scanning the stack is linear, and there are up to 3× 10^4 calls. The minimum changes only when a smaller value is pushed or the current min is popped. A parallel min-stack stores min(x, current min) on each push and pops in lockstep.

Python 3

```python
class MinStack:
    def __init__(self):
        self.stk1 = []
        self.stk2 = [inf]

    def push(self, val: int) -> None:
        self.stk1.append(val)
        self.stk2.append(min(val, self.stk2[-1]))

    def pop(self) -> None:
        self.stk1.pop()
        self.stk2.pop()

    def top(self) -> int:
        return self.stk1[-1]

    def getMin(self) -> int:
        return self.stk2[-1]

# Your MinStack object will be instantiated and called as such:
# obj = MinStack()
# obj.push(val)
# obj.pop()
# param_3 = obj.top()
# param_4 = obj.getMin()
```

PATTERN 8 · STACK · PROBLEM 8 OF 20

150. Evaluate Reverse Polish Notation

Medium · Stack, Array, Math

leetcode.com/problems/evaluate-reverse-polish-notation

★ **TOP 10 PROBLEM** in Stack: master this one first

PROBLEM

You are given an array of strings `tokens` that represents an arithmetic expression in a Reverse Polish Notation.

Evaluate the expression. Return *an integer that represents the value of the expression*.

Note that:

- The valid operators are `'+'`, `'-'`, `'*'`, and `'/'`.
- Each operand may be an integer or another expression.
- The division between two integers always **truncates toward zero**.
- There will not be any division by zero.
- The input represents a valid arithmetic expression in a reverse polish notation.
- The answer and all the intermediate calculations can be represented in a **32-bit** integer.

Example 1:

```
Input: tokens = ["2","1","+","3","*"]
Output: 9
Explanation: ((2 + 1) * 3) = 9
```

Example 2:

```
Input: tokens = ["4","13","5","/","+"]
Output: 6
Explanation: (4 + (13 / 5)) = 6
```

Example 3:

```
Input: tokens = ["10","6","9","3","+","-11","*","/","*","17","+","5","+"]
Output: 22
Explanation: ((10 * (6 / ((9 + 3) * -11))) + 17) + 5
= ((10 * (6 / (12 * -11))) + 17) + 5
= ((10 * (6 / -132)) + 17) + 5
= ((10 * 0) + 17) + 5
= (0 + 17) + 5
= 17 + 5
= 22
```

Constraints:

- `1 <= tokens.length <= 10^4`
- `tokens[i]` is either an operator: `"+"`, `"-"`, `"*"`, or `"/"`, or an integer in the range `[-200, 200]`.

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

Reverse Polish notation puts the operator after its operands, so evaluation order is already fixed and we need no parentheses or precedence. n≤ 10^4. Push numbers; on an operator pop two values, compute, and push back. The stack holds pending intermediates; one value remains.

Python 3

```python
import operator

class Solution:
    def evalRPN(self, tokens: List[str]) -> int:
        opt = {
            "+": operator.add,
            "-": operator.sub,
            "*": operator.mul,
            "/": operator.truediv,
        }
        s = []
        for token in tokens:
            if token in opt:
                s.append(int(opt[token](s.pop(-2), s.pop(-1))))
            else:
                s.append(int(token))
        return s[0]
```

Complexity. Time: O(n). Space: O(n).

Solution 2

> **How to think about it**
>
> Solution 1 maps operators to functions. This version mutates the stack top in place, branching on the four operators, and watches operand order and truncation toward zero. Same structure, no function table.

Python 3

```python
class Solution:
    def evalRPN(self, tokens: List[str]) -> int:
        nums = []
        for t in tokens:
            if len(t) > 1 or t.isdigit():
                nums.append(int(t))
            else:
                if t == "+":
                    nums[-2] += nums[-1]
                elif t == "-":
                    nums[-2] -= nums[-1]
                elif t == "*":
                    nums[-2] *= nums[-1]
                else:
                    nums[-2] = int(nums[-2] / nums[-1])
                nums.pop()
        return nums[0]
```

Complexity. Time: O(n). Space: O(n).

PATTERN 8 · STACK · PROBLEM 9 OF 20

22. Generate Parentheses

Medium · String, Dynamic Programming, Backtracking, Parentheses

leetcode.com/problems/generate-parentheses

★ **TOP 10 PROBLEM** in Stack: master this one first

Also appears in pattern 15 Backtracking / Subsets / Combinations / Permutations

PROBLEM

Given `n` pairs of parentheses, write a function to *generate all combinations of well-formed parentheses*.

Example 1:

```
Input: n = 3
Output: ["((()))","(()())","(())()","()(())","()()()"]
```

Example 2:

```
Input: n = 1
Output: ["()"]
```

Constraints:

- `1 <= n <= 8`

SOLUTION (PYTHON 3)

Solution 1: DFS + Pruning

How to think about it

The first idea is to enumerate every string of length 2n and keep the valid ones. n ≤ 8 gives 2^{16} candidates, so it would pass, but most prefixes are already illegal. The bottleneck is generate-then-check: once a prefix has more `)` than `(`, or either count exceeds n, no suffix can save it. A valid prefix only needs the two counts l and r: keep l ≥ r and neither above n. When l=r=n, record the string. DFS therefore tries appending `(` or `)` and prunes on those three inequalities. The search tree is much smaller than full enumeration; extra space is just the current string, O(n).

The range of n in the problem is [1, 8], so we can directly solve this problem through "brute force search + pruning".

We design a function dfs(l, r, t), where l and r represent the number of left and right brackets respectively, and t represents the current bracket sequence. Then we can get the following recursive structure:

- If l > n or r > n or l < r, then the current bracket combination t is invalid, return directly;
- If l = n and r = n, then the current bracket combination t is valid, add it to the answer array `ans`, and return directly;
- We can choose to add a left bracket, and recursively execute `dfs(l + 1, r, t + "(")`;
- We can also choose to add a right bracket, and recursively execute `dfs(l, r + 1, t + ")")`.

The time complexity is $O(2^{n\times 2} \times n)$, and the space complexity is O(n).

Python 3

```
class Solution:
    def generateParenthesis(self, n: int) -> List[str]:
        def dfs(l: int, r: int, t: str):
            if l > n or r > n or l < r:
                return
            if l == n and r == n:
                ans.append(t)
                return
            dfs(l + 1, r, t + "(")
            dfs(l, r + 1, t + ")")

        ans = []
        dfs(0, 0, "")
        return ans
```

PATTERN 8 · STACK · PROBLEM 10 OF 20

739. Daily Temperatures

Medium · Stack, Array, Monotonic Stack

leetcode.com/problems/daily-temperatures

★ **TOP 10 PROBLEM** in Stack, Monotonic Stack / Queue (Specific Variants): master this one first

Also appears in pattern 9 Monotonic Stack / Queue (Specific Variants)

PROBLEM

Given an array of integers `temperatures` represents the daily temperatures, return *an array* `answer` *such that* `answer[i]` *is the number of days you have to wait after the* `i`th *day to get a warmer temperature*. If there is no future day for which this is possible, keep `answer[i] == 0` instead.

Example 1:

```
Input: temperatures = [73,74,75,71,69,72,76,73]
Output: [1,1,4,2,1,1,0,0]
```

Example 2:

```
Input: temperatures = [30,40,50,60]
Output: [1,1,1,0]
```

Example 3:

```
Input: temperatures = [30,60,90]
Output: [1,1,0]
```

Constraints:

- `1 <= temperatures.length <=` 10^5
- `30 <= temperatures[i] <= 100`

SOLUTION (PYTHON 3)

Solution 1: Monotonic Stack

How to think about it

For each day, the wait until a warmer day. n≤ 10^5 forbids a rightward scan from every index. This is next-greater-element. A monotonic stack of indices still waiting for a warmer day, scanned right to left, pops every temperature that is not strictly warmer; the new top is the answer. Temperatures increase from top to bottom. Each index is pushed and popped once, O(n).

This problem requires us to find the position of the first element greater than each element to its right, which is a typical application scenario for a monotonic stack.

We traverse the array temperatures from right to left, maintaining a stack stk that is monotonically increasing from top to bottom in terms of temperature. The stack stores the indices of the array elements. For each element temperatures[i], we continuously compare it with the top element of the stack. If the temperature corresponding to the top element of the stack is less than or equal to temperatures[i], we pop the top element of the stack in a loop until the stack is empty or the temperature corresponding to the top element of the stack is greater than temperatures[i]. At this point, the top element of the stack is the first element greater than temperatures[i] to its right, and the distance is stk.top() - i. We update the answer array accordingly. Then we push temperatures[i] onto the stack and continue traversing.

After the traversal, we return the answer array.

The time complexity is O(n), and the space complexity is O(n). Here, n is the length of the array temperatures.

Python 3

```python
class Solution:
    def dailyTemperatures(self, temperatures: List[int]) -> List[int]:
        stk = []
        n = len(temperatures)
        ans = [0] * n
        for i in range(n - 1, -1, -1):
            while stk and temperatures[stk[-1]] <= temperatures[i]:
                stk.pop()
            if stk:
                ans[i] = stk[-1] - i
            stk.append(i)
        return ans
```

PATTERN 8 · STACK · PROBLEM 12 OF 20

735. Asteroid Collision

Medium · Stack, Array, Simulation

leetcode.com/problems/asteroid-collision

PROBLEM

We are given an array `asteroids` of integers representing asteroids in a row. The indices of the asteroid in the array represent their relative position in space.

For each asteroid, the absolute value represents its size, and the sign represents its direction (positive meaning right, negative meaning left). Each asteroid moves at the same speed.

Find out the state of the asteroids after all collisions. If two asteroids meet, the smaller one will explode. If both are the same size, both will explode. Two asteroids moving in the same direction will never meet.

Example 1:

```
Input: asteroids = [5,10,-5]
Output: [5,10]
Explanation: The 10 and -5 collide resulting in 10. The 5 and 10 never collide.
```

Example 2:

```
Input: asteroids = [8,-8]
Output: []
Explanation: The 8 and -8 collide exploding each other.
```

Example 3:

```
Input: asteroids = [10,2,-5]
Output: [10]
Explanation: The 2 and -5 collide resulting in -5. The 10 and -5 collide resulting in 10.
```

Example 4:

```
Input: asteroids = [3,5,-6,2,-1,4]
Output: [-6,2,4]
Explanation: The asteroid -6 makes the asteroid 3 and 5 explode, and then continues going left. On the
other side, the asteroid 2 destroys -1. Since 2 and 4 are both moving right, they never collide.
```

Constraints:

- `2 <= asteroids.length <= 10^4`
- `-1000 <= asteroids[i] <= 1000`
- `asteroids[i] != 0`

SOLUTION (PYTHON 3)

Solution 1: Stack

How to think about it

Collisions happen only when a right-moving rock meets a left-moving one. $n \le 10^4$. A stack holds the still-alive prefix, which is the natural surviving sequence. A positive rock cannot hit anything to its left, so it is pushed. A negative one fights the positive top: smaller tops explode, equal tops both vanish, a larger top destroys the new rock. Each rock is pushed and popped at most once, so the scan is O(n).

We traverse each asteroid x from left to right. Since each asteroid may collide with multiple asteroids before it, we consider using a stack to store.

- For the current asteroid, if x>0, it will definitely not collide with the previous asteroid, and we can directly push x into the stack.
- Otherwise, if the stack is not empty and the top element of the stack is greater than 0, and the top element of the stack is less than -x, then the top element of the stack corresponds to the asteroid will explode, we loop to the top element of the stack Pop out until the condition is not satisfied. At this time, if the top element of the stack is equal to -x, then the two asteroids will explode, and we only need to pop the top element of the stack; if the stack is empty, or the top element of the stack is less than 0, then the current asteroid will not collide, we will push x into the stack.

Finally, we return the elements in the stack as the answer.

The time complexity is O(n), and the space complexity is O(n). Where n is the length of the array asteroids.

Python 3

```python
class Solution:
    def asteroidCollision(self, asteroids: List[int]) -> List[int]:
        stk = []
        for x in asteroids:
            if x > 0:
                stk.append(x)
            else:
                while stk and stk[-1] > 0 and stk[-1] < -x:
                    stk.pop()
                if stk and stk[-1] == -x:
                    stk.pop()
                elif not stk or stk[-1] < 0:
                    stk.append(x)
        return stk
```

PATTERN 8 · STACK · PROBLEM 14 OF 20

227. Basic Calculator II

Medium · Stack, Math, String

leetcode.com/problems/basic-calculator-ii

★ **TOP 10 PROBLEM** in Stack: master this one first

PROBLEM

Given a string `s` which represents an expression, *evaluate this expression and return its value*.

The integer division should truncate toward zero.

You may assume that the given expression is always valid. All intermediate results will be in the range of $[-2^{31}, 2^{31} - 1]$.

Note: You are not allowed to use any built-in function which evaluates strings as mathematical expressions, such as `eval()`.

Example 1:

```
Input: s = "3+2*2"
Output: 7
```

Example 2:

```
Input: s = " 3/2 "
Output: 1
```

Example 3:

```
Input: s = " 3+5 / 2 "
Output: 5
```

Constraints:

- $1 \le s.length \le 3 * 10^5$
- `s` consists of integers and operators `('+', '-', '*', '/')` separated by some number of spaces.
- `s` represents a valid expression.
- All the integers in the expression are non-negative integers in the range $[0, 2^{31} - 1]$.
- The answer is **guaranteed** to fit in a **32-bit integer**.

SOLUTION (PYTHON 3)

Solution 1: Stack

How to think about it

Multiplication and division bind tighter than addition, and there are no parentheses, so we cannot add every number immediately. Treat + and - as signed terms on a stack, and fold * and / into the top. sign remembers the previous operator; after a number is complete we push or update the top, then sum the stack.

We traverse the string s, and use a variable `sign` to record the operator before each number. For the first number, its previous operator is considered as a plus sign. Each time we traverse to the end of a number, we decide the calculation method based on `sign`:

- Plus sign: push the number into the stack;
- Minus sign: push the opposite number into the stack;
- Multiplication and division signs: calculate the number with the top element of the stack, and replace the top element of the stack with the calculation result.

After the traversal ends, the sum of the elements in the stack is the answer.

The time complexity is O(n), and the space complexity is O(n), where n is the length of the string s.

Python 3

```python
class Solution:
    def calculate(self, s: str) -> int:
        v, n = 0, len(s)
        sign = '+'
        stk = []
        for i, c in enumerate(s):
            if c.isdigit():
                v = v * 10 + int(c)
            if i == n - 1 or c in '+-*/':
                match sign:
                    case '+':
                        stk.append(v)
                    case '-':
                        stk.append(-v)
                    case '*':
                        stk.append(stk.pop() * v)
                    case '/':
                        stk.append(int(stk.pop() / v))
                sign = c
                v = 0
        return sum(stk)
```

```

1209. Remove All Adjacent Duplicates in String II

Medium · Stack, String

leetcode.com/problems/remove-all-adjacent-duplicates-in-string-ii

PROBLEM

You are given a string `s` and an integer `k`, a `k` **duplicate removal** consists of choosing `k` adjacent and equal letters from `s` and removing them, causing the left and the right side of the deleted substring to concatenate together.

We repeatedly make `k` **duplicate removals** on `s` until we no longer can.

Return *the final string after all such duplicate removals have been made*. It is guaranteed that the answer is **unique**.

Example 1:

```
Input: s = "abcd", k = 2
Output: "abcd"
Explanation: There's nothing to delete.
```

Example 2:

```
Input: s = "deeedbbcccbdaa", k = 3
Output: "aa"
Explanation:
First delete "eee" and "ccc", get "ddbbbdaa"
Then delete "bbb", get "dddaa"
Finally delete "ddd", get "aa"
```

Example 3:

```
Input: s = "pbbcggttciiippooaais", k = 2
Output: "ps"
```

Constraints:

- `1 <= s.length <= 10^5`
- `2 <= k <= 10^4`
- `s` only contains lowercase English letters.

SOLUTION (PYTHON 3)

Solution 1: Stack

How to think about it

Repeatedly scanning and deleting k equal characters can rescan the string many times when n ≤ 10^5. Deletion is local: only adjacent runs merge, and the two sides may meet again after a deletion. A stack keeps surviving characters and their run lengths in left-to-right order. Matching the top increments the count; reaching k pops the run, i.e. one erasure. We store (char, count) and take the count modulo k so a full run pops immediately. After one pass the stack is the final string.

We can traverse the string s, maintaining a stack that stores the characters and their occurrence counts. When traversing to character c, if the character at the top of the stack is the same as c, we increment the count of the top element by one; otherwise, we push the character c and count 1 into the stack. When the count of the top element equals k, we pop the top element from the stack.

After traversing the string s, the elements remaining in the stack form the final result. We can pop the elements from the stack one by one, concatenate them into a string, and that's our answer.

The time complexity is O(n), and the space complexity is O(n). Here, n is the length of the string s.

Python 3

```python
class Solution:
    def removeDuplicates(self, s: str, k: int) -> str:
        stk = []
        for c in s:
            if stk and stk[-1][0] == c:
                stk[-1][1] = (stk[-1][1] + 1) % k
                if stk[-1][1] == 0:
                    stk.pop()
            else:
                stk.append([c, 1])
        ans = [c * v for c, v in stk]
        return "".join(ans)
```

    return removed
```

PATTERN 8 · STACK · PROBLEM 16 OF 20

856. Score of Parentheses

Medium · Stack, String, Parentheses

leetcode.com/problems/score-of-parentheses

PROBLEM

Given a balanced parentheses string `s`, return *the **score** of the string*.

The **score** of a balanced parentheses string is based on the following rule:

- "`()`" has score `1`.
- `AB` has score `A + B`, where `A` and `B` are balanced parentheses strings.
- `(A)` has score `2 * A`, where `A` is a balanced parentheses string.

Example 1:

```
Input: s = "()"
Output: 1
```

Example 2:

```
Input: s = "(())"
Output: 2
```

Example 3:

```
Input: s = "()()"
Output: 2
```

Constraints:

- `2 <= s.length <= 50`
- `s` consists of only `'('` and `')'`.
- `s` is a balanced parentheses string.

SOLUTION (PYTHON 3)

Solution 1: Counting

> **How to think about it**
>
> The score doubles with nesting: an innermost () is 1. We need not build a tree or fully evaluate on a stack. Scan with depth d; when a () pair closes, add 1≪ d. Other closing parentheses only decrease depth.

By observing, we find that `()` is the only structure that contributes to the score, and the outer parentheses just add some multipliers to this structure. So, we only need to focus on `()`.

We use d to maintain the current depth of parentheses. For each `(`, we increase the depth by one, and for each `)`, we decrease the depth by one. When we encounter `()`, we add 2^d to the answer.

Let's take `(()(()))` as an example. We first find the two closed parentheses `()` inside, and then add the corresponding 2^d to the score. In fact, we are calculating the score of `(()) + ((()))`.

```
( ( ) ( ( ) ) )
  ^ ^   ^ ^

( ( ) ) + ( ( ( ) ) )
  ^ ^         ^ ^
```

The time complexity is O(n), and the space complexity is O(1). Here, n is the length of the string.

```

636. Exclusive Time of Functions

Medium · Stack, Array

leetcode.com/problems/exclusive-time-of-functions

PROBLEM

On a **single-threaded** CPU, we execute a program containing `n` functions. Each function has a unique ID between 0 and `n - 1`.

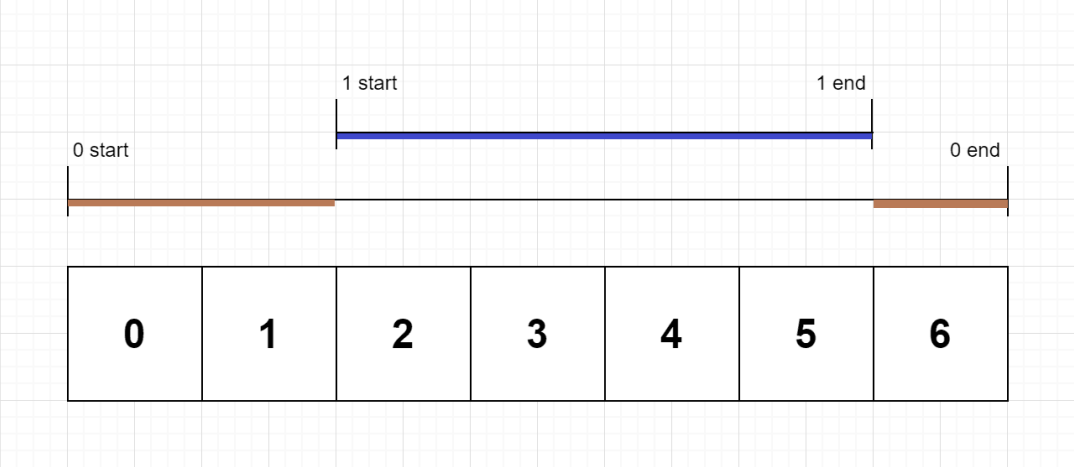
Function calls are **stored in a call stack**: when a function call starts, its ID is pushed onto the stack, and when a function call ends, its ID is popped off the stack. The function whose ID is at the top of the stack is **the current function being executed**. Each time a function starts or ends, we write a log with the ID, whether it started or ended, and the timestamp.

You are given a list `logs`, where `logs[i]` represents the i^{th} log message formatted as a string `"{function_id}:{"start" | "end"}:{timestamp}"`. For example, `"0:start:3"` means a function call with function ID 0 **started at the beginning** of timestamp 3, and `"1:end:2"` means a function call with function ID 1 **ended at the end** of timestamp 2. Note that a function can be called **multiple times, possibly recursively**.

A function's **exclusive time** is the sum of execution times for all function calls in the program. For example, if a function is called twice, one call executing for 2 time units and another call executing for 1 time unit, the **exclusive time** is `2 + 1 = 3`.

Return *the **exclusive time** of each function in an array, where the value at the* i^{th} *index represents the exclusive time for the function with ID* `i`.

Example 1:



```
Input: n = 2, logs = ["0:start:0","1:start:2","1:end:5","0:end:6"]
Output: [3,4]
Explanation:
Function 0 starts at the beginning of time 0, then it executes 2 for units of time and reaches the end of time 1.
Function 1 starts at the beginning of time 2, executes for 4 units of time, and ends at the end of time 5.
Function 0 resumes execution at the beginning of time 6 and executes for 1 unit of time.
So function 0 spends 2 + 1 = 3 units of total time executing, and function 1 spends 4 units of total time executing.
```

Example 2:

```
Input: n = 1, logs = ["0:start:0","0:start:2","0:end:5","0:start:6","0:end:6","0:end:7"]
Output: [8]
Explanation:
Function 0 starts at the beginning of time 0, executes for 2 units of time, and recursively calls
itself.
Function 0 (recursive call) starts at the beginning of time 2 and executes for 4 units of time.
Function 0 (initial call) resumes execution then immediately calls itself again.
Function 0 (2nd recursive call) starts at the beginning of time 6 and executes for 1 unit of time.
Function 0 (initial call) resumes execution at the beginning of time 7 and executes for 1 unit of time.
So function 0 spends 2 + 4 + 1 + 1 = 8 units of total time executing.
```

Example 3:

```
Input: n = 2, logs = ["0:start:0","0:start:2","0:end:5","1:start:6","1:end:6","0:end:7"]
Output: [7,1]
Explanation:
Function 0 starts at the beginning of time 0, executes for 2 units of time, and recursively calls
itself.
Function 0 (recursive call) starts at the beginning of time 2 and executes for 4 units of time.
Function 0 (initial call) resumes execution then immediately calls function 1.
Function 1 starts at the beginning of time 6, executes 1 unit of time, and ends at the end of time 6.
Function 0 resumes execution at the beginning of time 7 and executes for 1 unit of time.
So function 0 spends 2 + 4 + 1 = 7 units of total time executing, and function 1 spends 1 unit of total
time executing.
```

Constraints:

- `1 <= n <= 100`
- `2 <= logs.length <= 500`
- `0 <= function_id < n`
- `0 <= timestamp <= 10^9`
- No two start events will happen at the same timestamp.
- No two end events will happen at the same timestamp.
- Each function has an `"end"` log for each `"start"` log.

SOLUTION (PYTHON 3)

Solution 1: Stack + Simulation

> **How to think about it**
>
> Functions nest and we need exclusive time. Stepping the timeline second-by-second is impossible for large timestamps. A stack matches the nesting: on `start`, credit the top with [pre, cur); on `end`, credit [pre, cur] and set pre=cur+1. One pass over the logs.

We define a stack stk to store the identifiers of the currently executing functions. We also define an array ans to store the exclusive time of each function, initially setting the exclusive time of each function to 0. We use a variable pre to record the previous timestamp.

We traverse the log array. For each log entry, we first split it by colons to get the function identifier i, the operation type op, and the timestamp t.

If op is start, it means function i starts executing. We need to check if the stack is empty. If it is not empty, we add cur - pre to the exclusive time of the function at the top of the stack, then push i onto the stack and update pre to cur. If op is end, it means function i finishes executing. We add cur - pre + 1 to the exclusive time of the function at the top of the stack, then pop the top element from the stack and update pre to cur + 1.

Finally, we return the array ans.

The time complexity is O(n), and the space complexity is O(n). Here, n is the length of the log array.

Python 3

```python
class Solution:
    def exclusiveTime(self, n: int, logs: List[str]) -> List[int]:
        stk = []
        ans = [0] * n
        pre = 0
        for log in logs:
            i, op, t = log.split(":")
            i, cur = int(i), int(t)
            if op[0] == "s":
                if stk:
                    ans[stk[-1]] += cur - pre
                stk.append(i)
                pre = cur
            else:
                ans[stk.pop()] += cur - pre + 1
                pre = cur + 1
        return ans
```

PATTERN 8 · STACK · PROBLEM 18 OF 20

921. Minimum Add to Make Parentheses Valid

Medium · Stack, Greedy, String, Parentheses

leetcode.com/problems/minimum-add-to-make-parentheses-valid

Also appears in pattern 21 Greedy

PROBLEM

A parentheses string is valid if and only if:

- It is the empty string,
- It can be written as `AB` (`A` concatenated with `B`), where `A` and `B` are valid strings, or
- It can be written as `(A)`, where `A` is a valid string.

You are given a parentheses string `s`. In one move, you can insert a parenthesis at any position of the string.

- For example, if `s = "())))"`, you can insert an opening parenthesis to be `"(**(**))))"` or a closing parenthesis to be `"())))**)**"`.

Return *the minimum number of moves required to make* `s` *valid*.

Example 1:

```
Input: s = "())"
Output: 1
```

Example 2:

```
Input: s = "((("
Output: 3
```

Constraints:

- `1 <= s.length <= 1000`
- `s[i]` is either `'('` or `')'`.

SOLUTIONS (PYTHON 3)

Solution 1: Greedy + Stack

> **How to think about it**
>
> We must add the fewest parentheses to make the string valid. Whatever remains on a matching stack needs one counterpart each. Push a left parenthesis; a right one pops a matching left if possible, otherwise it stays. The final stack size is the answer.

This problem is a classic parenthesis matching problem, which can be solved using "Greedy + Stack".

Iterate through each character c in the string s:

- If c is a left parenthesis, directly push c into the stack;
- If c is a right parenthesis, at this point if the stack is not empty, and the top element of the stack is a left parenthesis, then pop the top element of the stack, indicating a successful match; otherwise, push c into the stack.

After the iteration ends, the number of remaining elements in the stack is the number of parentheses that need to be added.

The time complexity is O(n), and the space complexity is O(n), where n is the length of the string s.

Python 3

```python
class Solution:
    def minAddToMakeValid(self, s: str) -> int:
        stk = []
        for c in s:
            if c == ')' and stk and stk[-1] == '(':
                stk.pop()
            else:
                stk.append(c)
        return len(stk)
```

Solution 2: Greedy + Counting

> **How to think about it**
>
> The stack only needs the count of unmatched left parentheses, not the characters. cnt tracks those lefts, unmatched rights go into ans, and the leftover cnt is added at the end, using constant extra space.

Solution 1 uses a stack to implement parenthesis matching, but we can also directly implement it through counting.

Define a variable `cnt` to represent the current number of left parentheses to be matched, and a variable `ans` to record the answer. Initially, both variables are set to 0.

Iterate through each character c in the string s:

- If c is a left parenthesis, increase the value of `cnt` by 1;
- If c is a right parenthesis, at this point if cnt > 0, it means that there are left parentheses that can be matched, so decrease the value of `cnt` by 1; otherwise, it means that the current right parenthesis cannot be matched, so increase the value of `ans` by 1.

After the iteration ends, add the value of `cnt` to `ans`, which is the answer.

The time complexity is O(n), and the space complexity is O(1), where n is the length of the string s.

Python 3

```python
class Solution:
    def minAddToMakeValid(self, s: str) -> int:
        ans = cnt = 0
        for c in s:
            if c == '(':
                cnt += 1
            elif cnt:
                cnt -= 1
            else:
                ans += 1
        ans += cnt
        return ans
```

Solution 3: Replace + recursion

> **How to think about it**
>
> A matched `()` pair does not affect the answer and can be deleted. Repeatedly replace one `()`; if the length does not change, nothing remains to pair and the length is the number of additions; otherwise recurse. n≤ 1000, so the replacements are affordable.

Python 3 (written for this guide: the doocs page has no Python 3 version of this solution)

```python
class Solution:
    def minAddToMakeValid(self, s: str) -> int:
        # remove matched "()" pairs again and again; what is left is exactly the missing brackets
        while "()" in s:
            s = s.replace("()", "")
        return len(s)
```

Complexity. Time: O(n^2) in the worst case (each replace is O(n), up to n / 2 rounds). Space: O(n).

    return "".join(result)
```

PATTERN 8 · STACK · PROBLEM 19 OF 20

946. Validate Stack Sequences

Medium · Stack, Array, Simulation

leetcode.com/problems/validate-stack-sequences

PROBLEM

Given two integer arrays `pushed` and `popped` each with distinct values, return `true` *if this could have been the result of a sequence of push and pop operations on an initially empty stack, or* `false` *otherwise.*

Example 1:

```
Input: pushed = [1,2,3,4,5], popped = [4,5,3,2,1]
Output: true
Explanation: We might do the following sequence:
push(1), push(2), push(3), push(4),
pop() -> 4,
push(5),
pop() -> 5, pop() -> 3, pop() -> 2, pop() -> 1
```

Example 2:

```
Input: pushed = [1,2,3,4,5], popped = [4,3,5,1,2]
Output: false
Explanation: 1 cannot be popped before 2.
```

Constraints:

- `1 <= pushed.length <= 1000`
- `0 <= pushed[i] <= 1000`
- All the elements of `pushed` are **unique**.
- `popped.length == pushed.length`
- `popped` is a permutation of `pushed`.

SOLUTION (PYTHON 3)

Solution 1: Stack Simulation

> **How to think about it**
>
> Check whether popped is a valid pop sequence for pushed. Values are unique, so push in given order and pop whenever the top matches the next needed pop. If every pop is consumed, the sequence is legal.

We iterate through the pushed array. For the current element x being iterated, we push it into the stack stk. Then, we check if the top element of the stack is equal to the next element to be popped in the popped array. If they are equal, we pop the top element from the stack and increment the index i of the next element to be popped in the popped array. Finally, if all elements can be popped in the order specified by the popped array, return true; otherwise, return false.

The time complexity is O(n), and the space complexity is O(n). Here, n is the length of the pushed array.

Python 3

```python
class Solution:
    def validateStackSequences(self, pushed: List[int], popped: List[int]) -> bool:
        stk = []
        i = 0
        for x in pushed:
            stk.append(x)
            while stk and stk[-1] == popped[i]:
                stk.pop()
                i += 1
        return i == len(popped)
```

503. Next Greater Element II

Medium · Stack, Array, Monotonic Stack

leetcode.com/problems/next-greater-element-ii

★ **TOP 10 PROBLEM** in Monotonic Stack / Queue (Specific Variants): master this one first

PROBLEM

Given a circular integer array `nums` (i.e., the next element of `nums[nums.length - 1]` is `nums[0]`), return *the **next greater number** for every element in* `nums`.

The **next greater number** of a number `x` is the first greater number to its traversing-order next in the array, which means you could search circularly to find its next greater number. If it doesn't exist, return `-1` for this number.

Example 1:

```
Input: nums = [1,2,1]
Output: [2,-1,2]
Explanation: The first 1's next greater number is 2;
The number 2 can't find next greater number.
The second 1's next greater number needs to search circularly, which is also 2.
```

Example 2:

```
Input: nums = [1,2,3,4,3]
Output: [2,3,4,-1,4]
```

Constraints:

- `1 <= nums.length <= 10^4`
- `-10^9 <= nums[i] <= 10^9`

SOLUTION (PYTHON 3)

Solution 1: Monotonic Stack

How to think about it

A naive rightward scan for the next greater value is $O(n^2)$, tight for a circular array with $n \le 10^4$. Indices wrap after n. Walk right to left with a decreasing stack of candidates that have not yet been beaten. Two passes unroll the circle; modulo maps back to the original index. Each value enters and leaves the stack at most once.

The problem requires us to find the next greater element for each element. Therefore, we can traverse the array from back to front, which effectively turns the problem into finding the previous greater element. Additionally, since the array is circular, we can traverse the array twice.

Specifically, we start traversing the array from index n × 2 - 1, where n is the length of the array. Then, we let j = i mod n, where mod represents the modulo operation. If the stack is not empty and the top element of the stack is less than or equal to nums[j], then we continuously pop the top element of the stack until the stack is empty or the top element of the stack is greater than nums[j]. At this point, the top element of the stack is the previous greater element for nums[j], and we assign it to ans[j]. Finally, we push nums[j] onto the stack. We continue to the next element.

After the traversal is complete, we can obtain the array ans, which represents the next greater element for each element in the array nums.

The time complexity is O(n), and the space complexity is O(n), where n is the length of the array nums.

Python 3

```python
class Solution:
    def nextGreaterElements(self, nums: List[int]) -> List[int]:
        n = len(nums)
        ans = [-1] * n
        stk = []
        for i in range(n * 2 - 1, -1, -1):
            i %= n
            while stk and stk[-1] <= nums[i]:
                stk.pop()
            if stk:
                ans[i] = stk[-1]
            stk.append(nums[i])
        return ans
```

402. Remove K Digits

Medium · Stack, Greedy, String, Monotonic Stack

leetcode.com/problems/remove-k-digits

★ **TOP 10 PROBLEM** in Monotonic Stack / Queue (Specific Variants): master this one first

Also appears in pattern 21 Greedy

PROBLEM

Given string num representing a non-negative integer `num`, and an integer `k`, return *the smallest possible integer after removing* `k` *digits from* `num`.

Example 1:

```
Input: num = "1432219", k = 3
Output: "1219"
Explanation: Remove the three digits 4, 3, and 2 to form the new number 1219 which is the smallest.
```

Example 2:

```
Input: num = "10200", k = 1
Output: "200"
Explanation: Remove the leading 1 and the number is 200. Note that the output must not contain leading zeroes.
```

Example 3:

```
Input: num = "10", k = 2
Output: "0"
Explanation: Remove all the digits from the number and it is left with nothing which is 0.
```

Constraints:

- `1 <= k <= num.length <= 10^5`
- `num` consists of only digits.
- `num` does not have any leading zeros except for the zero itself.

SOLUTION (PYTHON 3)

Solution 1: Greedy Algorithm

How to think about it

After deleting k digits we want the smallest remaining number. Equal-length integers are compared from the first differing digit, so larger digits on the left should be removed first. A non-decreasing stack from left to right pops the top whenever the current digit is smaller, spending one deletion. Then keep the leftover length and strip leading zeros. The scan has to go left to right: a smaller digit can occupy a higher place only after a larger left digit is gone.

Python 3

```python
class Solution:
    def removeKdigits(self, num: str, k: int) -> str:
        stk = []
        remain = len(num) - k
        for c in num:
            while k and stk and stk[-1] > c:
                stk.pop()
                k -= 1
            stk.append(c)
        return ''.join(stk[:remain]).lstrip('0') or '0'
```

Complexity. Time: O(n). Space: O(n).

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

```
# FOLLOW-UPS (answered below, in this order):
# 1. Remove k digits to get the LARGEST possible number
# 2. Return the positions of the digits that were removed
# (smallest result)

# ============================================================
# FOLLOW-UP 1: Remove k digits to get the LARGEST possible
# number
# ============================================================

# ---- follow-up 1: function ----
# Answer: Flip the comparison: pop the top digit while it
# is smaller than the new digit and removals remain.
# Time: O(n).  Space: O(n).
def remove_k_digits_largest(num, k):
    stack = []
    for digit in num:
        while k > 0 and stack and stack[-1] < digit:
            stack.pop()
            k -= 1
        stack.append(digit)
    if k > 0:
        stack = stack[:len(stack) - k]
    return "".join(stack)

# ============================================================
# FOLLOW-UP 2: Return the positions of the digits that
# were removed (smallest result)
# ============================================================

# ---- follow-up 2: function ----
# Answer: Keep positions on the stack instead of digits;
# every popped position and every position cut from the
# end is a removed digit.
# Time: O(n).  Space: O(n).
def removed_positions(num, k):
    stack = []                                      # positions of kept digits
    removed = []
    for i in range(len(num)):
        while k > 0 and stack and num[stack[-1]] > num[i]:
            removed.append(stack.pop())
            k -= 1
        stack.append(i)
    while k > 0 and stack:
        removed.append(stack.pop())
        k -= 1
    return sorted(removed)
```

316. Remove Duplicate Letters

Medium · Stack, Greedy, String, Monotonic Stack

leetcode.com/problems/remove-duplicate-letters

PROBLEM

Given a string `s`, remove duplicate letters so that every letter appears once and only once. You must make sure your result is **the smallest in lexicographical order** among all possible results.

Example 1:

```
Input: s = "bcabc"
Output: "abc"
```

Example 2:

```
Input: s = "cbacdcbc"
Output: "acdb"
```

Constraints:

- `1 <= s.length <= 10^4`
- `s` consists of lowercase English letters.

Note: This question is the same as 1081: https://leetcode.com/problems/smallest-subsequence-of-distinct-characters/

SOLUTIONS (PYTHON 3)

Solution 1: Stack

> **How to think about it**
>
> We want the lexicographically smallest subsequence that uses each present letter once. Searching all subsequences is too large. Record each letter's last index. Scan left to right: skip a letter already on the stack; otherwise pop a larger top while it still occurs later, then push. The monotone stack keeps the prefix small; last indices guarantee a popped letter can return.

We use an array `last` to record the last occurrence of each character, a stack to save the result string, and an array `vis` or an integer variable `mask` to record whether the current character is in the stack.

Traverse the string s, for each character c, if c is not in the stack, we need to check whether the top element of the stack is greater than c. If it is greater than c and the top element of the stack will appear later, we pop the top element of the stack and push c into the stack.

Finally, concatenate the elements in the stack into a string and return it as the result.

The time complexity is O(n), and the space complexity is O(n). Where n is the length of the string s.

Python 3

```python
class Solution:
    def removeDuplicateLetters(self, s: str) -> str:
        last = {c: i for i, c in enumerate(s)}
        stk = []
        vis = set()
        for i, c in enumerate(s):
            if c in vis:
                continue
            while stk and stk[-1] > c and last[stk[-1]] > i:
                vis.remove(stk.pop())
            stk.append(c)
            vis.add(c)
        return ''.join(stk)
```

Solution 2

How to think about it

Method 1 uses last indices to test leftover occurrences. Count frequencies first and decrement while scanning; pop the top while its remaining count is positive. The test is equivalent without storing last positions.

Python 3

```python
class Solution:
    def removeDuplicateLetters(self, s: str) -> str:
        count, in_stack = [0] * 128, [False] * 128
        stack = []
        for c in s:
            count[ord(c)] += 1
        for c in s:
            count[ord(c)] -= 1
            if in_stack[ord(c)]:
                continue
            while len(stack) and stack[-1] > c:
                peek = stack[-1]
                if count[ord(peek)] < 1:
                    break
                in_stack[ord(peek)] = False
                stack.pop()
            stack.append(c)
            in_stack[ord(c)] = True
        return ''.join(stack)
```

Complexity. Time: O(n). Space: O(C), C = 128 characters.

PATTERN 9 · MONOTONIC STACK / QUEUE (SPECIFIC VARIANTS) · PROBLEM 6 OF 20

907. Sum of Subarray Minimums

Medium · Stack, Array, Dynamic Programming, Monotonic Stack

leetcode.com/problems/sum-of-subarray-minimums

★ **TOP 10 PROBLEM** in Monotonic Stack / Queue (Specific Variants): master this one first

Also appears in pattern 10 Queue / Deque, 35 Sliding Window Maximum / Minimum (Specific Variants)

PROBLEM

Given an array of integers arr, find the sum of `min(b)`, where `b` ranges over every (contiguous) subarray of `arr`. Since the answer may be large, return the answer **modulo** $10^9 + 7$.

Example 1:

```
Input: arr = [3,1,2,4]
Output: 17
Explanation:
Subarrays are [3], [1], [2], [4], [3,1], [1,2], [2,4], [3,1,2], [1,2,4], [3,1,2,4].
Minimums are 3, 1, 2, 4, 1, 1, 2, 1, 1, 1.
Sum is 17.
```

Example 2:

```
Input: arr = [11,81,94,43,3]
Output: 444
```

Constraints:

- `1 <= arr.length <= 3 * 10^4`
- `1 <= arr[i] <= 3 * 10^4`

SOLUTION (PYTHON 3)

Solution 1: Monotonic Stack

How to think about it

Summing the minimum of every subarray is quadratic if we enumerate intervals. Switch to contribution: multiply arr[i] by how often it is the minimum. Monotonic stacks find the previous strictly smaller value on the left and the next smaller-or-equal on the right, so equal values are credited once. The product of the two spans is the number of subarrays.

The problem asks for the sum of the minimum values of each subarray, which is equivalent to finding the number of subarrays for which each element arr[i] is the minimum, then multiplying by arr[i], and finally summing these up.

Therefore, the focus of the problem is to find the number of subarrays for which arr[i] is the minimum. For arr[i], we find the first position left[i] to its left that is less than arr[i], and the first position right[i] to its right that is less than or equal to arr[i]. The number of subarrays for which arr[i] is the minimum is (i - left[i]) × (right[i] - i).

Note, why do we find the first position right[i] to the right that is less than or equal to arr[i], rather than less than arr[i]? This is because if we find the first position right[i] to the right that is less than arr[i], it will lead to duplicate calculations.

Let's take an example to illustrate. For the following array:

The element at index 3 is 2, the first element to its left that is less than 2 is at index 0. If we find the first element to its right that is less than 2, we get index 7. That is, the subarray interval is (0, 7). Note that this is an open interval.

```
0 4 3 2 5 3 2 1
*     ^       *
```

In the same way, we can find the subarray interval for the element at index 6, and find that its subarray interval is also (0, 7). That is, the subarray intervals for the elements at index 3 and index 6 are the same. This leads to duplicate calculations.

```
0 4 3 2 5 3 2 1
*           ^ *
```

If we find the first element to its right that is less than or equal to its value, there will be no duplication, because the subarray interval for the element at index 3 becomes (0, 6), and the subarray interval for the element at index 6 is (0, 7), which are not the same.

Back to this problem, we just need to traverse the array, for each element arr[i], use a monotonic stack to find the first position left[i] to its left that is less than arr[i], and the first position right[i] to its right that is less than or equal to arr[i]. The number of subarrays for which arr[i] is the minimum is (i - left[i]) × (right[i] - i), then multiply by arr[i], and finally sum these up.

Be aware of data overflow and modulo operations.

The time complexity is O(n), and the space complexity is O(n), where n is the length of the array arr.

Python 3

```python
class Solution:
    def sumSubarrayMins(self, arr: List[int]) -> int:
        n = len(arr)
        left = [-1] * n
        right = [n] * n
        stk = []
        for i, v in enumerate(arr):
            while stk and arr[stk[-1]] >= v:
                stk.pop()
            if stk:
                left[i] = stk[-1]
            stk.append(i)

        stk = []
        for i in range(n - 1, -1, -1):
            while stk and arr[stk[-1]] > arr[i]:
                stk.pop()
            if stk:
                right[i] = stk[-1]
            stk.append(i)
        mod = 10**9 + 7
        return sum((i - left[i]) * (right[i] - i) * v for i, v in enumerate(arr)) % mod
```

901. Online Stock Span

Medium · Stack, Design, Data Stream, Monotonic Stack

leetcode.com/problems/online-stock-span

★ **TOP 10 PROBLEM** in Monotonic Stack / Queue (Specific Variants): master this one first

Also appears in pattern 29 Design Problems

PROBLEM

Design an algorithm that collects daily price quotes for some stock and returns **the span** of that stock's price for the current day.

The **span** of the stock's price in one day is the maximum number of consecutive days (starting from that day and going backward) for which the stock price was less than or equal to the price of that day.

- For example, if the prices of the stock in the last four days are `[7,2,1,2]` and the price of the stock today is 2, then the span of today is 4 because starting from today, the price of the stock was less than or equal to 2 for 4 consecutive days.
- Also, if the prices of the stock in the last four days is `[7,34,1,2]` and the price of the stock today is `8`, then the span of today is `3` because starting from today, the price of the stock was less than or equal `8` for `3` consecutive days.

Implement the `StockSpanner` class:

- `StockSpanner()` Initializes the object of the class.
- `int next(int price)` Returns the **span** of the stock's price given that today's price is `price`.

Example 1:

```
Input
["StockSpanner", "next", "next", "next", "next", "next", "next", "next"]
[[], [100], [80], [60], [70], [60], [75], [85]]
Output
[null, 1, 1, 1, 2, 1, 4, 6]

Explanation
StockSpanner stockSpanner = new StockSpanner();
stockSpanner.next(100); // return 1
stockSpanner.next(80); // return 1
stockSpanner.next(60); // return 1
stockSpanner.next(70); // return 2
stockSpanner.next(60); // return 1
stockSpanner.next(75); // return 4, because the last 4 prices (including today's price of 75) were
less than or equal to today's price.
stockSpanner.next(85); // return 6
```

Constraints:

- $1 <= price <= 10^5$
- At most 10^4 calls will be made to `next`.

SOLUTION (PYTHON 3)

Solution 1: Monotonic Stack

> **How to think about it**
>
> Scanning backward from today until a strictly higher price appears is quadratic over many queries. Spans already covered by an earlier price need not be recounted: if the stack top is at most today's price, its span can be merged in. A stack that is decreasing in price, storing (price, cnt), pops and accumulates those spans before pushing. Each price enters and leaves once, so each query is amortized constant time.

Based on the problem description, we know that for the current day's price price, we start from this price and look backwards to find the first price that is larger than this price. The difference in indices cnt between these two prices is the span of the current day's price.

This is actually a classic monotonic stack model, where we find the first element larger than the current element on the left.

We maintain a stack where the prices from the bottom to the top of the stack are monotonically decreasing. Each element in the stack is a (price, cnt) data pair, where price represents the price, and cnt represents the span of the current price.

When the price price appears, we compare it with the top element of the stack. If the price of the top element of the stack is less than or equal to price, we add the span cnt of the current day's price to the span of the top element of the stack, and then pop the top element of the stack. This continues until the price of the top element of the stack is greater than price, or the stack is empty.

Finally, we push (price, cnt) onto the stack and return cnt.

The time complexity is O(n), and the space complexity is O(n). Here, n is the number of times `next(price)` is called.

Python 3

```python
class StockSpanner:
    def __init__(self):
        self.stk = []

    def next(self, price: int) -> int:
        cnt = 1
        while self.stk and self.stk[-1][0] <= price:
            cnt += self.stk.pop()[1]
        self.stk.append((price, cnt))
        return cnt

# Your StockSpanner object will be instantiated and called as such:
# obj = StockSpanner()
# param_1 = obj.next(price)
```

leetcode.com/problems/132-pattern

PROBLEM

Given an array of `n` integers `nums`, a **132 pattern** is a subsequence of three integers `nums[i]`, `nums[j]` and `nums[k]` such that `i < j < k` and `nums[i] < nums[k] < nums[j]`.

Return `true` *if there is a* ***132 pattern*** *in* `nums`*, otherwise, return* `false`*.*

Example 1:

```
Input: nums = [1,2,3,4]
Output: false
Explanation: There is no 132 pattern in the sequence.
```

Example 2:

```
Input: nums = [3,1,4,2]
Output: true
Explanation: There is a 132 pattern in the sequence: [1, 4, 2].
```

Example 3:

```
Input: nums = [-1,3,2,0]
Output: true
Explanation: There are three 132 patterns in the sequence: [-1, 3, 2], [-1, 3, 0] and [-1, 2, 0].
```

Constraints:

- `n == nums.length`
- `1 <= n <= 2 * 10^5`
- `-10^9 <= nums[i] <= 10^9`

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

We need i<j<k with nums[i]<nums[k]<nums[j]. Triple loops are O(n^3); fixing j and scanning both sides is still O(n^2). Walk right to left with a decreasing stack. vk is the largest value popped (a candidate nums[k] below the current peak). If the current value is less than vk, it can be nums[i]. The stack holds candidate peaks nums[j]. Update vk before pushing so k stays to the right of j.

Python 3

```python
class Solution:
    def find132pattern(self, nums: List[int]) -> bool:
        vk = -inf
        stk = []
        for x in nums[::-1]:
            if x < vk:
                return True
            while stk and stk[-1] < x:
                vk = stk.pop()
            stk.append(x)
        return False
```

Solution 2

How to think about it

Solution 1 is linear but tied to a right-to-left stack. We can also store the prefix minimum and, from the right, ask a Fenwick tree whether a value in (left[i],nums[i]) has been seen. After discretization the tree counts values already scanned on the right. A logarithmic factor appears; the structure is an interval counter rather than a monotone stack.

Python 3

```python
class BinaryIndexedTree:
    def __init__(self, n):
        self.n = n
        self.c = [0] * (n + 1)

    def update(self, x, delta):
        while x <= self.n:
            self.c[x] += delta
            x += x & -x

    def query(self, x):
        s = 0
        while x:
            s += self.c[x]
            x -= x & -x
        return s

class Solution:
    def find132pattern(self, nums: List[int]) -> bool:
        s = sorted(set(nums))
        n = len(nums)
        left = [inf] * (n + 1)
        for i, x in enumerate(nums):
            left[i + 1] = min(left[i], x)
        tree = BinaryIndexedTree(len(s))
        for i in range(n - 1, -1, -1):
            x = bisect_left(s, nums[i]) + 1
            y = bisect_left(s, left[i]) + 1
            if x > y and tree.query(x - 1) > tree.query(y):
                return True
            tree.update(x, 1)
        return False
```

Complexity. Time: O(n log n). Space: O(n).

```

853. Car Fleet

Medium · Stack, Array, Sorting, Monotonic Stack

leetcode.com/problems/car-fleet

PROBLEM

There are `n` cars at given miles away from the starting mile 0, traveling to reach the mile `target`.

You are given two integer arrays `position` and `speed`, both of length `n`, where `position[i]` is the starting mile of the i^{th} car and `speed[i]` is the speed of the i^{th} car in miles per hour.

A car cannot pass another car, but it can catch up and then travel next to it at the speed of the slower car.

A **car fleet** is a single car or a group of cars driving next to each other. The speed of the car fleet is the **minimum** speed of any car in the fleet.

If a car catches up to a car fleet at the mile `target`, it will still be considered as part of the car fleet.

Return the number of car fleets that will arrive at the destination.

Example 1:

Input: target = 12, position = [10,8,0,5,3], speed = [2,4,1,1,3]

Output: 3

Explanation:

- The cars starting at 10 (speed 2) and 8 (speed 4) become a fleet, meeting each other at 12. The fleet forms at `target`.
- The car starting at 0 (speed 1) does not catch up to any other car, so it is a fleet by itself.
- The cars starting at 5 (speed 1) and 3 (speed 3) become a fleet, meeting each other at 6. The fleet moves at speed 1 until it reaches `target`.

Example 2:

Input: target = 10, position = [3], speed = [3]

Output: 1

Explanation:

There is only one car, hence there is only one fleet.

Example 3:

Input: target = 100, position = [0,2,4], speed = [4,2,1]

Output: 1

Explanation:

- The cars starting at 0 (speed 4) and 2 (speed 2) become a fleet, meeting each other at 4. The car starting at 4 (speed 1) travels to 5.
- Then, the fleet at 4 (speed 2) and the car at position 5 (speed 1) become one fleet, meeting each other at 6. The fleet moves at speed 1 until it reaches `target`.

Constraints:

- `n == position.length == speed.length`
- `1 <= n <= 10^5`
- `0 < target <= 10^6`
- `0 <= position[i] < target`
- All the values of `position` are **unique**.
- `0 < speed[i] <= 10^6`

SOLUTION (PYTHON 3)

Solution 1

How to think about it

A car closer to the target cannot be passed; a faster car behind catches up and joins the same fleet. n≤ 10^5, so simulating overtakes is slow. Sort by position from the target backward and look at arrival times. A car slower than the fleet ahead starts a new fleet; otherwise it merges. The number of such leaders is the answer.

Python 3

```
class Solution:
    def carFleet(self, target: int, position: List[int], speed: List[int]) -> int:
        idx = sorted(range(len(position)), key=lambda i: position[i])
        ans = pre = 0
        for i in idx[::-1]:
            t = (target - position[i]) / speed[i]
            if t > pre:
                ans += 1
                pre = t
        return ans
```

Complexity. Time: O(n log n). Space: O(n).

        if time > slowest_time:
            slowest_time = time
    return slowest_time
```

1019. Next Greater Node In Linked List

Medium · Stack, Array, Linked List, Monotonic Stack

leetcode.com/problems/next-greater-node-in-linked-list

Also appears in pattern 24 Fast & Slow Pointers (Linked List)

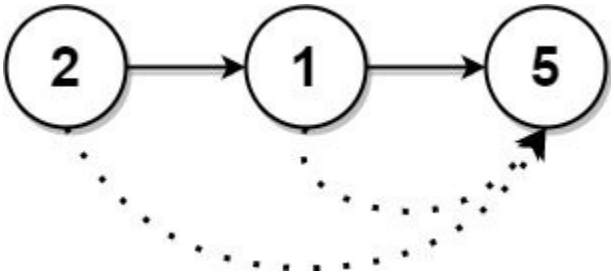
PROBLEM

You are given the `head` of a linked list with `n` nodes.

For each node in the list, find the value of the **next greater node**. That is, for each node, find the value of the first node that is next to it and has a **strictly larger** value than it.

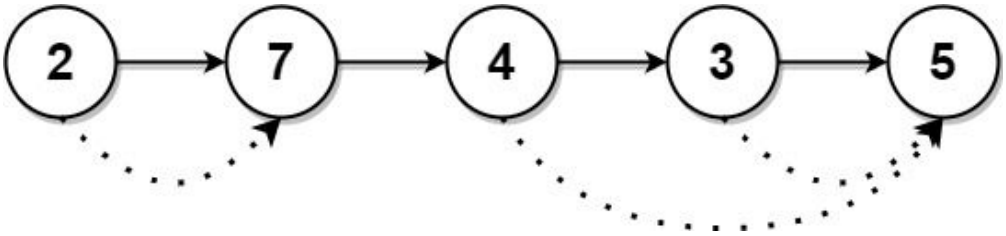
Return an integer array `answer` where `answer[i]` is the value of the next greater node of the i^{th} node (**1-indexed**). If the i^{th} node does not have a next greater node, set `answer[i] = 0`.

Example 1:



```
Input: head = [2,1,5]
Output: [5,5,0]
```

Example 2:



```
Input: head = [2,7,4,3,5]
Output: [7,0,5,5,0]
```

Constraints:

- The number of nodes in the list is `n`.
- `1 <= n <= 10^4`
- `1 <= Node.val <= 10^9`

SOLUTION (PYTHON 3)

Solution 1: Monotonic Stack

How to think about it

Scanning rightward from every node is $O(n^2)$ and tight at $n \le 10^4$. The query is the next greater element on the right, the same as the array problem. A decreasing stack from right to left holds candidates. The current value pops every top that is not strictly larger; the new top, if any, is the next greater value. We flatten the list into an array and fill the answer in one reverse pass.

The problem requires finding the next larger node for each node in the linked list, that is, finding the first node to the right of each node in the linked list that is larger than it. We first traverse the linked list and store the values in the linked list in an array nums. For each element in the array nums, we just need to find the first element to its right that is larger than it. The problem of finding the next larger element can be solved using a monotonic stack.

We traverse the array nums from back to front, maintaining a stack stk that is monotonically decreasing from the bottom to the top. During the traversal, if the top element of the stack is less than or equal to the current element, we loop to pop the top element of the stack until the top element of the stack is larger than the current element or the stack is empty.

If the stack is empty at this time, it means that the current element does not have a next larger element, otherwise, the next larger element of the current element is the top element of the stack, and we update the answer array ans. Then we push the current element into the stack and continue the traversal.

After the traversal is over, we return the answer array ans.

The time complexity is O(n), and the space complexity is O(n). Where n is the length of the linked list.

Python 3

```python
# Definition for singly-linked list.
# class ListNode:
#     def __init__(self, val=0, next=None):
#         self.val = val
#         self.next = next
class Solution:
    def nextLargerNodes(self, head: Optional[ListNode]) -> List[int]:
        nums = []
        while head:
            nums.append(head.val)
            head = head.next
        stk = []
        n = len(nums)
        ans = [0] * n
        for i in range(n - 1, -1, -1):
            while stk and stk[-1] <= nums[i]:
                stk.pop()
            if stk:
                ans[i] = stk[-1]
            stk.append(nums[i])
        return ans
```

        node = node.next
    for value, pending in waiting:
        pending.val = 0
```

```
    return head
```

1673. Find the Most Competitive Subsequence

Medium · Stack, Greedy, Array, Monotonic Stack

leetcode.com/problems/find-the-most-competitive-subsequence

Also appears in pattern 39 Game Theory / Minimax

PROBLEM

Given an integer array `nums` and a positive integer `k`, return *the most **competitive** subsequence of* `nums` *of size* `k`.

An array's subsequence is a resulting sequence obtained by erasing some (possibly zero) elements from the array.

We define that a subsequence `a` is more **competitive** than a subsequence `b` (of the same length) if in the first position where `a` and `b` differ, subsequence `a` has a number **less** than the corresponding number in `b`. For example, `[1,3,4]` is more competitive than `[1,3,5]` because the first position they differ is at the final number, and `4` is less than `5`.

Example 1:

```
Input: nums = [3,5,2,6], k = 2
Output: [2,6]
Explanation: Among the set of every possible subsequence: {[3,5], [3,2], [3,6], [5,2], [5,6], [2,6]},
[2,6] is the most competitive.
```

Example 2:

```
Input: nums = [2,4,3,3,5,4,9,6], k = 4
Output: [2,3,3,4]
```

Constraints:

- `1 <= nums.length <= 10^5`
- `0 <= nums[i] <= 10^9`
- `1 <= k <= nums.length`

SOLUTION (PYTHON 3)

Solution 1: Stack

> **How to think about it**
>
> The most competitive subsequence of length k is the lexicographically smallest subsequence of that length. n is 10^5, so a monotone stack pops a larger top while enough elements remain to fill k. Push the current value when the stack is shorter than k; the stack is the answer.

We traverse the array `nums` from left to right, maintaining a stack `stk`. During the traversal, if the current element `nums[i]` is less than the top element of the stack, and the number of elements in the stack plus n-i is greater than k, then we pop the top element of the stack until the above condition is no longer satisfied. At this point, if the number of elements in the stack is less than k, then we push the current element into the stack.

After the traversal, the elements in the stack are the answer.

The time complexity is O(n), and the space complexity is O(k). Where n is the length of the array `nums`.

Python 3

```python
class Solution:
    def mostCompetitive(self, nums: List[int], k: int) -> List[int]:
        stk = []
        n = len(nums)
        for i, v in enumerate(nums):
            while stk and stk[-1] > v and len(stk) + n - i > k:
                stk.pop()
            if len(stk) < k:
                stk.append(v)
        return stk
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

Built on the solutions above: helper functions, then the function for each follow-up. No tests and no restating of the question.

```python
# FOLLOW-UPS (answered below, in this order):

    return stack
```

962. Maximum Width Ramp

Medium · Stack, Array, Two Pointers, Monotonic Stack

leetcode.com/problems/maximum-width-ramp

PROBLEM

A **ramp** in an integer array `nums` is a pair `(i, j)` for which `i < j` and `nums[i] <= nums[j]`. The **width** of such a ramp is `j - i`.

Given an integer array `nums`, return *the maximum width of a **ramp** in* `nums`. If there is no **ramp** in `nums`, return `0`.

Example 1:

```
Input: nums = [6,0,8,2,1,5]
Output: 4
Explanation: The maximum width ramp is achieved at (i, j) = (1, 5): nums[1] = 0 and nums[5] = 5.
```

Example 2:

```
Input: nums = [9,8,1,0,1,9,4,0,4,1]
Output: 7
Explanation: The maximum width ramp is achieved at (i, j) = (2, 9): nums[2] = 1 and nums[9] = 1.
```

Constraints:

- `2 <= nums.length <= 5 * 10^4`
- `0 <= nums[i] <= 5 * 10^4`

SOLUTION (PYTHON 3)

Solution 1: Monotonic Stack

> **How to think about it**
>
> Find the widest i<j with nums[i]≤ nums[j]. All pairs are quadratic. Useful left ends form a strictly decreasing sequence from the start; a later larger value is never a better left. A monotonic stack stores those candidates, then j walks from the right and pops every stack top that forms a ramp, keeping the maximum width.

According to the problem, we can find that the subsequence formed by all possible nums[i] must be monotonically decreasing. Why is that? Let's prove it by contradiction.

Suppose there exist $i_1<i_2$ and $nums[i_1]\le nums[i_2]$, then actually $nums[i_2]$ cannot be a candidate value, because $nums[i_1]$ is more to the left and would be a better value. Therefore, the subsequence formed by nums[i] must be monotonically decreasing, and i must start from 0.

We use a monotonically decreasing stack stk (from bottom to top) to store all possible nums[i]. Then we traverse j starting from the right boundary. If we encounter $nums[stk.top()]\le nums[j]$, it means a ramp is formed at this point. We cyclically pop the top elements from the stack and update ans.

The time complexity is O(n) and the space complexity is O(n), where n represents the length of nums.

Python 3

```python
class Solution:
    def maxWidthRamp(self, nums: List[int]) -> int:
        stk = []
        for i, v in enumerate(nums):
            if not stk or nums[stk[-1]] > v:
                stk.append(i)
        ans = 0
        for i in range(len(nums) - 1, -1, -1):
            while stk and nums[stk[-1]] <= nums[i]:
                ans = max(ans, i - stk.pop())
            if not stk:
                break
        return ans
```

    return best
```

2104. Sum of Subarray Ranges

Medium · Stack, Array, Monotonic Stack

leetcode.com/problems/sum-of-subarray-ranges

Also appears in pattern 35 Sliding Window Maximum / Minimum (Specific Variants)

PROBLEM

You are given an integer array `nums`. The **range** of a subarray of `nums` is the difference between the largest and smallest element in the subarray.

Return *the **sum of all** subarray ranges of* `nums`.

A subarray is a contiguous **non-empty** sequence of elements within an array.

Example 1:

```
Input: nums = [1,2,3]
Output: 4
Explanation: The 6 subarrays of nums are the following:
[1], range = largest - smallest = 1 - 1 = 0
[2], range = 2 - 2 = 0
[3], range = 3 - 3 = 0
[1,2], range = 2 - 1 = 1
[2,3], range = 3 - 2 = 1
[1,2,3], range = 3 - 1 = 2
So the sum of all ranges is 0 + 0 + 0 + 1 + 1 + 2 = 4.
```

Example 2:

```
Input: nums = [1,3,3]
Output: 4
Explanation: The 6 subarrays of nums are the following:
[1], range = largest - smallest = 1 - 1 = 0
[3], range = 3 - 3 = 0
[3], range = 3 - 3 = 0
[1,3], range = 3 - 1 = 2
[3,3], range = 3 - 3 = 0
[1,3,3], range = 3 - 1 = 2
So the sum of all ranges is 0 + 0 + 0 + 2 + 0 + 2 = 4.
```

Example 3:

```
Input: nums = [4,-2,-3,4,1]
Output: 59
Explanation: The sum of all subarray ranges of nums is 59.
```

Constraints:

- `1 <= nums.length <= 1000`
- -10^9 `<= nums[i] <=` 10^9

Follow-up: Could you find a solution with `O(n)` time complexity?

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

The sum of ranges is the sum of max-min over every subarray. With n≤ 1000, enumerating endpoints while maintaining the current max and min is $O(n^2)$ and acceptable. The inner scan need not restart: after fixing left index i, extending j only updates mi and mx and adds their difference. A double loop therefore accumulates every range.

Python 3

```python
class Solution:
    def subArrayRanges(self, nums: List[int]) -> int:
        ans, n = 0, len(nums)
        for i in range(n - 1):
            mi = mx = nums[i]
            for j in range(i + 1, n):
                mi = min(mi, nums[j])
                mx = max(mx, nums[j])
                ans += mx - mi
        return ans
```

Solution 2

How to think about it

Solution 1 becomes heavy for larger n. Each value's contribution as a subarray maximum (or minimum) is its value times the number of subarrays where it attains that extremum, so the range sum is "max contributions minus min contributions". A monotonic stack finds, for each index, the previous greater-or-equal and the next strictly greater positions, counting those subarrays in linear time. Negating the array and repeating yields the minimum side. We therefore implement f and return f(nums)+f([-v]).

Python 3

```python
class Solution:
    def subArrayRanges(self, nums: List[int]) -> int:
        def f(nums):
            stk = []
            n = len(nums)
            left = [-1] * n
            right = [n] * n
            for i, v in enumerate(nums):
                while stk and nums[stk[-1]] <= v:
                    stk.pop()
                if stk:
                    left[i] = stk[-1]
                stk.append(i)
            stk = []
            for i in range(n - 1, -1, -1):
                while stk and nums[stk[-1]] < nums[i]:
                    stk.pop()
                if stk:
                    right[i] = stk[-1]
                stk.append(i)
            return sum((i - left[i]) * (right[i] - i) * v for i, v in enumerate(nums))

        mx = f(nums)
        mi = f([-v for v in nums])
        return mx + mi
```

Complexity. Time: O(n). Space: O(n).

```

2289. Steps to Make Array Non-decreasing

Medium · Stack, Array, Linked List, Dynamic Programming, Monotonic Stack, Simulation

leetcode.com/problems/steps-to-make-array-non-decreasing

PROBLEM

You are given a **0-indexed** integer array `nums`. In one step, **remove** all elements `nums[i]` where `nums[i - 1] > nums[i]` for all `0 < i < nums.length`.

Return *the number of steps performed until* `nums` *becomes a* ***non-decreasing*** *array*.

Example 1:

```
Input: nums = [5,3,4,4,7,3,6,11,8,5,11]
Output: 3
Explanation: The following are the steps performed:
- Step 1: [5,3,4,4,7,3,6,11,8,5,11] becomes [5,4,4,7,6,11,11]
- Step 2: [5,4,4,7,6,11,11] becomes [5,4,7,11,11]
- Step 3: [5,4,7,11,11] becomes [5,7,11,11]
[5,7,11,11] is a non-decreasing array. Therefore, we return 3.
```

Example 2:

```
Input: nums = [4,5,7,7,13]
Output: 0
Explanation: nums is already a non-decreasing array. Therefore, we return 0.
```

Constraints:

- `1 <= nums.length <= 10^5`
- `1 <= nums[i] <= 10^9`

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Each round deletes every element that is strictly smaller than its left neighbor; we want the number of rounds. n ≤ 10^5 forbids simulating rounds. The deletion time of an index is determined by how long a decreasing suffix to its right takes to be absorbed by a larger left value. A stack from the right holds indices not yet eaten. Popping updates dp[i] = max(dp[i]+1, dp[top]). The answer is max(dp).

Python 3

```python
class Solution:
    def totalSteps(self, nums: List[int]) -> int:
        stk = []
        ans, n = 0, len(nums)
        dp = [0] * n
        for i in range(n - 1, -1, -1):
            while stk and nums[i] > nums[stk[-1]]:
                dp[i] = max(dp[i] + 1, dp[stk.pop()])
            stk.append(i)
        return max(dp)
```

Complexity. Time: O(n). Space: O(n).

            steps += 1
        else:
            steps = 0
        stack.append((x, steps))
        if steps > answer:
            answer = steps
    return answer
```

84. Largest Rectangle in Histogram

Hard · Stack, Array, Monotonic Stack, Range Query

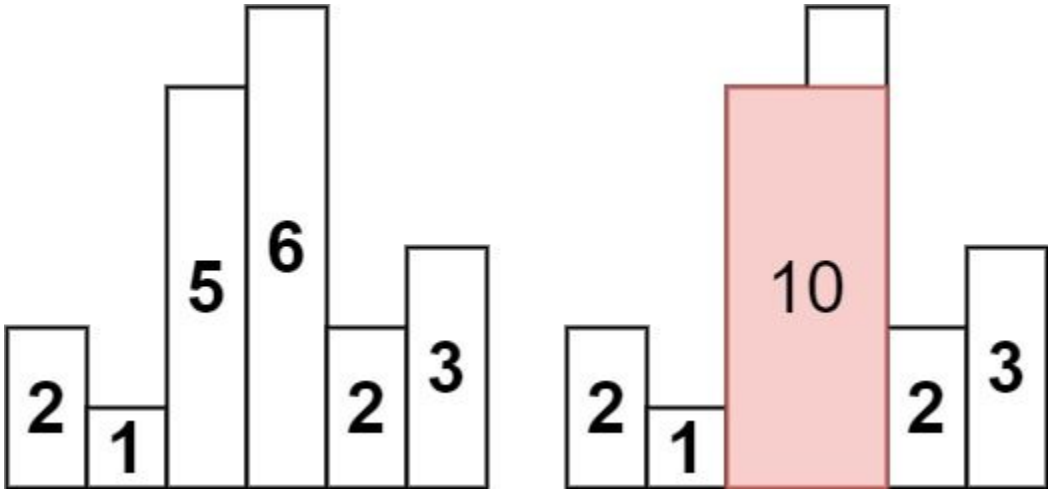
leetcode.com/problems/largest-rectangle-in-histogram

★ **TOP 10 PROBLEM** in Monotonic Stack / Queue (Specific Variants): master this one first

PROBLEM

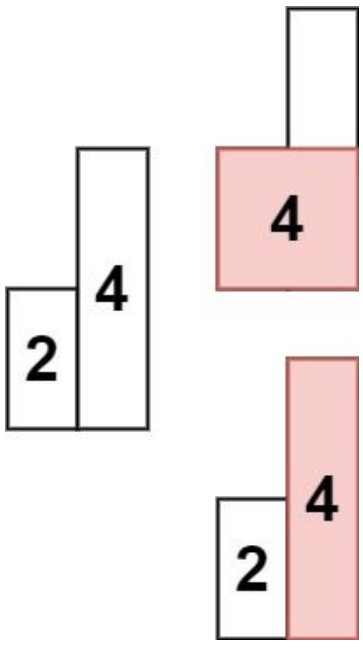
Given an array of integers `heights` representing the histogram's bar height where the width of each bar is `1`, return *the area of the largest rectangle in the histogram*.

Example 1:



```
Input: heights = [2,1,5,6,2,3]
Output: 10
Explanation: The above is a histogram where width of each bar is 1.
The largest rectangle is shown in the red area, which has an area = 10 units.
```

Example 2:



```
Input: heights = [2,4]
Output: 4
```

Constraints:

- `1 <= heights.length <= 10^5`
- `0 <= heights[i] <= 10^4`

SOLUTION (PYTHON 3)

Solution 1: Monotonic Stack

How to think about it

The first idea is enumerate every interval [l, r], take the min height, area (r - l + 1) × min. Correct, but $O(n^2)$. $n \le 10^5$ will time out. The bottleneck is recomputing the min over every range. Flip the enumeration: let bar i be the shortest bar of the rectangle; the width is the span to the nearest strictly shorter bars on both sides. “Nearest smaller on left/right” is the monotonic-stack model. Indices in the stack have increasing heights; a shorter bar pops others and becomes their right bound, while the new top is the left bound. Each bar enters and leaves once, so one linear pass.

We can enumerate the height h of each bar as the height of the rectangle. Using a monotonic stack, we find the index $left_i$, $right_i$ of the first bar with a height less than h to the left and right. The area of the rectangle at this time is h × ($right_i$-$left_i$-1). We can find the maximum value.

The time complexity is O(n), and the space complexity is O(n). Here, n represents the length of heights.

Common model of monotonic stack: Find the **nearest** number to the left/right of each number that is **larger/smaller** than it. Template:

```
stk = []
for i in range(n):
    while stk and check(stk[-1], i):
        stk.pop()
    stk.append(i)
```

Python 3

```
class Solution:
    def largestRectangleArea(self, heights: List[int]) -> int:
        n = len(heights)
        stk = []
        left = [-1] * n
        right = [n] * n
        for i, h in enumerate(heights):
            while stk and heights[stk[-1]] >= h:
                right[stk[-1]] = i
                stk.pop()
            if stk:
                left[i] = stk[-1]
            stk.append(i)
        return max(h * (right[i] - left[i] - 1) for i, h in enumerate(heights))
```

            if side > best:
                best = side
        stack.append(i)
    return best * best
```

85. Maximal Rectangle

Hard · Stack, Array, Dynamic Programming, Matrix, Monotonic Stack

leetcode.com/problems/maximal-rectangle

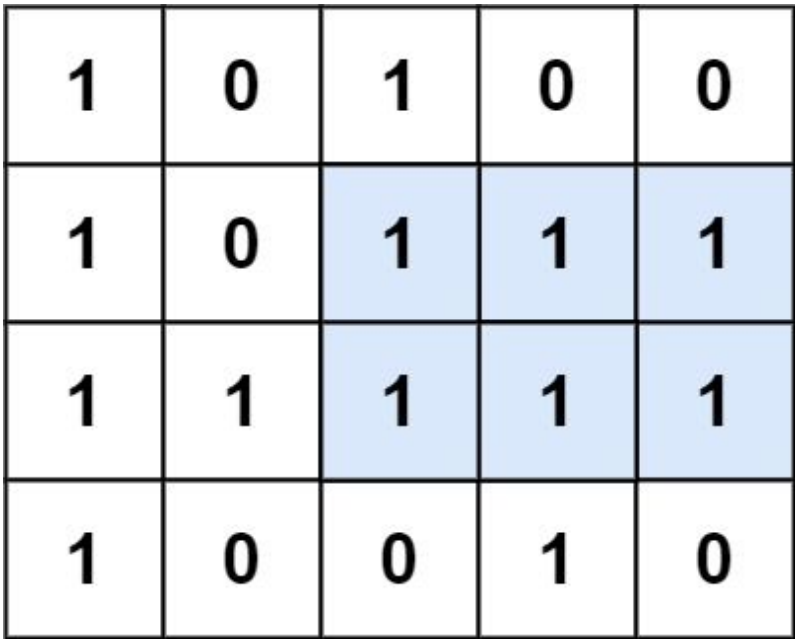
★ **TOP 10 PROBLEM** in Monotonic Stack / Queue (Specific Variants): master this one first

Also appears in pattern 22 Dynamic Programming - 2D / Grid

PROBLEM

Given a `rows x cols` binary `matrix` filled with `0`'s and `1`'s, find the largest rectangle containing only `1`'s and return *its area*.

Example 1:



```
Input: matrix =
[["1","0","1","0","0"],["1","0","1","1","1"],["1","1","1","1","1"],["1","0","0","1","0"]]
Output: 6
Explanation: The maximal rectangle is shown in the above picture.
```

Example 2:

```
Input: matrix = [["0"]]
Output: 0
```

Example 3:

```
Input: matrix = [["1"]]
Output: 1
```

Constraints:

- `rows == matrix.length`
- `cols == matrix[i].length`
- `1 <= rows, cols <= 200`
- `matrix[i][j]` is `'0'` or `'1'`.

SOLUTION (PYTHON 3)

Solution 1: Monotonic Stack

> **How to think about it**
>
> The first idea is pick two cells as opposite corners and test whether the rectangle is all 1s. Correct, but $O(m^2 n^2)$. m, n ≤ 200 will time out. The bottleneck is rechecking 2D ranges. Observation: the count of consecutive 1s upward from row i, column j is exactly a histogram bar. Each row becomes “largest rectangle in histogram.” That is problem 84. Maintain heights[j] per row: increment on 1, reset on 0, then run the monotonic stack. Total time O(mn).

We can treat each row as the base of a histogram and calculate the maximum area of the histogram for each row.

Specifically, we maintain an array heights with the same length as the number of columns in the matrix, where heights[j] represents the height of the column at the j-th position with the current row as the base. For each row, we iterate through each column:

- If the current element is '1', increment heights[j] by 1.
- If the current element is '0', set heights[j] to 0.

Then, we use the monotonic stack algorithm to calculate the maximum rectangle area of the current histogram and update the answer.

The specific steps of the monotonic stack are as follows:

1. Initialize an empty stack stk to store the indices of the columns.
2. Initialize two arrays left and right, representing the index of the first column to the left and right of each column that is shorter than the current column.
3. Iterate through the heights array heights, first calculating the index of the first column to the left of each column that is shorter than the current column, and store it in left.
4. Then iterate through the heights array heights in reverse order, calculating the index of the first column to the right of each column that is shorter than the current column, and store it in right.
5. Finally, calculate the maximum rectangle area for each column and update the answer.

The time complexity is O(m × n), where m is the number of rows in matrix and n is the number of columns in matrix.

Python 3

```python
class Solution:
    def maximalRectangle(self, matrix: List[List[str]]) -> int:
        heights = [0] * len(matrix[0])
        ans = 0
        for row in matrix:
            for j, v in enumerate(row):
                if v == "1":
                    heights[j] += 1
                else:
                    heights[j] = 0
            ans = max(ans, self.largestRectangleArea(heights))
        return ans

    def largestRectangleArea(self, heights: List[int]) -> int:
        n = len(heights)
        stk = []
        left = [-1] * n
        right = [n] * n
        for i, h in enumerate(heights):
            while stk and heights[stk[-1]] >= h:
                stk.pop()
            if stk:
                left[i] = stk[-1]
            stk.append(i)
        stk = []
        for i in range(n - 1, -1, -1):
            h = heights[i]
            while stk and heights[stk[-1]] >= h:
                stk.pop()
            if stk:
                right[i] = stk[-1]
            stk.append(i)

            stack.append(i)
    return best[1]
```

862. Shortest Subarray with Sum at Least K

Hard · Queue, Array, Binary Search, Prefix Sum, Sliding Window, Monotonic Queue, Heap (Priority Queue)

leetcode.com/problems/shortest-subarray-with-sum-at-least-k

★ **TOP 10 PROBLEM** in Monotonic Stack / Queue (Specific Variants), Queue / Deque, Sliding Window Maximum / Minimum (Specific Variants): master this one first

Also appears in pattern 10 Queue / Deque, 35 Sliding Window Maximum / Minimum (Specific Variants)

PROBLEM

Given an integer array `nums` and an integer `k`, return *the length of the shortest non-empty* ***subarray*** *of* `nums` *with a sum of at least* `k`. If there is no such **subarray**, return `-1`.

A **subarray** is a **contiguous** part of an array.

Example 1:

```
Input: nums = [1], k = 1
Output: 1
```

Example 2:

```
Input: nums = [1,2], k = 4
Output: -1
```

Example 3:

```
Input: nums = [2,-1,2], k = 3
Output: 3
```

Constraints:

- `1 <= nums.length <= 10^5`
- `-10^5 <= nums[i] <= 10^5`
- `1 <= k <= 10^9`

SOLUTION (PYTHON 3)

Solution 1

How to think about it

The shortest subarray whose sum is at least k. Negatives break a sliding window, and n≤ 10^5 forbids quadratic enumeration. On prefix sums we want the smallest j-i with s[j]-s[i]≥ k. Keep a monotone increasing deque of indices: pop the front when it already yields ≥ k, and drop a tail that is at least the current prefix, because a later, smaller prefix is a better start.

Python 3

```python
class Solution:
    def shortestSubarray(self, nums: List[int], k: int) -> int:
        s = list(accumulate(nums, initial=0))
        q = deque()
        ans = inf
        for i, v in enumerate(s):
            while q and v - s[q[0]] >= k:
                ans = min(ans, i - q.popleft())
            while q and s[q[-1]] >= v:
                q.pop()
            q.append(i)
        return -1 if ans == inf else ans
```

Complexity. Time: O(n). Space: O(n).

Built on the solutions above: helper functions, then the function for each follow-up. No tests and no restating of the question.

```python
# FOLLOW-UPS (answered below, in this order):
# 1. Return the positions of the shortest subarray

# ============================================================
# FOLLOW-UP 1: Return the positions of the shortest
# subarray
# ============================================================

# ---- follow-up 1: function ----
# Answer: Same deque of prefix-sum positions; when a
# window is found remember its start (the position taken
# from the front) and end.
# Time: O(n).  Space: O(n).
from collections import deque

def shortest_subarray_positions_with_negatives(nums, k):
    prefix = [0]
    for x in nums:
        prefix.append(prefix[-1] + x)
    candidates = deque()
    best = None
    for i in range(len(prefix)):
        while candidates and prefix[i] - prefix[candidates[0]] >= k:
            start = candidates.popleft()
            if best is None or i - start < best[1] - best[0] + 1:
                best = (start, i - 1)
        while candidates and prefix[candidates[-1]] >= prefix[i]:
            candidates.pop()
        candidates.append(i)
    return best
```

1425. Constrained Subsequence Sum

Hard · Queue, Array, Dynamic Programming, Sliding Window, Monotonic Queue, Heap (Priority Queue)

leetcode.com/problems/constrained-subsequence-sum

★ **TOP 10 PROBLEM** in Sliding Window Maximum / Minimum (Specific Variants): master this one first

Also appears in pattern 10 Queue / Deque, 35 Sliding Window Maximum / Minimum (Specific Variants), 37 Two Heaps

PROBLEM

Given an integer array `nums` and an integer `k`, return the maximum sum of a **non-empty** subsequence of that array such that for every two **consecutive** integers in the subsequence, `nums[i]` and `nums[j]`, where `i < j`, the condition `j - i <= k` is satisfied.

A *subsequence* of an array is obtained by deleting some number of elements (can be zero) from the array, leaving the remaining elements in their original order.

Example 1:

```
Input: nums = [10,2,-10,5,20], k = 2
Output: 37
Explanation: The subsequence is [10, 2, 5, 20].
```

Example 2:

```
Input: nums = [-1,-2,-3], k = 1
Output: -1
Explanation: The subsequence must be non-empty, so we choose the largest number.
```

Example 3:

```
Input: nums = [10,-2,-10,-5,20], k = 2
Output: 23
Explanation: The subsequence is [10, -2, -5, 20].
```

Constraints:

- `1 <= k <= nums.length <= 10^5`
- `-10^4 <= nums[i] <= 10^4`

SOLUTION (PYTHON 3)

Solution 1: Dynamic Programming + Monotonic Queue

How to think about it

Adjacent indices in the subsequence differ by at most k. n≤ 10^5, so scanning [i-k,i-1] for every i is O(nk). f[i]=nums[i]+max(0,$\max_{i-k\le j<i}$f[j]) is a sliding-window maximum on f. A decreasing deque of indices makes each transition amortized O(1). Values may be negative, so we may start a new subsequence at i. The answer is the maximum f[i].

We define f[i] to represent the maximum sum of the subsequence ending at nums[i] that meets the conditions. Initially, f[i] = 0, and the answer is $\max_{0 \le i < n} f(i)$.

We notice that the problem requires us to maintain the maximum value of a sliding window, which is a typical application scenario for a monotonic queue. We can use a monotonic queue to optimize the dynamic programming transition.

We maintain a monotonic queue q that is decreasing from the front to the back, storing the indices i. Initially, we add a sentinel 0 to the queue.

We traverse i from 0 to n - 1. For each i, we perform the following operations:

- If the front element q[0] satisfies i - q[0] > k, it means the front element is no longer within the sliding window, and we need to remove the front element from the queue;
- Then, we calculate f[i] = max(0, f[q[0]]) + nums[i], which means we add nums[i] to the sliding window to get the maximum subsequence sum;
- Next, we update the answer ans = max(ans, f[i]);
- Finally, we add i to the back of the queue and maintain the monotonicity of the queue. If f[q[back]] ≤ f[i], we need to remove the back element until the queue is empty or f[q[back]] > f[i].

The final answer is ans.

The time complexity is O(n), and the space complexity is O(n). Here, n is the length of the array nums.

Python 3

```python
class Solution:
    def constrainedSubsetSum(self, nums: List[int], k: int) -> int:
        q = deque([0])
        n = len(nums)
        f = [0] * n
        ans = -inf
        for i, x in enumerate(nums):
            while i - q[0] > k:
                q.popleft()
            f[i] = max(0, f[q[0]]) + x
            ans = max(ans, f[i])
            while q and f[q[-1]] <= f[i]:
                q.pop()
            q.append(i)
        return ans
```

PATTERN 10 · QUEUE / DEQUE · PROBLEM 1 OF 20

232. Implement Queue using Stacks

Easy · Stack, Design, Queue

leetcode.com/problems/implement-queue-using-stacks

★ **TOP 10 PROBLEM** in Queue / Deque: master this one first

PROBLEM

Implement a first in first out (FIFO) queue using only two stacks. The implemented queue should support all the functions of a normal queue (`push`, `peek`, `pop`, and `empty`).

Implement the `MyQueue` class:

- `void push(int x)` Pushes element x to the back of the queue.
- `int pop()` Removes the element from the front of the queue and returns it.
- `int peek()` Returns the element at the front of the queue.
- `boolean empty()` Returns `true` if the queue is empty, `false` otherwise.

Notes:

- You must use **only** standard operations of a stack, which means only `push to top`, `peek/pop from top`, `size`, and `is empty` operations are valid.
- Depending on your language, the stack may not be supported natively. You may simulate a stack using a list or deque (double-ended queue) as long as you use only a stack's standard operations.

Example 1:

```
Input
["MyQueue", "push", "push", "peek", "pop", "empty"]
[[], [1], [2], [], [], []]
Output
[null, null, null, 1, 1, false]

Explanation
MyQueue myQueue = new MyQueue();
myQueue.push(1); // queue is: [1]
myQueue.push(2); // queue is: [1, 2] (leftmost is front of the queue)
myQueue.peek(); // return 1
myQueue.pop(); // return 1, queue is [2]
myQueue.empty(); // return false
```

Constraints:

- `1 <= x <= 9`
- At most `100` calls will be made to `push`, `pop`, `peek`, and `empty`.
- All the calls to `pop` and `peek` are valid.

Follow-up: Can you implement the queue such that each operation is **amortized** `O(1)` time complexity? In other words, performing `n` operations will take overall `O(n)` time even if one of those operations may take longer.

SOLUTION (PYTHON 3)

Solution 1: Double Stack

How to think about it

A stack is LIFO and a queue is FIFO, so one stack cannot serve both ends. Push into stk1 and pop from stk2. When stk2 is empty, pour stk1 into it so the oldest value sits on top. Each element moves at most once, and dequeue is amortized constant.

We use two stacks, where `stk1` is used for enqueue, and another stack `stk2` is used for dequeue.

When enqueueing, we directly push the element into `stk1`. The time complexity is O(1).

When dequeueing, we first check whether `stk2` is empty. If it is empty, we pop all elements from `stk1` and push them into `stk2`, and then pop an element from `stk2`. If `stk2` is not empty, we directly pop an element from `stk2`. The amortized time complexity is O(1).

When getting the front element, we first check whether `stk2` is empty. If it is empty, we pop all elements from `stk1` and push them into `stk2`, and then get the top element from `stk2`. If `stk2` is not empty, we directly get the top element from `stk2`. The amortized time complexity is O(1).

When checking whether the queue is empty, we only need to check whether both stacks are empty. The time complexity is O(1).

Python 3

```
class MyQueue:
    def __init__(self):
        self.stk1 = []
        self.stk2 = []

    def push(self, x: int) -> None:
        self.stk1.append(x)

    def pop(self) -> int:
        self.move()
        return self.stk2.pop()

    def peek(self) -> int:
        self.move()
        return self.stk2[-1]

    def empty(self) -> bool:
        return not self.stk1 and not self.stk2

    def move(self):
        if not self.stk2:
            while self.stk1:
                self.stk2.append(self.stk1.pop())

# Your MyQueue object will be instantiated and called as such:
# obj = MyQueue()
# obj.push(x)
# param_2 = obj.pop()
# param_3 = obj.peek()
# param_4 = obj.empty()
```

        self.stack.append(top)
        return front
```

PATTERN 10 · QUEUE / DEQUE · PROBLEM 2 OF 20

225. Implement Stack using Queues

Easy · Stack, Design, Queue

leetcode.com/problems/implement-stack-using-queues

★ **TOP 10 PROBLEM** in Queue / Deque: master this one first

PROBLEM

Implement a last-in-first-out (LIFO) stack using only two queues. The implemented stack should support all the functions of a normal stack (`push`, `top`, `pop`, and `empty`).

Implement the `MyStack` class:

- `void push(int x)` Pushes element x to the top of the stack.
- `int pop()` Removes the element on the top of the stack and returns it.
- `int top()` Returns the element on the top of the stack.
- `boolean empty()` Returns `true` if the stack is empty, `false` otherwise.

Notes:

- You must use **only** standard operations of a queue, which means that only `push to back`, `peek/pop from front`, `size` and `is empty` operations are valid.
- Depending on your language, the queue may not be supported natively. You may simulate a queue using a list or deque (double-ended queue) as long as you use only a queue's standard operations.

Example 1:

```
Input
["MyStack", "push", "push", "top", "pop", "empty"]
[[], [1], [2], [], [], []]
Output
[null, null, null, 2, 2, false]

Explanation
MyStack myStack = new MyStack();
myStack.push(1);
myStack.push(2);
myStack.top(); // return 2
myStack.pop(); // return 2
myStack.empty(); // return False
```

Constraints:

- `1 <= x <= 9`
- At most `100` calls will be made to `push`, `pop`, `top`, and `empty`.
- All the calls to `pop` and `top` are valid.

Follow-up: Can you implement the stack using only one queue?

SOLUTION (PYTHON 3)

Solution 1: Two Queues

How to think about it

A queue inserts at the back and removes from the front, while a stack is LIFO. If each push rotates the new value to the front, pop and top become a dequeue. We enqueue x into q_2, move everything from q_1 behind it, and swap, so the front of q_1 is always the stack top.

We use two queues q_1 and q_2, where q_1 is used to store the elements in the stack, and q_2 is used to assist in implementing the stack operations.

- `push` operation: Push the element into q_2, then pop the elements in q_1 one by one and push them into q_2, finally swap the references of q_1 and q_2. The time complexity is O(n).
- `pop` operation: Directly pop the front element of q_1. The time complexity is O(1).
- `top` operation: Directly return the front element of q_1. The time complexity is O(1).
- `empty` operation: Check whether q_1 is empty. The time complexity is O(1).

The space complexity is O(n), where n is the number of elements in the stack.

Python 3

```
class MyStack:
    def __init__(self):
        self.q1 = deque()
        self.q2 = deque()

    def push(self, x: int) -> None:
        self.q2.append(x)
        while self.q1:
            self.q2.append(self.q1.popleft())
        self.q1, self.q2 = self.q2, self.q1

    def pop(self) -> int:
        return self.q1.popleft()

    def top(self) -> int:
        return self.q1[0]

    def empty(self) -> bool:
        return len(self.q1) == 0

# Your MyStack object will be instantiated and called as such:
# obj = MyStack()
# obj.push(x)
# param_2 = obj.pop()
# param_3 = obj.top()
# param_4 = obj.empty()
```

PATTERN 10 · QUEUE / DEQUE · PROBLEM 3 OF 20

933. Number of Recent Calls

Easy · Design, Queue, Data Stream

leetcode.com/problems/number-of-recent-calls

★ **TOP 10 PROBLEM** in Queue / Deque: master this one first

PROBLEM

You have a `RecentCounter` class which counts the number of recent requests within a certain time frame.

Implement the `RecentCounter` class:

- `RecentCounter()` Initializes the counter with zero recent requests.
- `int ping(int t)` Adds a new request at time `t`, where `t` represents some time in milliseconds, and returns the number of requests that have happened in the inclusive range `[t - 3000, t]`, that is, the new request plus every earlier request that is no more than `3000` milliseconds older.

It is **guaranteed** that every call to `ping` uses a strictly larger value of `t` than the previous call.

Example 1:

```
Input
["RecentCounter", "ping", "ping", "ping", "ping"]
[[], [1], [100], [3001], [3002]]
Output
[null, 1, 2, 3, 3]

Explanation
RecentCounter recentCounter = new RecentCounter();
recentCounter.ping(1); // requests = [1], range is [-2999,1], return 1
recentCounter.ping(100); // requests = [1, 100], range is [-2900,100], return 2
recentCounter.ping(3001); // requests = [1, 100, 3001], range is [1,3001], return 3
recentCounter.ping(3002); // requests = [1, 100, 3001, 3002], range is [2,3002], return 3
```

Constraints:

- $1 <= t <= 10^9$
- Each test case will call `ping` with **strictly increasing** values of `t`.
- At most 10^4 calls will be made to `ping`.

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

t is strictly increasing, so a request older than t-3000 never returns. Store times in a queue and pop from the front while expired; the queue size is the answer.

Python 3

```
class RecentCounter:
    def __init__(self):
        self.q = deque()

    def ping(self, t: int) -> int:
        self.q.append(t)
        while self.q[0] < t - 3000:
            self.q.popleft()
        return len(self.q)

# Your RecentCounter object will be instantiated and called as such:
# obj = RecentCounter()
# param_1 = obj.ping(t)
```

Complexity. Time: O(1) amortised per ping. Space: O(W), W = pings inside the 3000 ms window.

Solution 2

> **How to think about it**
>
> The queue is amortized linear. Because times are sorted, we may keep them in an array and binary-search the first index ≥ t-3000; the suffix length is the count. Extra space stays linear, and each query pays a logarithm.

Python 3

```
class RecentCounter:
    def __init__(self):
        self.s = []

    def ping(self, t: int) -> int:
        self.s.append(t)
        return len(self.s) - bisect_left(self.s, t - 3000)

# Your RecentCounter object will be instantiated and called as such:
# obj = RecentCounter()
# param_1 = obj.ping(t)
```

Complexity. Time: O(log n) per ping. Space: O(n).

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

Built on the solutions above: helper functions, then the function for each follow-up. No tests and no restating of the question.

```
# FOLLOW-UPS (answered below, in this order):
# 1. Calls can arrive out of order (timestamps are not
# increasing)
# 2. Count the recent calls of every user separately

# ============================================================
# FOLLOW-UP 1: Calls can arrive out of order (timestamps
# are not increasing)
# ============================================================

# ---- follow-up 1: function ----
# Answer: Keep the timestamps in a sorted list (insert at
# the right place with a binary search) and count the ones
# inside [t - 3000, t] with two binary searches.
# Time: O(n) per ping (inserting into a sorted list).
# Space: O(n).
import bisect

class RecentCounterUnordered:
```

```
    def __init__(self):
        self.times = []

    def ping(self, t):
        bisect.insort(self.times, t)
        low = bisect.bisect_left(self.times, t - 3000)
        high = bisect.bisect_right(self.times, t)
        return high - low

# ============================================================
# FOLLOW-UP 2: Count the recent calls of every user
# separately
# ============================================================

# ---- follow-up 2: function ----
# Answer: One queue per user, kept in a dictionary; each
# queue drops its old timestamps when that user pings.
# Time: O(1) amortised per ping.  Space: O(total pings in
# the window of every user).
from collections import deque

class RecentCounterPerUser:
    def __init__(self):
        self.queues = {}

    def ping(self, user, t):
        if user not in self.queues:
            self.queues[user] = deque()
        queue = self.queues[user]
        queue.append(t)
        while queue[0] < t - 3000:
            queue.popleft()
        return len(queue)
```

2073. Time Needed to Buy Tickets

Easy · Queue, Array, Simulation

leetcode.com/problems/time-needed-to-buy-tickets

PROBLEM

There are `n` people in a line queuing to buy tickets, where the `0`th person is at the **front** of the line and the `(n - 1)`th person is at the **back** of the line.

You are given a **0-indexed** integer array `tickets` of length `n` where the number of tickets that the `i`th person would like to buy is `tickets[i]`.

Each person takes **exactly 1 second** to buy a ticket. A person can only buy **1 ticket at a time** and has to go back to **the end** of the line (which happens **instantaneously**) in order to buy more tickets. If a person does not have any tickets left to buy, the person will **leave** the line.

Return the **time taken** for the person **initially** at position **k** (0-indexed) to finish buying tickets.

Example 1:

Input: tickets = [2,3,2], k = 2

Output: 6

Explanation:

- The queue starts as [2,3,2], where the kth person is underlined.
- After the person at the front has bought a ticket, the queue becomes [3,2,1] at 1 second.
- Continuing this process, the queue becomes [2,1,2] at 2 seconds.
- Continuing this process, the queue becomes [1,2,1] at 3 seconds.
- Continuing this process, the queue becomes [2,1] at 4 seconds. Note: the person at the front left the queue.
- Continuing this process, the queue becomes [1,1] at 5 seconds.
- Continuing this process, the queue becomes [1] at 6 seconds. The kth person has bought all their tickets, so return 6.

Example 2:

Input: tickets = [5,1,1,1], k = 0

Output: 8

Explanation:

- The queue starts as [5,1,1,1], where the kth person is underlined.
- After the person at the front has bought a ticket, the queue becomes [1,1,1,4] at 1 second.
- Continuing this process for 3 seconds, the queue becomes [4] at 4 seconds.
- Continuing this process for 4 seconds, the queue becomes [] at 8 seconds. The kth person has bought all their tickets, so return 8.

Constraints:

- `n == tickets.length`
- `1 <= n <= 100`
- `1 <= tickets[i] <= 100`
- `0 <= k < n`

SOLUTION (PYTHON 3)

Solution 1: Single Pass

> **How to think about it**
>
> Naively simulating the queue costs O(∑ tickets). When person k finishes, everyone ahead bought at most tickets[k] tickets and everyone behind at most tickets[k]-1. Sum min of that cap and each person's demand in one pass.

According to the problem description, when the k^{th} person finishes buying tickets, all the people in front of the k^{th} person will not buy more tickets than the k^{th} person, and all the people behind the k^{th} person will not buy more tickets than the k^{th} person minus 1.

Therefore, we can traverse the entire queue. For the i^{th} person, if $i \le k$, the time to buy tickets is min(tickets[i], tickets[k]); otherwise, the time to buy tickets is min(tickets[i], tickets[k] - 1). We sum the buying time for all people to get the result.

The time complexity is O(n), where n is the length of the queue. The space complexity is O(1).

Python 3

```python
class Solution:
    def timeRequiredToBuy(self, tickets: List[int], k: int) -> int:
        ans = 0
        for i, x in enumerate(tickets):
            ans += min(x, tickets[k] if i <= k else tickets[k] - 1)
        return ans
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

        if person == k and left == 0:
            return time
        if left > 0:
            queue.append((person, left))
    return time
```

PATTERN 10 · QUEUE / DEQUE · PROBLEM 5 OF 20

622. Design Circular Queue

Medium · Design, Queue, Array, Linked List

leetcode.com/problems/design-circular-queue

★ **TOP 10 PROBLEM** in Queue / Deque: master this one first

PROBLEM

Design your implementation of the circular queue. The circular queue is a linear data structure in which the operations are performed based on FIFO (First In First Out) principle, and the last position is connected back to the first position to make a circle. It is also called "Ring Buffer".

One of the benefits of the circular queue is that we can make use of the spaces in front of the queue. In a normal queue, once the queue becomes full, we cannot insert the next element even if there is a space in front of the queue. But using the circular queue, we can use the space to store new values.

Implement the `MyCircularQueue` class:

- `MyCircularQueue(k)` Initializes the object with the size of the queue to be `k`.
- `int Front()` Gets the front item from the queue. If the queue is empty, return `-1`.
- `int Rear()` Gets the last item from the queue. If the queue is empty, return `-1`.
- `boolean enQueue(int value)` Inserts an element into the circular queue. Return `true` if the operation is successful.
- `boolean deQueue()` Deletes an element from the circular queue. Return `true` if the operation is successful.
- `boolean isEmpty()` Checks whether the circular queue is empty or not.
- `boolean isFull()` Checks whether the circular queue is full or not.

You must solve the problem without using the built-in queue data structure in your programming language.

Example 1:

```
Input
["MyCircularQueue", "enQueue", "enQueue", "enQueue", "enQueue", "Rear", "isFull", "deQueue",
"enQueue", "Rear"]
[[3], [1], [2], [3], [4], [], [], [], [4], []]
Output
[null, true, true, true, false, 3, true, true, true, 4]

Explanation
MyCircularQueue myCircularQueue = new MyCircularQueue(3);
myCircularQueue.enQueue(1); // return True
myCircularQueue.enQueue(2); // return True
myCircularQueue.enQueue(3); // return True
myCircularQueue.enQueue(4); // return False
myCircularQueue.Rear(); // return 3
myCircularQueue.isFull(); // return True
myCircularQueue.deQueue(); // return True
myCircularQueue.enQueue(4); // return True
myCircularQueue.Rear(); // return 4
```

Constraints:

- `1 <= k <= 1000`
- `0 <= value <= 1000`
- At most `3000` calls will be made to `enQueue`, `deQueue`, `Front`, `Rear`, `isEmpty`, and `isFull`.

SOLUTION (PYTHON 3)

Solution 1: Array Simulation

How to think about it

A circular queue needs O(1) enqueue/dequeue on a fixed array and must tell empty from full. Head and tail alone collide when they wrap. Store size as well: write at (front+size) mod k, and read the rear at (front+size-1) mod k. Empty and full are just size checks.

We can use an array q of length k to simulate a circular queue, with a pointer front to record the position of the front element. Initially, the queue is empty, and front is 0. Additionally, we use a variable size to record the number of elements in the queue, initially size is 0.

When calling the `enQueue` method, we first check if the queue is full, i.e., size = k. If it is full, we return false. Otherwise, we insert the element at position (front + size) mod k, then size = size + 1, indicating that the number of elements in the queue has increased by 1. Finally, we return true.

When calling the `deQueue` method, we first check if the queue is empty, i.e., size = 0. If it is empty, we return false. Otherwise, we set front = (front + 1) mod k, indicating that the front element has been dequeued, then size = size - 1.

When calling the `Front` method, we first check if the queue is empty, i.e., size = 0. If it is empty, we return -1. Otherwise, we return q[front].

When calling the `Rear` method, we first check if the queue is empty, i.e., size = 0. If it is empty, we return -1. Otherwise, we return q[(front + size - 1) mod k].

When calling the `isEmpty` method, we simply check if size = 0.

When calling the `isFull` method, we simply check if size = k.

In terms of time complexity, the above operations all have a time complexity of O(1). The space complexity is O(k).

Python 3

```
class MyCircularQueue:

    def __init__(self, k: int):
        self.q = [0] * k
        self.size = 0
        self.capacity = k
        self.front = 0

    def enQueue(self, value: int) -> bool:
        if self.isFull():
            return False
        self.q[(self.front + self.size) % self.capacity] = value
        self.size += 1
        return True

    def deQueue(self) -> bool:
        if self.isEmpty():
            return False
        self.front = (self.front + 1) % self.capacity
        self.size -= 1
        return True

    def Front(self) -> int:
        return -1 if self.isEmpty() else self.q[self.front]

    def Rear(self) -> int:
        if self.isEmpty():
            return -1
        return self.q[(self.front + self.size - 1) % self.capacity]

    def isEmpty(self) -> bool:
        return self.size == 0

    def isFull(self) -> bool:
        return self.size == self.capacity

# Your MyCircularQueue object will be instantiated and called as such:
# obj = MyCircularQueue(k)
# param_1 = obj.enQueue(value)
# param_2 = obj.deQueue()
# param_3 = obj.Front()
# param_4 = obj.Rear()
# param_5 = obj.isEmpty()
# param_6 = obj.isFull()
```

        self.head = (self.head + 1) % len(self.items)
        self.size -= 1
        return value
```

641. Design Circular Deque

Medium · Design, Queue, Array, Linked List

leetcode.com/problems/design-circular-deque

★ **TOP 10 PROBLEM** in Queue / Deque: master this one first

Also appears in pattern 29 Design Problems

PROBLEM

Design your implementation of the circular double-ended queue (deque).

Implement the `MyCircularDeque` class:

- `MyCircularDeque(int k)` Initializes the deque with a maximum size of `k`.
- `boolean insertFront()` Adds an item at the front of Deque. Returns `true` if the operation is successful, or `false` otherwise.
- `boolean insertLast()` Adds an item at the rear of Deque. Returns `true` if the operation is successful, or `false` otherwise.
- `boolean deleteFront()` Deletes an item from the front of Deque. Returns `true` if the operation is successful, or `false` otherwise.
- `boolean deleteLast()` Deletes an item from the rear of Deque. Returns `true` if the operation is successful, or `false` otherwise.
- `int getFront()` Returns the front item from the Deque. Returns `-1` if the deque is empty.
- `int getRear()` Returns the last item from Deque. Returns `-1` if the deque is empty.
- `boolean isEmpty()` Returns `true` if the deque is empty, or `false` otherwise.
- `boolean isFull()` Returns `true` if the deque is full, or `false` otherwise.

Example 1:

```
Input
["MyCircularDeque", "insertLast", "insertLast", "insertFront", "insertFront", "getRear", "isFull",
"deleteLast", "insertFront", "getFront"]
[[3], [1], [2], [3], [4], [], [], [], [4], []]
Output
[null, true, true, true, false, 2, true, true, true, 4]

Explanation
MyCircularDeque myCircularDeque = new MyCircularDeque(3);
myCircularDeque.insertLast(1); // return True
myCircularDeque.insertLast(2); // return True
myCircularDeque.insertFront(3); // return True
myCircularDeque.insertFront(4); // return False, the queue is full.
myCircularDeque.getRear(); // return 2
myCircularDeque.isFull(); // return True
myCircularDeque.deleteLast(); // return True
myCircularDeque.insertFront(4); // return True
myCircularDeque.getFront(); // return 4
```

Constraints:

- `1 <= k <= 1000`
- `0 <= value <= 1000`
- At most `2000` calls will be made to `insertFront`, `insertLast`, `deleteFront`, `deleteLast`, `getFront`, `getRear`, `isEmpty`, `isFull`.

SOLUTION (PYTHON 3)

Solution 1: Array

How to think about it

A bounded deque needs O(1) inserts and deletes at both ends and a clear empty/full test. A linked list wastes pointers. Reuse a ring buffer with front and size: insert-front steps front backward, insert-last writes at (front+size) mod k.

We can use an array to implement the circular deque. We maintain a pointer front pointing to the front of the queue, a variable size representing the number of elements in the queue, and a variable capacity representing the queue's capacity. We use an array q to store the elements.

When insertFront is called, we first check if the queue is full; if so, return false. Otherwise, we move front one position forward (using modular arithmetic for circular wrapping), insert the new element at front, and increment size by 1.

When insertLast is called, we first check if the queue is full; if so, return false. Otherwise, we compute the insertion position (using front and size), insert the new element there, and increment size by 1.

When deleteFront is called, we first check if the queue is empty; if so, return false. Otherwise, we move front one position backward (using modular arithmetic for circular wrapping) and decrement size by 1.

When deleteLast is called, we first check if the queue is empty; if so, return false. Otherwise, we decrement size by 1.

When getFront is called, we first check if the queue is empty; if so, return -1. Otherwise, we return q[front].

When getRear is called, we first check if the queue is empty; if so, return -1. Otherwise, we compute the position of the rear element (using front and size) and return the element at that position.

When isEmpty is called, we check whether size equals 0.

When isFull is called, we check whether size equals capacity.

All operations above have a time complexity of O(1) and a space complexity of O(k), where k is the capacity of the deque.

Python 3

```
class MyCircularDeque:
    def __init__(self, k: int):
        """
        Initialize your data structure here. Set the size of the deque to be k.
        """
        self.q = [0] * k
        self.front = 0
        self.size = 0
        self.capacity = k

    def insertFront(self, value: int) -> bool:
        """
        Adds an item at the front of Deque. Return true if the operation is successful.
        """
        if self.isFull():
            return False
        if not self.isEmpty():
            self.front = (self.front - 1 + self.capacity) % self.capacity
        self.q[self.front] = value
        self.size += 1
        return True

    def insertLast(self, value: int) -> bool:
        """
        Adds an item at the rear of Deque. Return true if the operation is successful.
        """
        if self.isFull():
            return False
        idx = (self.front + self.size) % self.capacity
        self.q[idx] = value
        self.size += 1
        return True

    def deleteFront(self) -> bool:
        """
        Deletes an item from the front of Deque. Return true if the operation is successful.
        """
        if self.isEmpty():
            return False
        self.front = (self.front + 1) % self.capacity
        self.size -= 1
        return True

    def deleteLast(self) -> bool:
        """
        Deletes an item from the rear of Deque. Return true if the operation is successful.
        """
        if self.isEmpty():
            return False
        self.size -= 1
        return True

    def getFront(self) -> int:

PATTERN 10 · QUEUE / DEQUE · PROBLEM 7 OF 20

649. Dota2 Senate

Medium · Greedy, Queue, String

leetcode.com/problems/dota2-senate

★ **TOP 10 PROBLEM** in Queue / Deque: master this one first

PROBLEM

In the world of Dota2, there are two parties: the Radiant and the Dire.

The Dota2 senate consists of senators coming from two parties. Now the Senate wants to decide on a change in the Dota2 game. The voting for this change is a round-based procedure. In each round, each senator can exercise **one** of the two rights:

- **Ban one senator's right:** A senator can make another senator lose all his rights in this and all the following rounds.
- **Announce the victory:** If this senator found the senators who still have rights to vote are all from the same party, he can announce the victory and decide on the change in the game.

Given a string `senate` representing each senator's party belonging. The character `'R'` and `'D'` represent the Radiant party and the Dire party. Then if there are `n` senators, the size of the given string will be `n`.

The round-based procedure starts from the first senator to the last senator in the given order. This procedure will last until the end of voting. All the senators who have lost their rights will be skipped during the procedure.

Suppose every senator is smart enough and will play the best strategy for his own party. Predict which party will finally announce the victory and change the Dota2 game. The output should be `"Radiant"` or `"Dire"`.

Example 1:

```
Input: senate = "RD"
Output: "Radiant"
Explanation:
The first senator comes from Radiant and he can just ban the next senator's right in round 1.
And the second senator can't exercise any rights anymore since his right has been banned.
And in round 2, the first senator can just announce the victory since he is the only guy in the senate
who can vote.
```

Example 2:

```
Input: senate = "RDD"
Output: "Dire"
Explanation:
The first senator comes from Radiant and he can just ban the next senator's right in round 1.
And the second senator can't exercise any rights anymore since his right has been banned.
And the third senator comes from Dire and he can ban the first senator's right in round 1.
And in round 2, the third senator can just announce the victory since he is the only guy in the senate
who can vote.
```

Constraints:

- `n == senate.length`
- `1 <= n <= 10^4`
- `senate[i]` is either `'R'` or `'D'`.

SOLUTION (PYTHON 3)

Solution 1: Queue + Simulation

> **How to think about it**
>
> Senators ban the next opponent in order until one party is gone. Repeatedly deleting from the string is quadratic. Queue indices of each party. The smaller front acts first, pops the other, and re-enters at i+n for the next round. An empty queue loses.

We create two queues qr and qd to record the indices of the Radiant and Dire senators, respectively. Then we start the simulation, where in each round we dequeue one senator from each queue and perform different operations based on their factions:

- If the Radiant senator's index is less than the Dire senator's index, the Radiant senator can permanently ban the voting rights of the Dire senator. We add n to the Radiant senator's index and enqueue it back to the end of the queue, indicating that this senator will participate in the next round of voting.
- If the Dire senator's index is less than the Radiant senator's index, the Dire senator can permanently ban the voting rights of the Radiant senator. We add n to the Dire senator's index and enqueue it back to the end of the queue, indicating that this senator will participate in the next round of voting.

Finally, when there are only senators from one faction left in the queues, the senators from that faction win.

The time complexity is O(n), and the space complexity is O(n). Here, n is the number of senators.

Python 3

```python
class Solution:
    def predictPartyVictory(self, senate: str) -> str:
        qr = deque()
        qd = deque()
        for i, c in enumerate(senate):
            if c == "R":
                qr.append(i)
            else:
                qd.append(i)
        n = len(senate)
        while qr and qd:
            if qr[0] < qd[0]:
                qr.append(qr[0] + n)
            else:
                qd.append(qd[0] + n)
            qr.popleft()
            qd.popleft()
        return "Radiant" if qr else "Dire"
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

Built on the solutions above: helper functions, then the function for each follow-up. No tests and no restating of the question.

```python
# FOLLOW-UPS (answered below, in this order):
# 1. How many senators of the winning party are left when
# the vote ends?

# ============================================================
# FOLLOW-UP 1: How many senators of the winning party are
# left when the vote ends?
# ============================================================

# ---- follow-up 1: function ----
# Answer: Use the same two queues of positions. Each time
# the front senators of both parties meet, the earlier one
# bans the other and returns to the back with its position
# plus n (it votes again in the next round). When one
# queue is empty, the size of the other is the answer.
```

```

PATTERN 10 · QUEUE / DEQUE · PROBLEM 8 OF 20

950. Reveal Cards In Increasing Order

Medium · Queue, Array, Sorting, Simulation

leetcode.com/problems/reveal-cards-in-increasing-order

PROBLEM

You are given an integer array `deck`. There is a deck of cards where every card has a unique integer. The integer on the i^{th} card is `deck[i]`.

You can order the deck in any order you want. Initially, all the cards start face down (unrevealed) in one deck.

You will do the following steps repeatedly until all cards are revealed:

1. Take the top card of the deck, reveal it, and take it out of the deck.
2. If there are still cards in the deck then put the next top card of the deck at the bottom of the deck.
3. If there are still unrevealed cards, go back to step 1. Otherwise, stop.

Return *an ordering of the deck that would reveal the cards in increasing order*.

Note that the first entry in the answer is considered to be the top of the deck.

Example 1:

```
Input: deck = [17,13,11,2,3,5,7]
Output: [2,13,3,11,5,17,7]
Explanation:
We get the deck in the order [17,13,11,2,3,5,7] (this order does not matter), and reorder it.
After reordering, the deck starts as [2,13,3,11,5,17,7], where 2 is the top of the deck.
We reveal 2, and move 13 to the bottom. The deck is now [3,11,5,17,7,13].
We reveal 3, and move 11 to the bottom. The deck is now [5,17,7,13,11].
We reveal 5, and move 17 to the bottom. The deck is now [7,13,11,17].
We reveal 7, and move 13 to the bottom. The deck is now [11,17,13].
We reveal 11, and move 17 to the bottom. The deck is now [13,17].
We reveal 13, and move 17 to the bottom. The deck is now [17].
We reveal 17.
Since all the cards revealed are in increasing order, the answer is correct.
```

Example 2:

```
Input: deck = [1,1000]
Output: [1,1000]
```

Constraints:

- `1 <= deck.length <= 1000`
- `1 <= deck[i] <= 10^6`
- All the values of `deck` are **unique**.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Revealing takes the front card and moves the new front to the back. Simulating forward needs the unknown start order, while the reveal should be increasing. Invert the process: from large to small, rotate the current back to the front (if the queue is nonempty) and insert the card at the front. The queue is the initial deck.

Python 3

```
class Solution:
    def deckRevealedIncreasing(self, deck: List[int]) -> List[int]:
        q = deque()
        for v in sorted(deck, reverse=True):
            if q:
                q.appendleft(q.pop())
            q.appendleft(v)
        return list(q)
```

Complexity. Time: O(n log n). Space: O(n).

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

```

```
            queue.append(queue.popleft())
    for i in range(1, len(revealed)):
        if revealed[i] < revealed[i - 1]:
            return False
    return True
```

1670. Design Front Middle Back Queue

Medium · Design, Queue, Array, Linked List, Data Stream, Doubly-Linked List

leetcode.com/problems/design-front-middle-back-queue

PROBLEM

Design a queue that supports `push` and `pop` operations in the front, middle, and back.

Implement the `FrontMiddleBack` class:

- `FrontMiddleBack()` Initializes the queue.
- `void pushFront(int val)` Adds `val` to the **front** of the queue.
- `void pushMiddle(int val)` Adds `val` to the **middle** of the queue.
- `void pushBack(int val)` Adds `val` to the **back** of the queue.
- `int popFront()` Removes the **front** element of the queue and returns it. If the queue is empty, return `-1`.
- `int popMiddle()` Removes the **middle** element of the queue and returns it. If the queue is empty, return `-1`.
- `int popBack()` Removes the **back** element of the queue and returns it. If the queue is empty, return `-1`.

Notice that when there are **two** middle position choices, the operation is performed on the **frontmost** middle position choice. For example:

- Pushing `6` into the middle of `[1, 2, 3, 4, 5]` results in `[1, 2, 6, 3, 4, 5]`.
- Popping the middle from `[1, 2, 3, 4, 5, 6]` returns `3` and results in `[1, 2, 4, 5, 6]`.

Example 1:

```
Input:
["FrontMiddleBackQueue", "pushFront", "pushBack", "pushMiddle", "pushMiddle", "popFront", "popMiddle",
"popMiddle", "popBack", "popFront"]
[[], [1], [2], [3], [4], [], [], [], [], []]
Output:
[null, null, null, null, null, 1, 3, 4, 2, -1]

Explanation:
FrontMiddleBackQueue q = new FrontMiddleBackQueue();
q.pushFront(1); // [1]
q.pushBack(2); // [1, 2]
q.pushMiddle(3); // [1, 3, 2]
q.pushMiddle(4); // [1, 4, 3, 2]
q.popFront(); // return 1 -> [4, 3, 2]
q.popMiddle(); // return 3 -> [4, 2]
q.popMiddle(); // return 4 -> [2]
q.popBack(); // return 2 -> []
q.popFront(); // return -1 -> [] (The queue is empty)
```

Constraints:

- $1 <= val <= 10^9$
- At most `1000` calls will be made to `pushFront`, `pushMiddle`, `pushBack`, `popFront`, `popMiddle`, and `popBack`.

SOLUTION (PYTHON 3)

Solution 1: Two Deques

How to think about it

We need O(1) insert/delete at the front, middle, and back; finding the midpoint of one list is linear. Split into deques q_1 (front half) and q_2 (back half) with q_2 at most one longer than q_1. After an update, rebalance moves one element. The middle is the tail of q_1 when sizes are equal, otherwise the head of q_2.

We use two deques, where q_1 stores the first half, and q_2 stores the second half. The `rebalance` function is used to maintain the balance between the two queues, i.e., keeping the length of q_2 greater than or equal to the length of q_1, and the difference in length does not exceed 1.

In the `pushFront`, `pushMiddle`, and `pushBack` functions, we only need to add elements to q_1 or q_2, and call the `rebalance` function.

For the `popFront` function, we need to check whether q_1 and q_2 are empty. If both are empty, return -1. Otherwise, we need to check whether q_1 is empty. If not, pop the front element of q_1, otherwise pop the front element of q_2, and call the `rebalance` function.

For the `popMiddle` function, we need to check whether q_1 and q_2 are empty. If both are empty, return -1. Otherwise, we need to check whether the lengths of q_1 and q_2 are equal. If they are equal, pop the last element of q_1, otherwise pop the front element of q_2, and call the `rebalance` function.

For the `popBack` function, we only need to check whether q_2 is empty. If it is empty, return -1. Otherwise, pop the last element of q_2, and call the `rebalance` function.

The time complexity of the above operations is O(1), and the space complexity is O(n), where n is the number of elements in the queue.

Python 3

```
class FrontMiddleBackQueue:
    def __init__(self):
        self.q1 = deque()
        self.q2 = deque()

    def pushFront(self, val: int) -> None:
        self.q1.appendleft(val)
        self.rebalance()

    def pushMiddle(self, val: int) -> None:
        self.q1.append(val)
        self.rebalance()

    def pushBack(self, val: int) -> None:
        self.q2.append(val)
        self.rebalance()

    def popFront(self) -> int:
        if not self.q1 and not self.q2:
            return -1
        if self.q1:
            val = self.q1.popleft()
        else:
            val = self.q2.popleft()
        self.rebalance()
        return val

    def popMiddle(self) -> int:
        if not self.q1 and not self.q2:
            return -1
        if len(self.q1) == len(self.q2):
            val = self.q1.pop()
        else:
            val = self.q2.popleft()
        self.rebalance()
        return val

    def popBack(self) -> int:
        if not self.q2:
            return -1
        val = self.q2.pop()
        self.rebalance()
        return val

    def rebalance(self):
        if len(self.q1) > len(self.q2):
            self.q2.appendleft(self.q1.pop())
        if len(self.q2) > len(self.q1) + 1:
            self.q1.append(self.q2.popleft())

# Your FrontMiddleBackQueue object will be instantiated and called as such:
# obj = FrontMiddleBackQueue()
# obj.pushFront(val)
# obj.pushMiddle(val)
# obj.pushBack(val)
# param_4 = obj.popFront()
# param_5 = obj.popMiddle()
# param_6 = obj.popBack()
```

```

PATTERN 10 · QUEUE / DEQUE · PROBLEM 10 OF 20

2398. Maximum Number of Robots Within Budget

Hard · Queue, Array, Binary Search, Prefix Sum, Sliding Window, Monotonic Queue, Heap (Priority Queue)

leetcode.com/problems/maximum-number-of-robots-within-budget

★ **TOP 10 PROBLEM** in Sliding Window Maximum / Minimum (Specific Variants): master this one first

Also appears in pattern 35 Sliding Window Maximum / Minimum (Specific Variants)

PROBLEM

You have `n` robots. You are given two **0-indexed** integer arrays, `chargeTimes` and `runningCosts`, both of length `n`. The i^{th} robot costs `chargeTimes[i]` units to charge and costs `runningCosts[i]` units to run. You are also given an integer `budget`.

The **total cost** of running `k` chosen robots is equal to `max(chargeTimes) + k * sum(runningCosts)`, where `max(chargeTimes)` is the largest charge cost among the `k` robots and `sum(runningCosts)` is the sum of running costs among the `k` robots.

Return *the **maximum** number of **consecutive** robots you can run such that the total cost **does not** exceed* `budget`.

Example 1:

```
Input: chargeTimes = [3,6,1,3,4], runningCosts = [2,1,3,4,5], budget = 25
Output: 3
Explanation:
It is possible to run all individual and consecutive pairs of robots within budget.
To obtain answer 3, consider the first 3 robots. The total cost will be max(3,6,1) + 3 * sum(2,1,3) = 6
+ 3 * 6 = 24 which is less than 25.
It can be shown that it is not possible to run more than 3 consecutive robots within budget, so we
return 3.
```

Example 2:

```
Input: chargeTimes = [11,12,19], runningCosts = [10,8,7], budget = 19
Output: 0
Explanation: No robot can be run that does not exceed the budget, so we return 0.
```

Constraints:

- `chargeTimes.length == runningCosts.length == n`
- `1 <= n <= 5 * 10^4`
- `1 <= chargeTimes[i], runningCosts[i] <= 10^5`
- `1 <= budget <= 10^15`

SOLUTION (PYTHON 3)

Solution 1: Two Pointers + Monotonic Queue

How to think about it

A contiguous team costs the window's max charge time plus length times the sum of running costs. $n \le 5 \times 10^4$; scanning every window for the max is too slow. Cost grows with length, so the left end only moves right. Expand the right end with a monotonic deque for the max charge and a sum s for running costs. When over budget, drop stale indices and move left. The maximum width is the answer.

The problem is essentially finding the maximum value within a sliding window, which can be solved using a monotonic queue.

We only need to use binary search to enumerate the size of the window k, and find the largest k that satisfies the problem requirements.

In the implementation process, we don't actually need to perform binary search enumeration. We just need to change the fixed window to a non-fixed window with double pointers.

The time complexity is O(n), and the space complexity is O(n), where n is the number of robots in the problem.

Python 3

```python
class Solution:
    def maximumRobots(
        self, chargeTimes: List[int], runningCosts: List[int], budget: int
    ) -> int:
        q = deque()
        ans = s = l = 0
        for r, (t, c) in enumerate(zip(chargeTimes, runningCosts)):
            s += c
            while q and chargeTimes[q[-1]] <= t:
                q.pop()
            q.append(r)
            while q and (r - l + 1) * s + chargeTimes[q[0]] > budget:
                if q[0] == l:
                    q.popleft()
                s -= runningCosts[l]
                l += 1
            ans = max(ans, r - l + 1)
        return ans
```

                window.popleft()
            left += 1
        if right - left > best[1] - best[0]:
            best = (left, right)
    return best
```

PATTERN 10 · QUEUE / DEQUE · PROBLEM 11 OF 20

1429. First Unique Number

Medium · Design, Queue, Array, Hash Table, Data Stream

leetcode.com/problems/first-unique-number

PROBLEM

You have a queue of integers, you need to retrieve the first unique integer in the queue.

Implement the `FirstUnique` class:

- `FirstUnique(int[] nums)` Initializes the object with the numbers in the queue.
- `int showFirstUnique()` returns the value of **the first unique** integer of the queue, and returns **-1** if there is no such integer.
- `void add(int value)` insert value to the queue.

Example 1:

```
Input:
["FirstUnique","showFirstUnique","add","showFirstUnique","add","showFirstUnique","add","showFirstUniqu
e"]
[[[2,3,5]],[],[5],[],[2],[],[3],[]]
Output:
[null,2,null,2,null,3,null,-1]
Explanation:
FirstUnique firstUnique = new FirstUnique([2,3,5]);
firstUnique.showFirstUnique(); // return 2
firstUnique.add(5); // the queue is now [2,3,5,5]
firstUnique.showFirstUnique(); // return 2
firstUnique.add(2); // the queue is now [2,3,5,5,2]
firstUnique.showFirstUnique(); // return 3
firstUnique.add(3); // the queue is now [2,3,5,5,2,3]
firstUnique.showFirstUnique(); // return -1
```

Example 2:

```
Input:
["FirstUnique","showFirstUnique","add","add","add","add","add","showFirstUnique"]
[[[7,7,7,7,7,7]],[],[7],[3],[3],[7],[17],[]]
Output:
[null,-1,null,null,null,null,null,17]
Explanation:
FirstUnique firstUnique = new FirstUnique([7,7,7,7,7,7]);
firstUnique.showFirstUnique(); // return -1
firstUnique.add(7); // the queue is now [7,7,7,7,7,7,7]
firstUnique.add(3); // the queue is now [7,7,7,7,7,7,7,3]
firstUnique.add(3); // the queue is now [7,7,7,7,7,7,7,3,3]
firstUnique.add(7); // the queue is now [7,7,7,7,7,7,7,3,3,7]
firstUnique.add(17); // the queue is now [7,7,7,7,7,7,7,3,3,7,17]
firstUnique.showFirstUnique(); // return 17
```

Example 3:

```
Input:
["FirstUnique","showFirstUnique","add","showFirstUnique"]
[[[809]],[],[809],[]]
Output:
[null,809,null,-1]
Explanation:
FirstUnique firstUnique = new FirstUnique([809]);
firstUnique.showFirstUnique(); // return 809
firstUnique.add(809); // the queue is now [809,809]
firstUnique.showFirstUnique(); // return -1
```

Constraints:

- `1 <= nums.length <= 10^5`
- `1 <= nums[i] <= 10^8`
- `1 <= value <= 10^8`
- At most `50000` calls will be made to `showFirstUnique` and `add`.

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

After many `add`s we must report the oldest value that still occurs once. A counter alone loses order; a queue alone cannot delete a value that just became duplicate. Count frequencies and keep current uniques in an `OrderedDict`. On `add`, insert when the count becomes 1 and erase when it becomes 2. `showFirstUnique` returns the first remaining key.

Python 3

```python
class FirstUnique:
    def __init__(self, nums: List[int]):
        self.cnt = Counter(nums)
        self.unique = OrderedDict({v: 1 for v in nums if self.cnt[v] == 1})

    def showFirstUnique(self) -> int:
        return -1 if not self.unique else next(v for v in self.unique.keys())

    def add(self, value: int) -> None:
        self.cnt[value] += 1
        if self.cnt[value] == 1:
            self.unique[value] = 1
        elif value in self.unique:
            self.unique.pop(value)

# Your FirstUnique object will be instantiated and called as such:
# obj = FirstUnique(nums)
# param_1 = obj.showFirstUnique()
# obj.add(value)
```

Complexity. Time: constructor O(n), showFirstUnique and add O(1). Space: O(n).

Solution 2

How to think about it

Method 1 deletes from the ordered map as soon as a value repeats. We can instead append to a deque and, on query, pop front elements whose count is no longer one. Lazy deletion keeps the same answer with less bookkeeping.

Python 3

```python
class FirstUnique:
    def __init__(self, nums: List[int]):
        self.cnt = Counter(nums)
        self.q = deque(nums)

    def showFirstUnique(self) -> int:
        while self.q and self.cnt[self.q[0]] != 1:
            self.q.popleft()
        return -1 if not self.q else self.q[0]

    def add(self, value: int) -> None:
        self.cnt[value] += 1
        self.q.append(value)

# Your FirstUnique object will be instantiated and called as such:
# obj = FirstUnique(nums)
# param_1 = obj.showFirstUnique()
# obj.add(value)
```

Complexity. Time: constructor O(n), add O(1), showFirstUnique O(1) amortised. Space: O(n).

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

Built on the solutions above: helper functions, then the function for each follow-up. No tests and no restating of the question.

```python
# FOLLOW-UPS (answered below, in this order):
# 1. Support removing a number from the queue
# 2. The k-th unique number

# ========================================================
# FOLLOW-UP 1: Support removing a number from the queue
# ========================================================

# ---- follow-up 1: function ----
# Answer: Keep the count of every number and a queue of
# numbers in arrival order. Removing a number sets its
# count to 2 (so it is never unique again); the queue
# front is cleaned lazily.
# Time: add and remove O(1), show_first_unique O(1)
# amortised.  Space: O(n).
from collections import deque

class FirstUniqueWithRemoval:
    def __init__(self, nums):
        self.count = {}
        self.queue = deque()

    def add(self, value):
        self.count[value] = self.count.get(value, 0) + 1
        if self.count[value] == 1:
            self.queue.append(value)

    def remove(self, value):
        if value in self.count:
            self.count[value] = 2                    # never unique again

    def show_first_unique(self):
        while self.queue and self.count[self.queue[0]] > 1:
            self.queue.popleft()
        if self.queue:
            return self.queue[0]
        return -1
```

```
# ============================================================
# FOLLOW-UP 2: The k-th unique number
# ============================================================

# ---- follow-up 2: function ----
# Answer: Walk the arrival-order list and skip numbers
# that are no longer unique until the k-th unique one is
# found: O(n) per query.
# Time: add O(1), kth O(n).  Space: O(n).
class KthUnique:
    def __init__(self):
        self.count = {}
        self.order = []

    def add(self, value):
        self.count[value] = self.count.get(value, 0) + 1
        if self.count[value] == 1:
            self.order.append(value)

    def kth(self, k):
        seen = 0
        for value in self.order:
            if self.count[value] == 1:
                seen += 1
                if seen == k:
                    return value
        return -1
```

PATTERN 10 · QUEUE / DEQUE · PROBLEM 12 OF 20

353. Design Snake Game

Medium · Design, Queue, Array, Hash Table, Simulation

leetcode.com/problems/design-snake-game

★ **TOP 10 PROBLEM** in Queue / Deque: master this one first

PROBLEM

Design a Snake game that is played on a device with screen size `height x width`. Play the game online if you are not familiar with the game.

The snake is initially positioned at the top left corner `(0, 0)` with a length of `1` unit.

You are given an array `food` where `food[i] = (r_i, c_i)` is the row and column position of a piece of food that the snake can eat. When a snake eats a piece of food, its length and the game's score both increase by `1`.

Each piece of food appears one by one on the screen, meaning the second piece of food will not appear until the snake eats the first piece of food.

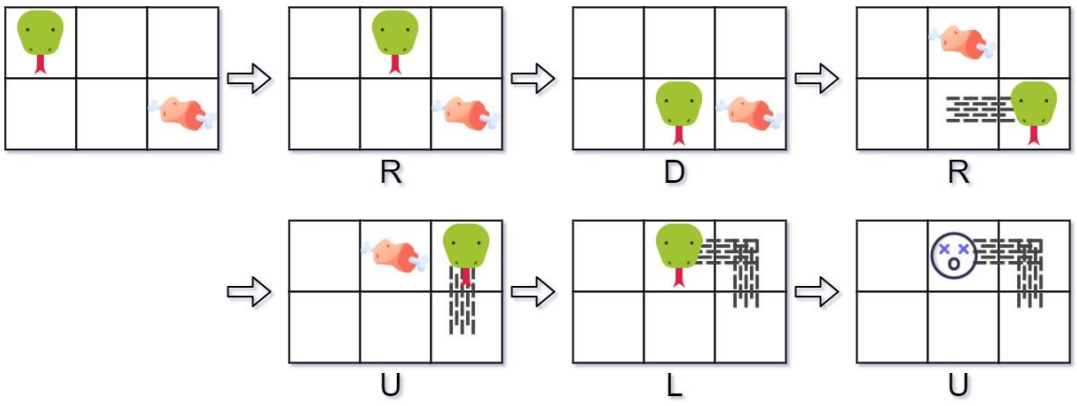
When a piece of food appears on the screen, it is **guaranteed** that it will not appear on a block occupied by the snake.

The game is over if the snake goes out of bounds (hits a wall) or if its head occupies a space that its body occupies **after** moving (i.e. a snake of length 4 cannot run into itself).

Implement the `SnakeGame` class:

- `SnakeGame(int width, int height, int[][] food)` Initializes the object with a screen of size `height x width` and the positions of the `food`.
- `int move(String direction)` Returns the score of the game after applying one `direction` move by the snake. If the game is over, return `-1`.

Example 1:



```
Input
["SnakeGame", "move", "move", "move", "move", "move", "move"]
[[3, 2, [[1, 2], [0, 1]]], ["R"], ["D"], ["R"], ["U"], ["L"], ["U"]]
Output
[null, 0, 0, 1, 1, 2, -1]

Explanation
SnakeGame snakeGame = new SnakeGame(3, 2, [[1, 2], [0, 1]]);
snakeGame.move("R"); // return 0
snakeGame.move("D"); // return 0
snakeGame.move("R"); // return 1, snake eats the first piece of food. The second piece of food appears
at (0, 1).
snakeGame.move("U"); // return 1
snakeGame.move("L"); // return 2, snake eats the second food. No more food appears.
snakeGame.move("U"); // return -1, game over because snake collides with border
```

Constraints:

- `1 <= width, height <= 10^4`
- `1 <= food.length <= 50`
- `food[i].length == 2`
- `0 <= r_i < height`
- `0 <= c_i < width`
- `direction.length == 1`
- `direction` is `'U'`, `'D'`, `'L'`, or `'R'`.
- At most `10^4` calls will be made to `move`.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Simulate snake: out of bounds or self-bite ends the game; food grows the body. The body is a queue with frequent head/tail updates. A deque stores the body (head at the front) and a set tests collisions. Compute the new head: -1 if out of bounds; on food, score and keep the tail, otherwise pop the tail. Then reject a body hit and push the head. Removing the tail first makes the old tail cell legal.

Python 3

```python
class SnakeGame:
    def __init__(self, width: int, height: int, food: List[List[int]]):
        self.m = height
        self.n = width
        self.food = food
        self.score = 0
        self.idx = 0
        self.q = deque([(0, 0)])
        self.vis = {(0, 0)}

    def move(self, direction: str) -> int:
        i, j = self.q[0]
        x, y = i, j
        match direction:
            case "U":
                x -= 1
            case "D":
                x += 1
            case "L":
                y -= 1
            case "R":
                y += 1
        if x < 0 or x >= self.m or y < 0 or y >= self.n:
            return -1
        if (
            self.idx < len(self.food)
            and x == self.food[self.idx][0]
            and y == self.food[self.idx][1]
        ):
            self.score += 1
            self.idx += 1
        else:
            self.vis.remove(self.q.pop())
        if (x, y) in self.vis:
            return -1
        self.q.appendleft((x, y))
        self.vis.add((x, y))
        return self.score

# Your SnakeGame object will be instantiated and called as such:
# obj = SnakeGame(width, height, food)
# param_1 = obj.move(direction)
```

Complexity. Time: O(1) per move. Space: O(L), L = length of the snake.

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

Built on the solutions above: helper functions, then the function for each follow-up. No tests and no restating of the question.

```python
# FOLLOW-UPS (answered below, in this order):
# 1. The snake wraps around the walls instead of dying,
# and there are obstacles

1696. Jump Game VI

Medium · Queue, Array, Dynamic Programming, Monotonic Queue, Heap (Priority Queue)

leetcode.com/problems/jump-game-vi

★ **TOP 10 PROBLEM** in Queue / Deque, Sliding Window Maximum / Minimum (Specific Variants): master this one first

Also appears in pattern 35 Sliding Window Maximum / Minimum (Specific Variants)

PROBLEM

You are given a **0-indexed** integer array `nums` and an integer `k`.

You are initially standing at index `0`. In one move, you can jump at most `k` steps forward without going outside the boundaries of the array. That is, you can jump from index `i` to any index in the range `[i + 1, min(n - 1, i + k)]` **inclusive**.

You want to reach the last index of the array (index `n - 1`). Your **score** is the **sum** of all `nums[j]` for each index `j` you visited in the array.

Return *the **maximum score** you can get*.

Example 1:

```
Input: nums = [1,-1,-2,4,-7,3], k = 2
Output: 7
Explanation: You can choose your jumps forming the subsequence [1,-1,4,3] (underlined above). The sum is 7.
```

Example 2:

```
Input: nums = [10,-5,-2,4,0,3], k = 3
Output: 17
Explanation: You can choose your jumps forming the subsequence [10,4,3] (underlined above). The sum is 17.
```

Example 3:

```
Input: nums = [1,-5,-20,4,-1,3,-6,-3], k = 2
Output: 0
```

Constraints:

- `1 <= nums.length, k <= 10^5`
- `-10^4 <= nums[i] <= 10^4`

SOLUTION (PYTHON 3)

Solution 1: Dynamic Programming + Monotonic Queue Optimization

How to think about it

From i we may jump into (i,i+k], adding the landing value, and want the best score at the end. Naive f[i]=nums[i]+max$_{i-k \le j < i}$ f[j] is O(nk) for n=10^5. A decreasing deque of indices holds the window maximum: f[q[0]] is the best predecessor; the back drops worse f values and the front drops indices that left the window.

We define f[i] as the maximum score when reaching index i. The value of f[i] can be transferred from f[j], where j satisfies i - k ≤ j ≤ i - 1. Therefore, we can use dynamic programming to solve this problem.

The state transition equation is:

$$f[i] = \max_{j \in [i-k,\, i-1]} f[j] + nums[i]$$

We can use a monotonic queue to optimize the state transition equation. Specifically, we maintain a monotonically decreasing queue, which stores the index j, and the f[j] values corresponding to the indices in the queue are monotonically decreasing. When performing state transition, we only need to take out the index j at the front of the queue to get the maximum value of f[j], and then update the value of f[i] to f[j] + nums[i].

The time complexity is O(n), and the space complexity is O(n). Here, n is the length of the array.

Python 3

```
class Solution:
    def maxResult(self, nums: List[int], k: int) -> int:
        n = len(nums)
        f = [0] * n
        q = deque([0])
        for i in range(n):
            if i - q[0] > k:
                q.popleft()
            f[i] = nums[i] + f[q[0]]
            while q and f[q[-1]] <= f[i]:
                q.pop()
            q.append(i)
        return f[-1]
```

1823. Find the Winner of the Circular Game

Medium · Recursion, Queue, Array, Math, Simulation

leetcode.com/problems/find-the-winner-of-the-circular-game

Also appears in pattern 39 Game Theory / Minimax

PROBLEM

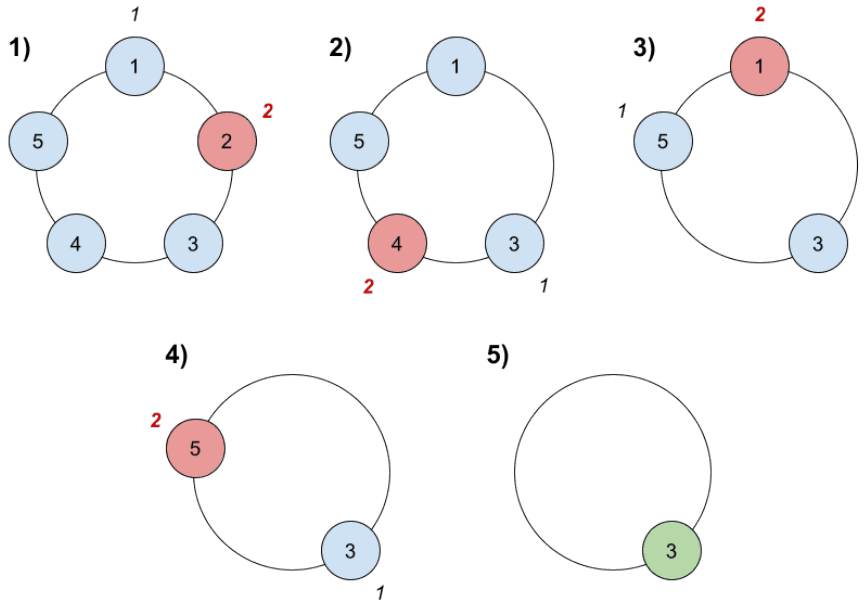
There are `n` friends that are playing a game. The friends are sitting in a circle and are numbered from `1` to `n` in **clockwise order**. More formally, moving clockwise from the `i`th friend brings you to the `(i+1)`th friend for `1 <= i < n`, and moving clockwise from the `n`th friend brings you to the `1`st friend.

The rules of the game are as follows:

1. **Start** at the `1`st friend.
2. Count the next `k` friends in the clockwise direction **including** the friend you started at. The counting wraps around the circle and may count some friends more than once.
3. The last friend you counted leaves the circle and loses the game.
4. If there is still more than one friend in the circle, go back to step `2` **starting** from the friend **immediately clockwise** of the friend who just lost and repeat.
5. Else, the last friend in the circle wins the game.

Given the number of friends, `n`, and an integer `k`, return *the winner of the game*.

Example 1:



```
Input: n = 5, k = 2
Output: 3
Explanation: Here are the steps of the game:
1) Start at friend 1.
2) Count 2 friends clockwise, which are friends 1 and 2.
3) Friend 2 leaves the circle. Next start is friend 3.
4) Count 2 friends clockwise, which are friends 3 and 4.
5) Friend 4 leaves the circle. Next start is friend 5.
6) Count 2 friends clockwise, which are friends 5 and 1.
7) Friend 1 leaves the circle. Next start is friend 3.
8) Count 2 friends clockwise, which are friends 3 and 5.
9) Friend 5 leaves the circle. Only friend 3 is left, so they are the winner.
```

Example 2:

```
Input: n = 6, k = 5
Output: 1
Explanation: The friends leave in this order: 5, 4, 6, 2, 3. The winner is friend 1.
```

Constraints:

- `1 <= k <= n <= 500`

Follow up:

Could you solve this problem in linear time with constant space?

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

n people stand in a circle and every k-th person is eliminated. n≤ 500, so a list simulation would pass, but counting k steps naively does not use the recurrence. The winner among n people is the winner among n-1 people shifted by k modulo n (treating 0 as n). The base case n=1 is person 1. The recurrence solves the game in O(n).

Python 3

```python
class Solution:
    def findTheWinner(self, n: int, k: int) -> int:
        if n == 1:
            return 1
        ans = (k + self.findTheWinner(n - 1, k)) % n
        return n if ans == 0 else ans
```

Solution 2: Simulation

How to think about it

Solution 1 is a compact index recurrence. We can instead keep the remaining people in a list or deque and repeatedly count to k and delete until one remains. With small n the simulation stays faithful to the statement and the 1-based labels.

Python 3 (written for this guide: the doocs page has no Python 3 version of this solution)

```python
class Solution:
    def findTheWinner(self, n: int, k: int) -> int:
        friends = list(range(1, n + 1))
        i = 0
        while len(friends) > 1:
            i = (i + k - 1) % len(friends)
            friends.pop(i)
        return friends[0]
```

Complexity. Time: O(n^2) (removing from the middle of a list is O(n)). Space: O(n).

```

PATTERN 10 · QUEUE / DEQUE · PROBLEM 20 OF 20

936. Stamping The Sequence

Hard · Stack, Greedy, Queue, String

leetcode.com/problems/stamping-the-sequence

PROBLEM

You are given two strings `stamp` and `target`. Initially, there is a string `s` of length `target.length` with all `s[i] == '?'`.

In one turn, you can place `stamp` over `s` and replace every letter in the `s` with the corresponding letter from `stamp`.

- For example, if `stamp = "abc"` and `target = "abcba"`, then `s` is `"?????"` initially. In one turn you can: Note that `stamp` must be fully contained in the boundaries of `s` in order to stamp (i.e., you cannot place `stamp` at index `3` of `s`).
  - place `stamp` at index `0` of `s` to obtain `"abc??"`,
  - place `stamp` at index `1` of `s` to obtain `"?abc?"`, or
  - place `stamp` at index `2` of `s` to obtain `"??abc"`.

We want to convert `s` to `target` using **at most** `10 * target.length` turns.

Return *an array of the index of the left-most letter being stamped at each turn*. If we cannot obtain `target` from `s` within `10 * target.length` turns, return an empty array.

Example 1:

```
Input: stamp = "abc", target = "ababc"
Output: [0,2]
Explanation: Initially s = "?????".
- Place stamp at index 0 to get "abc??".
- Place stamp at index 2 to get "ababc".
[1,0,2] would also be accepted as an answer, as well as some other answers.
```

Example 2:

```
Input: stamp = "abca", target = "aabcaca"
Output: [3,0,1]
Explanation: Initially s = "???????".
- Place stamp at index 3 to get "???abca".
- Place stamp at index 0 to get "abcabca".
- Place stamp at index 1 to get "aabcaca".
```

Constraints:

- `1 <= stamp.length <= target.length <= 1000`
- `stamp` and `target` consist of lowercase English letters.

SOLUTION (PYTHON 3)

Solution 1: Reverse Thinking + Topological Sorting

> **How to think about it**
>
> Forward stamping overwrites earlier marks, so it is hard to know when a stamp is legal. Work backward from target toward question marks: a window can be “unstamped” once every still-visible letter matches the stamp. The in-degree of a window is the number of mismatched letters; each position points at the windows that still need it. Windows of degree 0 enter a queue; unstamping them notifies neighbors. If every cell is covered, reverse the order to obtain a forward sequence.

If we operate on the sequence in a forward manner, it would be quite complicated because subsequent operations would overwrite previous ones. Therefore, we consider operating on the sequence in a reverse manner, i.e., starting from the

target string target and considering the process of turning target into ?????.

Let's denote the length of the stamp as m and the length of the target string as n. If we operate on the target string with the stamp, there are n-m+1 starting positions where the stamp can be placed. We can enumerate these n-m+1 starting positions and use a method similar to topological sorting to operate in reverse.

Firstly, we clarify that each starting position corresponds to a window of length m.

Next, we define the following data structures or variables:

- In-degree array indeg, where indeg[i] represents how many characters in the i-th window are different from the characters in the stamp. Initially, indeg[i]=m. If indeg[i]=0, it means that all characters in the i-th window are the same as those in the stamp, and we can place the stamp in the i-th window.
- Adjacency list g, where g[i] represents the set of all windows with different characters from the stamp on the i-th position of the target string target.
- Queue q, used to store the numbers of all windows with an in-degree of 0.
- Array vis, used to mark whether each position of the target string target has been covered.
- Array ans, used to store the answer.

Then, we perform topological sorting. In each step of the topological sorting, we take out the window number i at the head of the queue, and put i into the answer array ans. Then, we enumerate each position j in the stamp. If the j-th position in the i-th window has not been covered, we cover it and reduce the in-degree of all windows in the indeg array that are the same as the j-th position in the i-th window by 1. If the in-degree of a window becomes 0, we put it into the queue q for processing next time.

After the topological sorting is over, if every position of the target string target has been covered, then the answer array ans stores the answer we are looking for. Otherwise, the target string target cannot be covered, and we return an empty array.

The time complexity is O(n × (n - m + 1)), and the space complexity is O(n × (n - m + 1)). Here, n and m are the lengths of the target string target and the stamp, respectively.

Python 3

```python
class Solution:
    def movesToStamp(self, stamp: str, target: str) -> List[int]:
        m, n = len(stamp), len(target)
        indeg = [m] * (n - m + 1)
        q = deque()
        g = [[] for _ in range(n)]
        for i in range(n - m + 1):
            for j, c in enumerate(stamp):
                if target[i + j] == c:
                    indeg[i] -= 1
                    if indeg[i] == 0:
                        q.append(i)
                else:
                    g[i + j].append(i)
        ans = []
        vis = [False] * n
        while q:
            i = q.popleft()
            ans.append(i)
            for j in range(m):
                if not vis[i + j]:
                    vis[i + j] = True
                    for k in g[i + j]:
                        indeg[k] -= 1
                        if indeg[k] == 0:
                            q.append(k)
        return ans[::-1] if all(vis) else []
```

94. Binary Tree Inorder Traversal

Easy · Stack, Tree, Depth-First Search, Binary Tree

leetcode.com/problems/binary-tree-inorder-traversal

PROBLEM

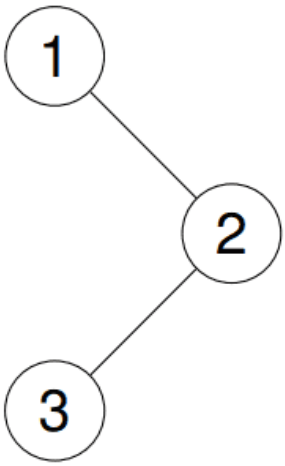
Given the `root` of a binary tree, return *the inorder traversal of its nodes' values*.

Example 1:

Input: root = [1,null,2,3]

Output: [1,3,2]

Explanation:

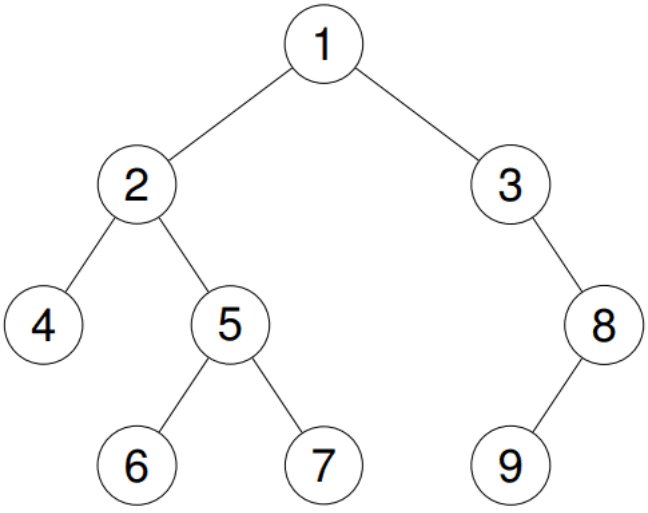


Example 2:

Input: root = [1,2,3,4,5,null,8,null,null,6,7,9]

Output: [4,2,6,5,7,1,3,9,8]

Explanation:



Example 3:

Input: root = []

Output: []

Example 4:

Input: root = [1]

Output: [1]

Constraints:

- The number of nodes in the tree is in the range `[0, 100]`.
- `-100 <= Node.val <= 100`

Follow up:

Recursive solution is trivial, could you do it iteratively?

SOLUTIONS (PYTHON 3)

Solution 1: Recursive Traversal

> **How to think about it**
>
> Inorder is left, root, right. A tree is already recursive, so the first idea is recursion: finish the left subtree, record the root, then walk the right. n ≤ 100, so an O(n) call stack is fine. The follow-up is what asks for iteration.

We first recursively traverse the left subtree, then visit the root node, and finally recursively traverse the right subtree.

The time complexity is O(n), and the space complexity is O(n). Here, n is the number of nodes in the binary tree, and the space complexity mainly depends on the stack space of the recursive call.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def inorderTraversal(self, root: Optional[TreeNode]) -> List[int]:
        def dfs(root):
            if root is None:
                return
            dfs(root.left)
            ans.append(root.val)
            dfs(root.right)

        ans = []
        dfs(root)
        return ans
```

Solution 2: Stack Implementation for Non-recursive Traversal

> **How to think about it**
>
> Solution 1 is correct; the follow-up drops the call stack. Recursion is “go left until you cannot, then pop, visit, and turn right”. An explicit stack simulates that: push while a left child exists, otherwise pop, visit, and move to the right child. Same order as inorder, still O(n) space.

The non-recursive approach is as follows:

1. Define a stack `stk`.
2. Push the left nodes of the tree into the stack in sequence.
3. When the left node is null, pop and process the top element of the stack.

4. Repeat steps 2-3.

The time complexity is O(n), and the space complexity is O(n). Here, n is the number of nodes in the binary tree, and the space complexity mainly depends on the stack space.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def inorderTraversal(self, root: Optional[TreeNode]) -> List[int]:
        ans, stk = [], []
        while root or stk:
            if root:
                stk.append(root)
                root = root.left
            else:
                root = stk.pop()
                ans.append(root.val)
                root = root.right
        return ans
```

Solution 3: Morris Implementation for In-order Traversal

> **How to think about it**
>
> A stack still costs O(h). Morris notices that the successor of the rightmost node in the left subtree is the current root, and that right pointer is unused. Temporarily thread it to the root, walk down the left chain, then undo the link on the way back. The tree's null pointers become the stack, inorder is preserved, and extra space is O(1).

Morris traversal does not require a stack, so the space complexity is O(1). The core idea is:

Traverse the binary tree nodes,

1. If the left subtree of the current node `root` is null, **add the current node value to the result list** `ans`, and update the current node to `root.right`.
2. If the left subtree of the current node `root` is not null, find the rightmost node `prev` of the left subtree (which is the predecessor node of the `root` node in in-order traversal):
   - If the right subtree of the predecessor node `prev` is null, point the right subtree of the predecessor node to the current node `root`, and update the current node to `root.left`.
   - If the right subtree of the predecessor node `prev` is not null, **add the current node value to the result list** `ans`, then point the right subtree of the predecessor node to null (i.e., disconnect `prev` and `root`), and update the current node to `root.right`.
3. Repeat the above steps until the binary tree node is null, and the traversal ends.

The time complexity is O(n), and the space complexity is O(1). Here, n is the number of nodes in the binary tree.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def inorderTraversal(self, root: Optional[TreeNode]) -> List[int]:
        ans = []
        while root:
            if root.left is None:
                ans.append(root.val)
                root = root.right
            else:
                prev = root.left
                while prev.right and prev.right != root:
                    prev = prev.right
                if prev.right is None:
                    prev.right = root
                    root = root.left
                else:
                    ans.append(root.val)
                    prev.right = None
                    root = root.right
        return ans
```

144. Binary Tree Preorder Traversal

Easy · Stack, Tree, Depth-First Search, Binary Tree

leetcode.com/problems/binary-tree-preorder-traversal

PROBLEM

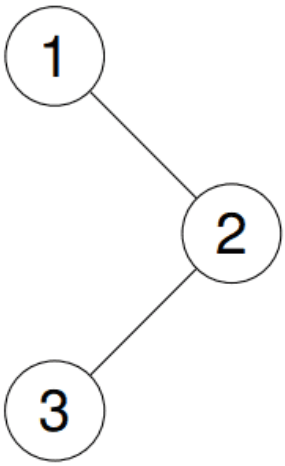
Given the `root` of a binary tree, return *the preorder traversal of its nodes' values*.

Example 1:

Input: root = [1,null,2,3]

Output: [1,2,3]

Explanation:

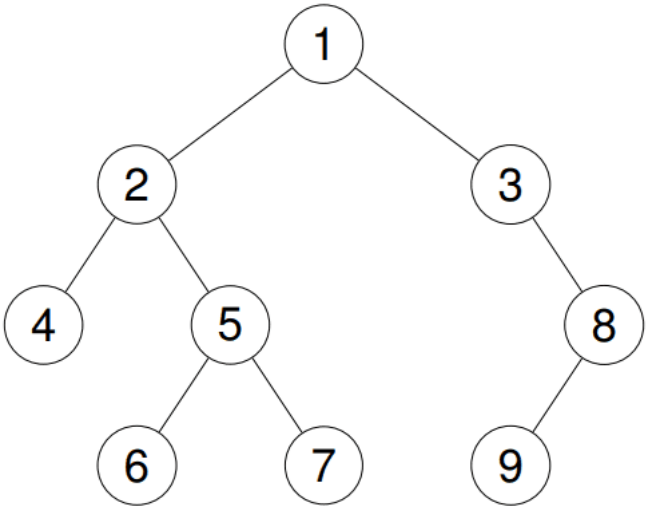


Example 2:

Input: root = [1,2,3,4,5,null,8,null,null,6,7,9]

Output: [1,2,4,5,6,7,3,8,9]

Explanation:



Example 3:

Input: root = []

Output: []

Example 4:

Input: root = [1]

Output: [1]

Constraints:

- The number of nodes in the tree is in the range `[0, 100]`.
- `-100 <= Node.val <= 100`

Follow up: Recursive solution is trivial, could you do it iteratively?

SOLUTIONS (PYTHON 3)

Solution 1: Recursive Traversal

How to think about it

Preorder is root, left, right. A tree is recursive, so record the root and recurse on both children. n≤ 100, so the call stack is fine. The follow-up asks for iteration.

We first visit the root node, then recursively traverse the left and right subtrees.

The time complexity is O(n), and the space complexity is O(n). Here, n is the number of nodes in the binary tree. The space complexity mainly depends on the stack space used for recursive calls.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def preorderTraversal(self, root: Optional[TreeNode]) -> List[int]:
        def dfs(root):
            if root is None:
                return
            ans.append(root.val)
            dfs(root.left)
            dfs(root.right)

        ans = []
        dfs(root)
        return ans
```

Solution 2: Stack Implementation for Non-Recursive Traversal

How to think about it

Solution 1 is already correct; the follow-up drops the call stack. An explicit stack pushes right then left, so popping visits root first. Same order, still O(n) space.

The idea of using a stack to implement non-recursive traversal is as follows:

1. Define a stack stk, and first push the root node into the stack.
2. If the stack is not empty, pop a node from the stack each time.
3. Process the node.
4. First push the right child of the node into the stack, then push the left child of the node into the stack (if there are child nodes).
5. Repeat steps 2-4.

6. Return the result.

The time complexity is O(n), and the space complexity is O(n). Here, n is the number of nodes in the binary tree. The space complexity mainly depends on the stack space.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def preorderTraversal(self, root: Optional[TreeNode]) -> List[int]:
        ans = []
        if root is None:
            return ans
        stk = [root]
        while stk:
            node = stk.pop()
            ans.append(node.val)
            if node.right:
                stk.append(node.right)
            if node.left:
                stk.append(node.left)
        return ans
```

Solution 3: Morris Preorder Traversal

> **How to think about it**
>
> Solution 2 still uses O(h) space. Morris temporarily links the rightmost node of the left subtree to the current root, emits the root on the first visit, and clears the link on return. The tree's null pointers act as the stack, O(1) space.

Morris traversal does not require a stack, and its space complexity is O(1). The core idea is:

Traverse the binary tree nodes,

1. If the left subtree of the current node `root` is empty, add the current node value to the result list ans, and update the current node to `root.right`.
1. If the left subtree of the current node `root` is not empty, find the rightmost node `pre` of the left subtree (which is the predecessor of the `root` node in inorder traversal):
   - If the right subtree of the predecessor node `pre` is empty, add the current node value to the result list ans, then point the right subtree of the predecessor node to the current node `root`, and update the current node to `root.left`.
   - If the right subtree of the predecessor node `pre` is not empty, point the right subtree of the predecessor node to null (i.e., disconnect `pre` and `root`), and update the current node to `root.right`.
1. Repeat the above steps until the binary tree node is null, and the traversal ends.

The time complexity is O(n), where n is the number of nodes in the binary tree. The space complexity is O(1).

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def preorderTraversal(self, root: Optional[TreeNode]) -> List[int]:
        ans = []
        while root:
            if root.left is None:
                ans.append(root.val)
                root = root.right
            else:
                prev = root.left
                while prev.right and prev.right != root:
                    prev = prev.right
                if prev.right is None:
                    ans.append(root.val)
                    prev.right = root
                    root = root.left
                else:
                    prev.right = None
                    root = root.right
        return ans
```

    return result
```

145. Binary Tree Postorder Traversal

Easy · Stack, Tree, Depth-First Search, Binary Tree

leetcode.com/problems/binary-tree-postorder-traversal

PROBLEM

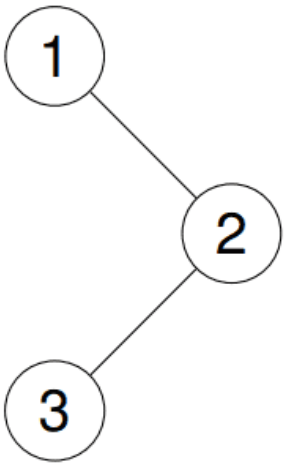
Given the `root` of a binary tree, return *the postorder traversal of its nodes' values*.

Example 1:

Input: root = [1,null,2,3]

Output: [3,2,1]

Explanation:

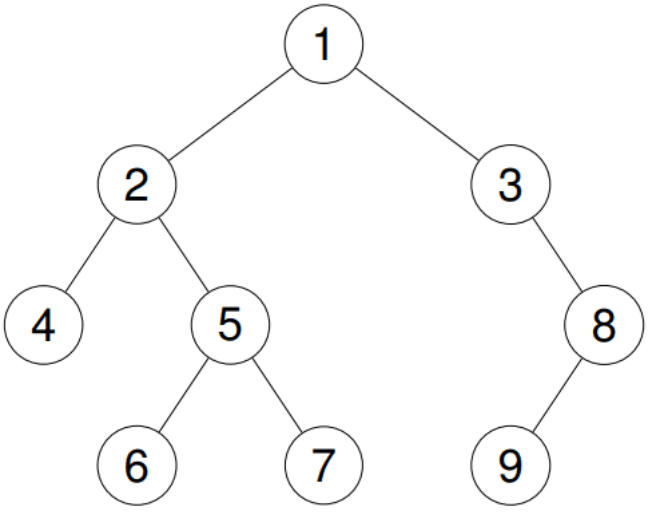


Example 2:

Input: root = [1,2,3,4,5,null,8,null,null,6,7,9]

Output: [4,6,7,5,2,9,8,3,1]

Explanation:



Example 3:

Input: root = []

Output: []

Example 4:

Input: root = [1]

Output: [1]

Constraints:

- The number of the nodes in the tree is in the range `[0, 100]`.
- `-100 <= Node.val <= 100`

Follow up:

Recursive solution is trivial, could you do it iteratively?

SOLUTIONS (PYTHON 3)

Solution 1: Recursion

> **How to think about it**
>
> Postorder is left, right, root. Recurse on both children, then record the root. n≤ 100, so recursion is fine. The follow-up asks for iteration.

We first recursively traverse the left and right subtrees, then visit the root node.

The time complexity is O(n), and the space complexity is O(n). Here, n is the number of nodes in the binary tree. The space complexity mainly depends on the stack space used for recursive calls.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def postorderTraversal(self, root: Optional[TreeNode]) -> List[int]:
        def dfs(root):
            if root is None:
                return
            dfs(root.left)
            dfs(root.right)
            ans.append(root.val)

        ans = []
        dfs(root)
        return ans
```

Solution 2: Stack Implementation for Postorder Traversal

> **How to think about it**
>
> Solution 1 uses the call stack. Root-right-left is preorder with children swapped; reversing it yields left-right-root. Traverse in that order with a stack and reverse the result, with no “second visit” flag.

The order of preorder traversal is: root, left, right. If we change the order of the left and right children, the order becomes: root, right, left. Finally, reversing the result gives us the postorder traversal result.

Therefore, the idea of using a stack to implement non-recursive traversal is as follows:

1. Define a stack stk, and first push the root node into the stack.
2. If the stack is not empty, pop a node from the stack each time.

3. Process the node.
4. First push the left child of the node into the stack, then push the right child of the node into the stack (if there are child nodes).
5. Repeat steps 2-4.
6. Reverse the result to get the postorder traversal result.

The time complexity is O(n), and the space complexity is O(n). Here, n is the number of nodes in the binary tree. The space complexity mainly depends on the stack space.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def postorderTraversal(self, root: Optional[TreeNode]) -> List[int]:
        ans = []
        if root is None:
            return ans
        stk = [root]
        while stk:
            node = stk.pop()
            ans.append(node.val)
            if node.left:
                stk.append(node.left)
            if node.right:
                stk.append(node.right)
        return ans[::-1]
```

Solution 3: Morris Implementation for Postorder Traversal

> **How to think about it**
>
> Solution 2 still needs an O(n) stack and a reverse. Morris threads the tree in root-right-left order and reverses the output, so extra space becomes O(1).

Morris traversal does not require a stack, and its space complexity is O(1). The core idea is:

Traverse the binary tree nodes,

1. If the right subtree of the current node `root` is empty, add the current node value to the result list ans, and update the current node to `root.left`.
1. If the right subtree of the current node `root` is not empty, find the leftmost node `next` of the right subtree (which is the successor of the `root` node in inorder traversal):
   - If the left subtree of the successor node `next` is empty, add the current node value to the result list ans, then point the left subtree of the successor node to the current node `root`, and update the current node to `root.right`.
   - If the left subtree of the successor node `next` is not empty, point the left subtree of the successor node to null (i.e., disconnect `next` and `root`), and update the current node to `root.left`.
1. Repeat the above steps until the binary tree node is null, and the traversal ends.
1. Finally, return the reverse of the result list.

The idea of Morris postorder traversal is consistent with Morris preorder traversal, just change the "root-left-right" of preorder to "root-right-left", and finally reverse the result to become "left-right-root".

The time complexity is O(n), where n is the number of nodes in the binary tree. The space complexity is O(1).

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def postorderTraversal(self, root: Optional[TreeNode]) -> List[int]:
        ans = []
        while root:
            if root.right is None:
                ans.append(root.val)
                root = root.left
            else:
                next = root.right
                while next.left and next.left != root:
                    next = next.left
                if next.left != root:
                    ans.append(root.val)
                    next.left = root
                    root = root.right
                else:
                    next.left = None
                    root = root.left
        return ans[::-1]
```

    return result
```

104. Maximum Depth of Binary Tree

Easy · Tree, Depth-First Search, Breadth-First Search, Binary Tree

leetcode.com/problems/maximum-depth-of-binary-tree

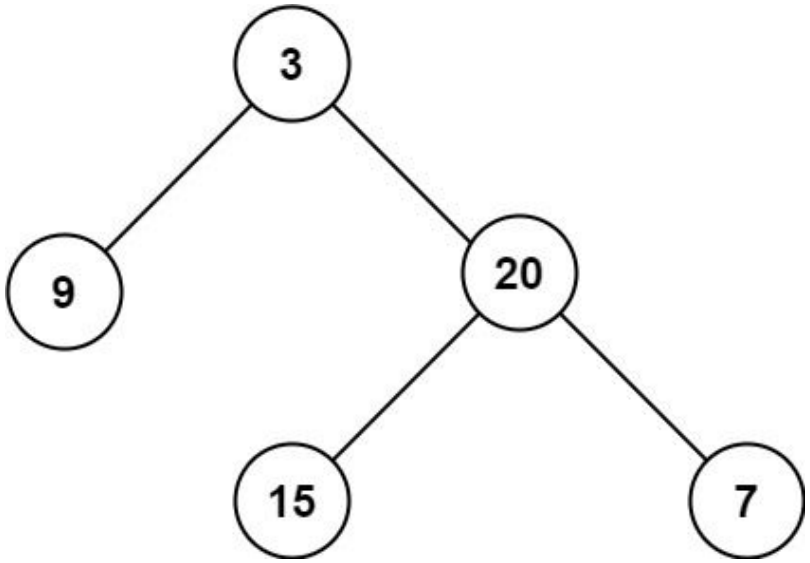
★ **TOP 10 PROBLEM** in Tree DFS (Preorder / Inorder / Postorder): master this one first

PROBLEM

Given the `root` of a binary tree, return *its maximum depth*.

A binary tree's **maximum depth** is the number of nodes along the longest path from the root node down to the farthest leaf node.

Example 1:



```
Input: root = [3,9,20,null,null,15,7]
Output: 3
```

Example 2:

```
Input: root = [1,null,2]
Output: 2
```

Constraints:

- The number of nodes in the tree is in the range `[0, 10^4]`.
- `-100 <= Node.val <= 100`

SOLUTION (PYTHON 3)

Solution 1: Recursion

How to think about it

Depth is the number of nodes on the longest root-to-leaf path. Level-order counting of layers works, and $n \le 10^4$ is fine. A tree is recursive: the depth is one plus the larger of the two subtree depths, and the empty tree has depth 0. Recurse on both children and take the max.

Recursively traverse the left and right subtrees, calculate the maximum depth of the left and right subtrees, and then take the maximum value plus 1.

The time complexity is O(n), where n is the number of nodes in the binary tree. Each node is traversed only once in the recursion.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def maxDepth(self, root: TreeNode) -> int:
        if root is None:
            return 0
        l, r = self.maxDepth(root.left), self.maxDepth(root.right)
        return 1 + max(l, r)
```

PATTERN 11 · TREE DFS (PREORDER / INORDER / POSTORDER) · PROBLEM 5 OF 20

112. Path Sum

Easy · Tree, Depth-First Search, Breadth-First Search, Binary Tree

leetcode.com/problems/path-sum

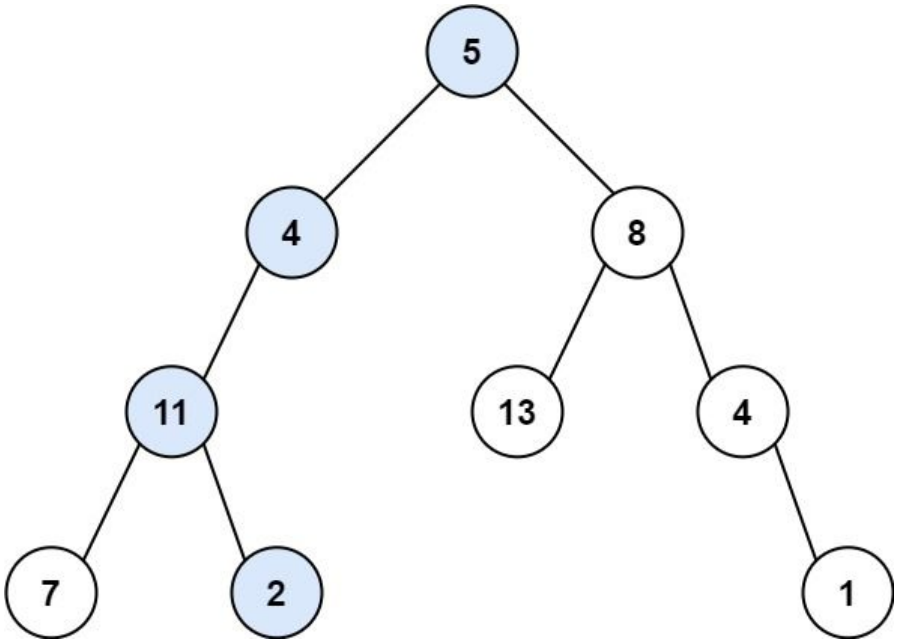
★ **TOP 10 PROBLEM** in Tree DFS (Preorder / Inorder / Postorder): master this one first

PROBLEM

Given the `root` of a binary tree and an integer `targetSum`, return `true` if the tree has a **root-to-leaf** path such that adding up all the values along the path equals `targetSum`.

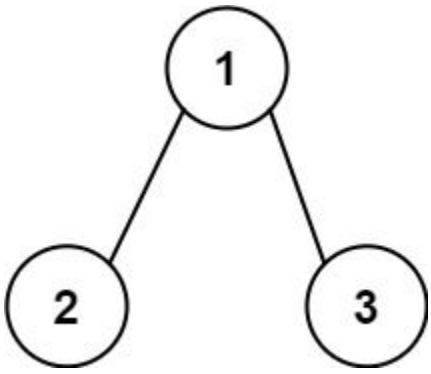
A **leaf** is a node with no children.

Example 1:



```
Input: root = [5,4,8,11,null,13,4,7,2,null,null,null,1], targetSum = 22
Output: true
Explanation: The root-to-leaf path with the target sum is shown.
```

Example 2:



```
Input: root = [1,2,3], targetSum = 5
Output: false
Explanation: There are two root-to-leaf paths in the tree:
(1 --> 2): The sum is 3.
(1 --> 3): The sum is 4.
There is no root-to-leaf path with sum = 5.
```

Example 3:

```
Input: root = [], targetSum = 0
Output: false
Explanation: Since the tree is empty, there are no root-to-leaf paths.
```

Constraints:

- The number of nodes in the tree is in the range `[0, 5000]`.
- `-1000 <= Node.val <= 1000`
- `-1000 <= targetSum <= 1000`

SOLUTION (PYTHON 3)

Solution 1: Recursion

How to think about it

We need a root-to-leaf path whose values sum to the target. Enumerating every path works for n ≤ 5000, but copying paths is extra work. Accumulate the running sum on the way down and test it only at a leaf. Either child succeeding is enough; the full path need not be stored.

Starting from the root node, recursively traverse the tree and update the value of the node to the path sum from the root node to that node. When you traverse to a leaf node, determine whether this path sum is equal to the target value. If it is equal, return `true`, otherwise return `false`.

The time complexity is O(n), where n is the number of nodes in the binary tree. Each node is visited once.

Python 3

```python
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def hasPathSum(self, root: Optional[TreeNode], targetSum: int) -> bool:
        def dfs(root, s):
            if root is None:
                return False
            s += root.val
            if root.left is None and root.right is None and s == targetSum:
                return True
            return dfs(root.left, s) or dfs(root.right, s)

        return dfs(root, 0)
```

root.val)
```

543. Diameter of Binary Tree

Easy · Tree, Depth-First Search, Binary Tree, Tree DP

leetcode.com/problems/diameter-of-binary-tree

★ **TOP 10 PROBLEM** in Tree DFS (Preorder / Inorder / Postorder): master this one first

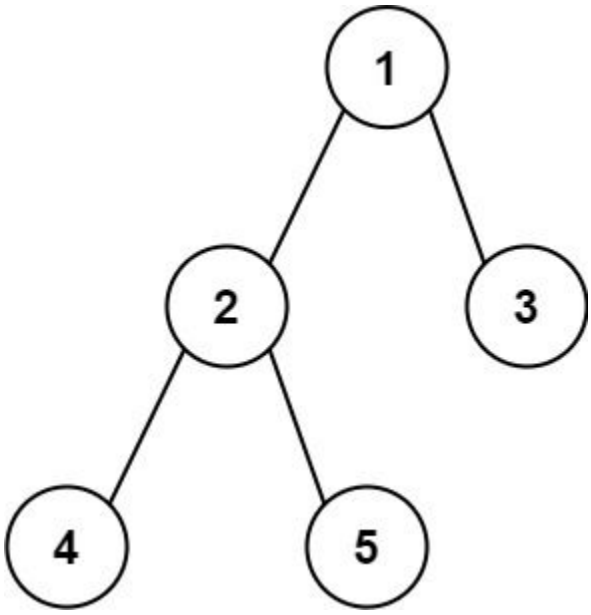
PROBLEM

Given the `root` of a binary tree, return *the length of the **diameter** of the tree*.

The **diameter** of a binary tree is the **length** of the longest path between any two nodes in a tree. This path may or may not pass through the `root`.

The **length** of a path between two nodes is represented by the number of edges between them.

Example 1:



```
Input: root = [1,2,3,4,5]
Output: 3
Explanation: 3 is the length of the path [4,2,1,3] or [5,2,1,3].
```

Example 2:

```
Input: root = [1,2]
Output: 1
```

Constraints:

- The number of nodes in the tree is in the range $[1, 10^4]$.
- `-100 <= Node.val <= 100`

SOLUTION (PYTHON 3)

Solution 1: Enumeration + DFS

> **How to think about it**
>
> The diameter is the longest number of edges between any two nodes. Pairwise paths are unrealistic. Any diameter passes through some node as the sum of that node's two subtree heights. DFS returns height and, on the way up, updates a global answer with l+r, then returns 1+max(l,r) to the parent. Each node is visited once.

We can enumerate each node of the binary tree, and for each node, calculate the maximum depth of its left and right subtrees, l and r, respectively. The diameter of the node is l + r. The maximum diameter among all nodes is the diameter of the binary tree.

The time complexity is O(n), and the space complexity is O(n). Here, n is the number of nodes in the binary tree.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def diameterOfBinaryTree(self, root: TreeNode) -> int:
        def dfs(root):
            if root is None:
                return 0
            nonlocal ans
            left, right = dfs(root.left), dfs(root.right)
            ans = max(ans, left + right)
            return 1 + max(left, right)

        ans = 0
        dfs(root)
        return ans
```

110. Balanced Binary Tree

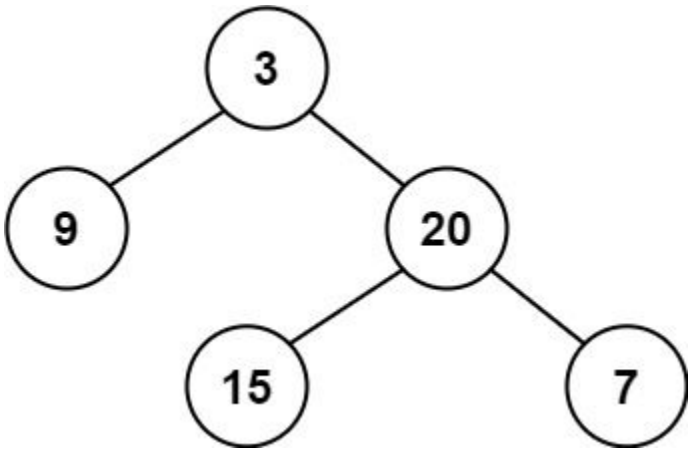
Easy · Tree, Depth-First Search, Binary Tree

leetcode.com/problems/balanced-binary-tree

PROBLEM

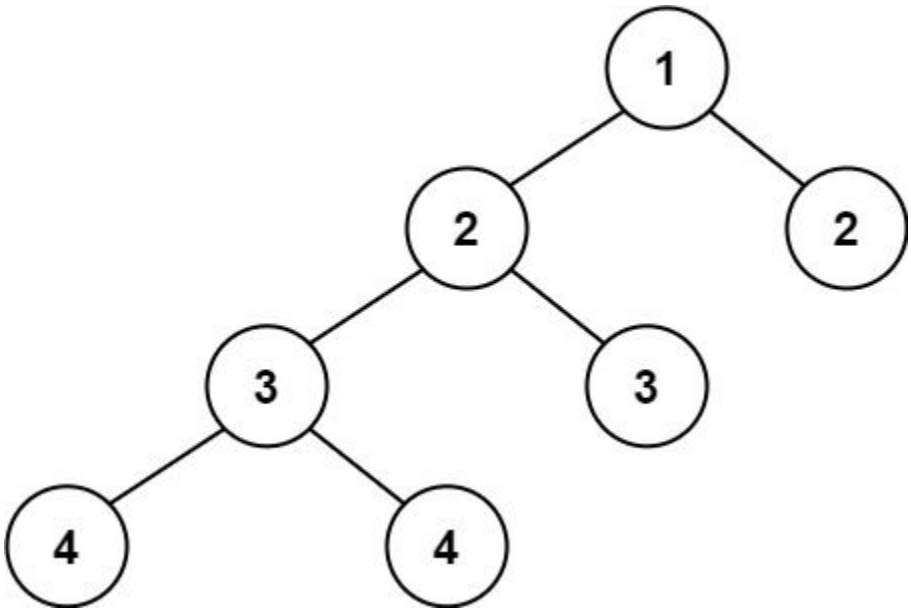
Given a binary tree, determine if it is **height-balanced**.

Example 1:



```
Input: root = [3,9,20,null,null,15,7]
Output: true
```

Example 2:



```
Input: root = [1,2,2,3,3,null,null,4,4]
Output: false
```

Example 3:

```
Input: root = []
Output: true
```

Constraints:

- The number of nodes in the tree is in the range `[0, 5000]`.
- -10^4 <= Node.val <= 10^4

SOLUTION (PYTHON 3)

Solution 1: Bottom-Up Recursion

How to think about it

Computing left and right heights from scratch at every node revisits the same subtrees and can hit $O(n^2)$; n ≤ 5000 is tight. Balance can be decided while computing height. A bottom-up pass returns the height, or a failure sentinel if a subtree is already unbalanced. One postorder walk answers both questions.

We define a function height(root) to calculate the height of a binary tree, with the following logic:

- If the binary tree root is null, return 0.
- Otherwise, recursively calculate the heights of the left and right subtrees, denoted as l and r respectively. If either l or r is -1, or the absolute difference between l and r is greater than 1, then return -1. Otherwise, return max(l, r) + 1.

Therefore, if the function height(root) returns -1, it means the binary tree root is not balanced. Otherwise, it is balanced.

The time complexity is O(n), and the space complexity is O(n). Here, n is the number of nodes in the binary tree.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def isBalanced(self, root: Optional[TreeNode]) -> bool:
        def height(root):
            if root is None:
                return 0
            l, r = height(root.left), height(root.right)
            if l == -1 or r == -1 or abs(l - r) > 1:
                return -1
            return 1 + max(l, r)

        return height(root) >= 0
```

```

100. Same Tree

Easy · Tree, Depth-First Search, Breadth-First Search, Binary Tree

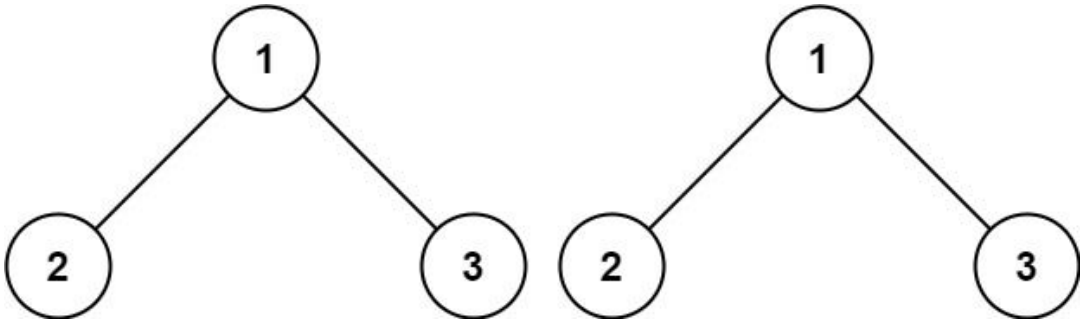
leetcode.com/problems/same-tree

PROBLEM

Given the roots of two binary trees `p` and `q`, write a function to check if they are the same or not.

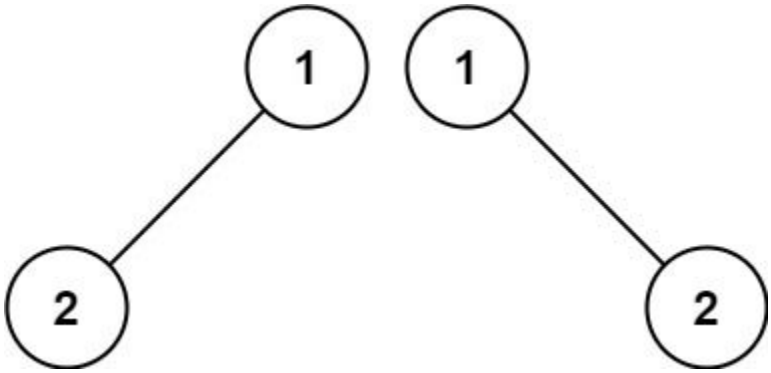
Two binary trees are considered the same if they are structurally identical, and the nodes have the same value.

Example 1:



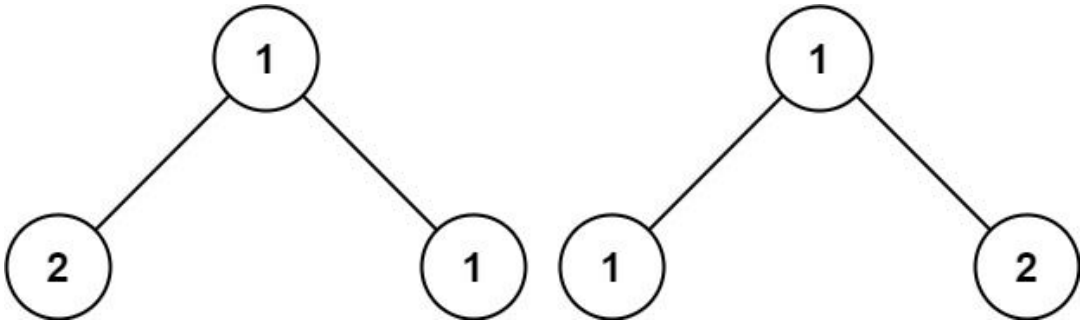
```
Input: p = [1,2,3], q = [1,2,3]
Output: true
```

Example 2:



```
Input: p = [1,2], q = [1,null,2]
Output: false
```

Example 3:



```
Input: p = [1,2,1], q = [1,1,2]
Output: false
```

Constraints:

- The number of nodes in both trees is in the range `[0, 100]`.
- -10^4 `<= Node.val <=` 10^4

SOLUTIONS (PYTHON 3)

Solution 1: DFS

> **How to think about it**
>
> Whether two trees are the same depends on matching structure and values at every corresponding position. Collecting both traversals and comparing sequences still needs a sentinel encoding for missing children. n ≤ 100, so recursion is fine. A tree is defined by its root and two subtrees, so we only compare the current pair: both null means equal; one null or unequal values means not; otherwise recurse on the left children and the right children.

We can use the DFS recursive method to solve this problem.

First, determine whether the root nodes of the two binary trees are the same. If both root nodes are null, then the two binary trees are the same. If only one of the root nodes is null, then the two binary trees are definitely different. If both root nodes are not null, then determine whether their values are the same. If they are not the same, then the two binary trees are definitely different. If they are the same, then determine whether the left subtrees of the two binary trees are the same and whether the right subtrees are the same. The two binary trees are the same only when all the above conditions are met.

The time complexity is O(min(m, n)), and the space complexity is O(min(m, n)). Here, m and n are the number of nodes in the two binary trees, respectively. The space complexity mainly depends on the number of layers of recursive calls, which will not exceed the number of nodes in the smaller binary tree.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def isSameTree(self, p: Optional[TreeNode], q: Optional[TreeNode]) -> bool:
        if p == q:
            return True
        if p is None or q is None or p.val != q.val:
            return False
        return self.isSameTree(p.left, q.left) and self.isSameTree(p.right, q.right)
```

Solution 2: BFS

> **How to think about it**
>
> Solution 1 already produces the answer, at the cost of the call stack. An iterative version must visit both trees in lockstep. A pair of BFS queues can dequeue nodes together, check values and child presence, then enqueue matching children, so we no longer recurse.

We can also use the BFS iterative method to solve this problem.

First, add the root nodes of the two binary trees to two queues. Each time, take out one node from each of the two queues and perform the following comparison operations. If the values of the two nodes are not the same, then the structures of the two binary trees are definitely different. If the values of the two nodes are the same, then determine whether the child nodes of the two nodes are null. If only the left child node of one node is null, then the structures of the two binary trees are definitely different. If only the right child node of one node is null, then the structures of the two binary trees are definitely different. If the structures of the left and right child nodes are the same, then add the left and right child nodes of the two nodes to the two queues respectively. For the next iteration, take out one node from each of the two queues for comparison. When both queues are empty at the same time, it means that we have compared all the nodes, and the structures of the two binary trees are completely the same.

The time complexity is O(min(m, n)), and the space complexity is O(min(m, n)). Here, m and n are the number of nodes in the two binary trees, respectively. The space complexity mainly depends on the number of elements in the queue, which will not exceed the number of nodes in the smaller binary tree.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def isSameTree(self, p: TreeNode, q: TreeNode) -> bool:
        if p == q:
            return True
        if p is None or q is None:
            return False
        q1, q2 = deque([p]), deque([q])
        while q1 and q2:
            a, b = q1.popleft(), q2.popleft()
            if a.val != b.val:
                return False
            la, ra = a.left, a.right
            lb, rb = b.left, b.right
            if (la and not lb) or (lb and not la):
                return False
            if (ra and not rb) or (rb and not ra):
                return False
            if la:
                q1.append(la)
                q2.append(lb)
            if ra:
                q1.append(ra)
                q2.append(rb)
        return True
```

```

101. Symmetric Tree

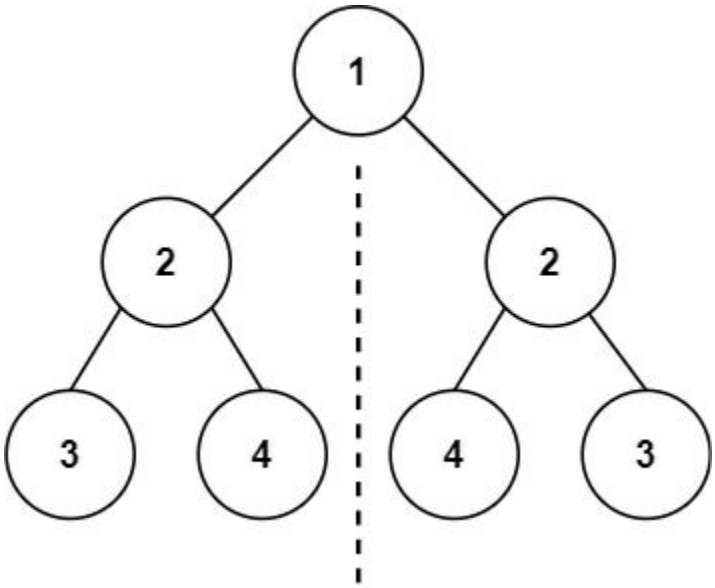
Easy · Tree, Depth-First Search, Breadth-First Search, Binary Tree

leetcode.com/problems/symmetric-tree

PROBLEM

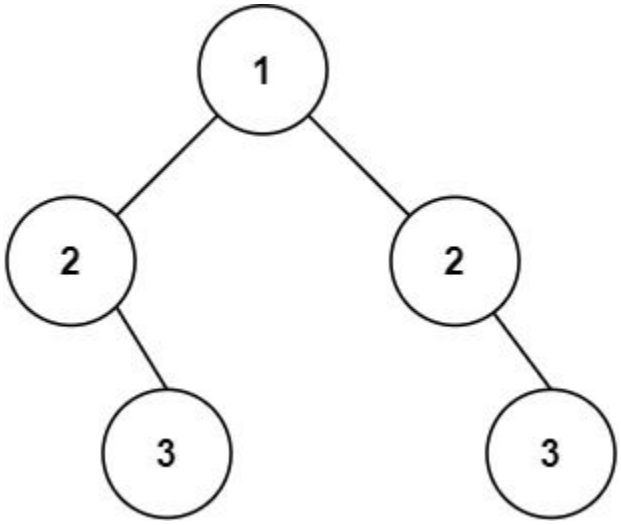
Given the `root` of a binary tree, *check whether it is a mirror of itself* (i.e., symmetric around its center).

Example 1:



```
Input: root = [1,2,2,3,4,4,3]
Output: true
```

Example 2:



```
Input: root = [1,2,2,null,3,null,3]
Output: false
```

Constraints:

- The number of nodes in the tree is in the range `[1, 1000]`.
- `-100 <= Node.val <= 100`

Follow up:

Could you solve it both recursively and iteratively?

SOLUTION (PYTHON 3)

Solution 1: Recursion

> **How to think about it**
>
> Symmetry means the left subtree mirrors the right, not that each subtree matches itself. The follow-up asks for both recursion and iteration; n ≤ 1000, so one pass is enough. A pair of nodes is symmetric iff their values match and the left child of one mirrors the right child of the other (and vice versa). We therefore start from the root's two children and recurse crosswise.

We design a function dfs(root1, root2) to determine whether two binary trees are symmetric. The answer is dfs(root.left, root.right).

The logic of the function dfs(root1, root2) is as follows:

- If both root1 and root2 are null, the two binary trees are symmetric, and we return `true`;
- If only one of root1 and root2 is null, or root1.val ≠ root2.val, we return `false`;
- Otherwise, we check whether the left subtree of root1 is symmetric with the right subtree of root2, and whether the right subtree of root1 is symmetric with the left subtree of root2, using recursion.

The time complexity is O(n), and the space complexity is O(n). Here, n is the number of nodes in the binary tree.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def isSymmetric(self, root: Optional[TreeNode]) -> bool:
        def dfs(root1: Optional[TreeNode], root2: Optional[TreeNode]) -> bool:
            if root1 == root2:
                return True
            if root1 is None or root2 is None or root1.val != root2.val:
                return False
            return dfs(root1.left, root2.right) and dfs(root1.right, root2.left)

        return dfs(root.left, root.right)
```

PATTERN 11 · TREE DFS (PREORDER / INORDER / POSTORDER) · PROBLEM 10 OF 20

226. Invert Binary Tree

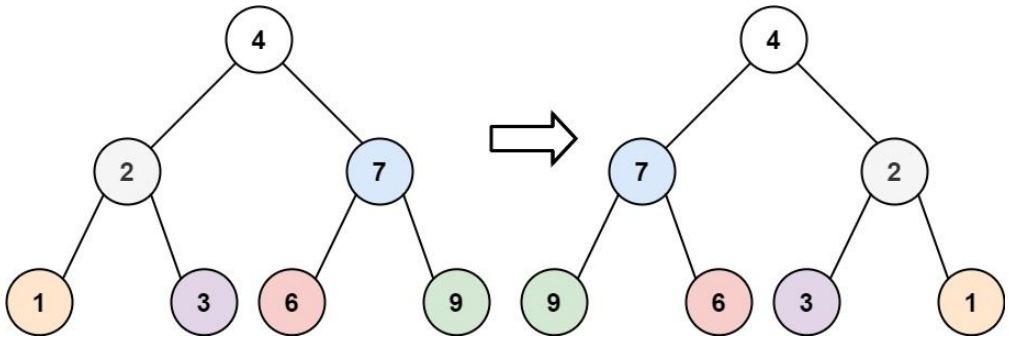
Easy · Tree, Depth-First Search, Breadth-First Search, Binary Tree

leetcode.com/problems/invert-binary-tree

PROBLEM

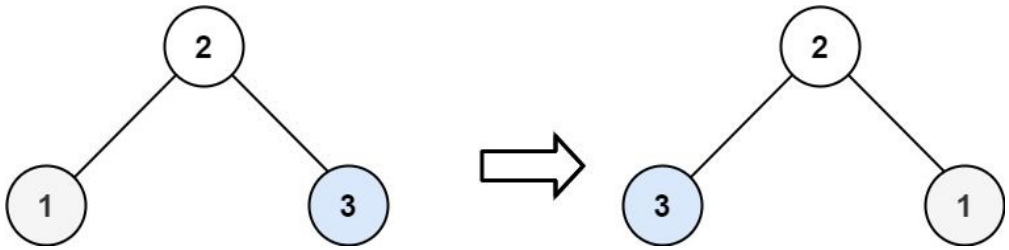
Given the `root` of a binary tree, invert the tree, and return *its root*.

Example 1:



```
Input: root = [4,2,7,1,3,6,9]
Output: [4,7,2,9,6,3,1]
```

Example 2:



```
Input: root = [2,1,3]
Output: [2,3,1]
```

Example 3:

```
Input: root = []
Output: []
```

Constraints:

- The number of nodes in the tree is in the range `[0, 100]`.
- `-100 <= Node.val <= 100`

SOLUTION (PYTHON 3)

Solution 1: Recursion

> **How to think about it**
>
> Inverting a tree means swapping every node's children and doing the same in both subtrees. One recursive walk is enough. Invert the two subtrees first, then swap the child pointers.

First, we check if root is null. If it is, we return null. Then, we recursively invert the left and right subtrees, set the inverted right subtree as the new left subtree, and set the inverted left subtree as the new right subtree. Finally, we return root.

The time complexity is O(n), and the space complexity is O(n). Here, n is the number of nodes in the binary tree.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def invertTree(self, root: Optional[TreeNode]) -> Optional[TreeNode]:
        if root is None:
            return None
        l, r = self.invertTree(root.left), self.invertTree(root.right)
        root.left, root.right = r, l
        return root
```

PATTERN 11 · TREE DFS (PREORDER / INORDER / POSTORDER) · PROBLEM 11 OF 20

113. Path Sum II

Medium · Tree, Depth-First Search, Backtracking, Binary Tree

leetcode.com/problems/path-sum-ii

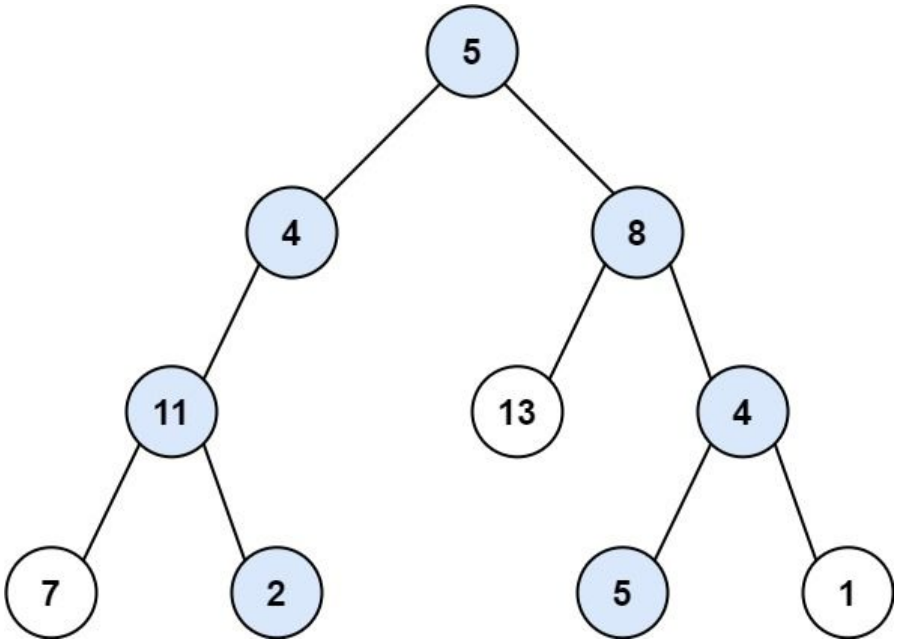
★ **TOP 10 PROBLEM** in Tree DFS (Preorder / Inorder / Postorder): master this one first

PROBLEM

Given the `root` of a binary tree and an integer `targetSum`, return *all **root-to-leaf** paths where the sum of the node values in the path equals* `targetSum`*. Each path should be returned as a list of the node **values**, not node references.*

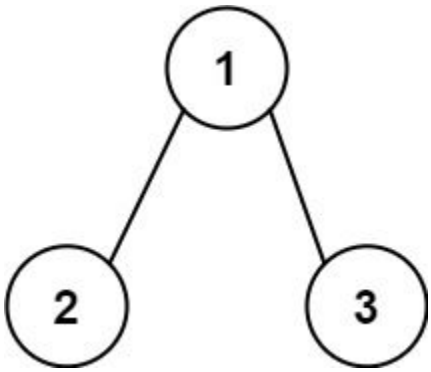
A **root-to-leaf** path is a path starting from the root and ending at any leaf node. A **leaf** is a node with no children.

Example 1:



```
Input: root = [5,4,8,11,null,13,4,7,2,null,null,5,1], targetSum = 22
Output: [[5,4,11,2],[5,8,4,5]]
Explanation: There are two paths whose sum equals targetSum:
5 + 4 + 11 + 2 = 22
5 + 8 + 4 + 5 = 22
```

Example 2:



```
Input: root = [1,2,3], targetSum = 5
Output: []
```

Example 3:

```
Input: root = [1,2], targetSum = 0
Output: []
```

Constraints:

- The number of nodes in the tree is in the range `[0, 5000]`.
- `-1000 <= Node.val <= 1000`
- `-1000 <= targetSum <= 1000`

SOLUTION (PYTHON 3)

Solution 1: DFS

> **How to think about it**
>
> Unlike Path Sum, we must list every root-to-leaf path that sums to targetSum. n ≤ 5000; copying every path into the answer can cost O(n^2). DFS pushes the node onto a shared path and adds its value. At a matching leaf we copy the path; on the way back we pop, so both children reuse the same buffer.

We start from the root node, recursively traverse all paths from the root node to the leaf nodes, and record the path sum. When we traverse to a leaf node, if the current path sum equals `targetSum`, then we add this path to the answer.

The time complexity is O(n^2), where n is the number of nodes in the binary tree. The space complexity is O(n).

Python 3

```python
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def pathSum(self, root: Optional[TreeNode], targetSum: int) -> List[List[int]]:
        def dfs(root, s):
            if root is None:
                return
            s += root.val
            t.append(root.val)
            if root.left is None and root.right is None and s == targetSum:
                ans.append(t[:])
            dfs(root.left, s)
            dfs(root.right, s)
            t.pop()

        ans = []
        t = []
        dfs(root, 0)
        return ans
```

```

236. Lowest Common Ancestor of a Binary Tree

Medium · Tree, Depth-First Search, Binary Tree, Lowest Common Ancestor, Binary Lifting

leetcode.com/problems/lowest-common-ancestor-of-a-binary-tree

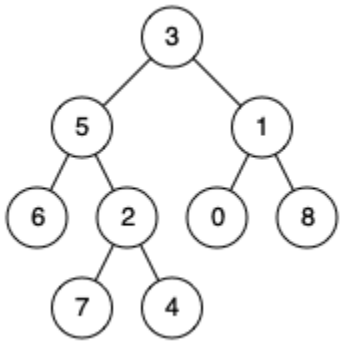
★ **TOP 10 PROBLEM** in Tree DFS (Preorder / Inorder / Postorder): master this one first

PROBLEM

Given a binary tree, find the lowest common ancestor (LCA) of two given nodes in the tree.

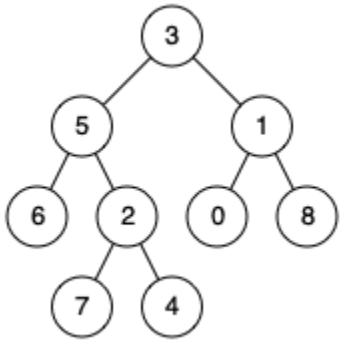
According to the definition of LCA on Wikipedia: "The lowest common ancestor is defined between two nodes `p` and `q` as the lowest node in `T` that has both `p` and `q` as descendants (where we allow **a node to be a descendant of itself**)."

Example 1:



```
Input: root = [3,5,1,6,2,0,8,null,null,7,4], p = 5, q = 1
Output: 3
Explanation: The LCA of nodes 5 and 1 is 3.
```

Example 2:



```
Input: root = [3,5,1,6,2,0,8,null,null,7,4], p = 5, q = 4
Output: 5
Explanation: The LCA of nodes 5 and 4 is 5, since a node can be a descendant of itself according to the
LCA definition.
```

Example 3:

```
Input: root = [1,2], p = 1, q = 2
Output: 1
```

Constraints:

- The number of nodes in the tree is in the range `[2, 10^5]`.

- -10^9 <= Node.val <= 10^9
- All Node.val are **unique**.
- p != q
- p and q will exist in the tree.

SOLUTION (PYTHON 3)

Solution 1: Recursion

> **How to think about it**
>
> A general binary tree has no key order, so we cannot walk by value. The LCA is the deepest node that covers both p and q. A postorder recursion returns a found node from a subtree. If both sides are non-empty the current root is the LCA; otherwise we pass up the non-empty side.

We recursively traverse the binary tree:

If the current node is null or equals to p or q, then we return the current node;

Otherwise, we recursively traverse the left and right subtrees, and record the returned results as left and right. If both left and right are not null, it means that p and q are in the left and right subtrees respectively, so the current node is the nearest common ancestor; If only one of left and right is not null, we return the one that is not null.

The time complexity is O(n), and the space complexity is O(n). Here, n is the number of nodes in the binary tree.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, x):
#         self.val = x
#         self.left = None
#         self.right = None

class Solution:
    def lowestCommonAncestor(
        self, root: "TreeNode", p: "TreeNode", q: "TreeNode"
    ) -> "TreeNode":
        if root in (None, p, q):
            return root
        left = self.lowestCommonAncestor(root.left, p, q)
        right = self.lowestCommonAncestor(root.right, p, q)
        return root if left and right else (left or right)
```

105. Construct Binary Tree from Preorder and Inorder Traversal

Medium · Tree, Array, Hash Table, Divide and Conquer, Binary Tree

leetcode.com/problems/construct-binary-tree-from-preorder-and-inorder-traversal

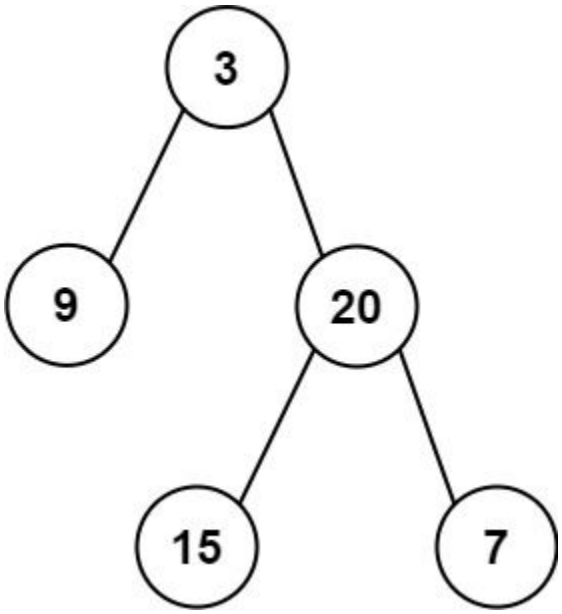
★ **TOP 10 PROBLEM** in Tree DFS (Preorder / Inorder / Postorder): master this one first

Also appears in pattern 14 Recursion / Divide and Conquer

PROBLEM

Given two integer arrays `preorder` and `inorder` where `preorder` is the preorder traversal of a binary tree and `inorder` is the inorder traversal of the same tree, construct and return *the binary tree*.

Example 1:



```
Input: preorder = [3,9,20,15,7], inorder = [9,3,15,20,7]
Output: [3,9,20,null,null,15,7]
```

Example 2:

```
Input: preorder = [-1], inorder = [-1]
Output: [-1]
```

Constraints:

- `1 <= preorder.length <= 3000`
- `inorder.length == preorder.length`
- `-3000 <= preorder[i], inorder[i] <= 3000`
- `preorder` and `inorder` consist of **unique** values.
- Each value of `inorder` also appears in `preorder`.
- `preorder` is **guaranteed** to be the preorder traversal of the tree.
- `inorder` is **guaranteed** to be the inorder traversal of the tree.

SOLUTIONS (PYTHON 3)

Solution 1: Hash Table + Recursion

> **How to think about it**
>
> Preorder gives the root order; inorder splits each root into left and right subtrees. Scanning inorder for the root every time can cost $O(n^2)$; $n \le 3000$ is tight. Values are unique, so we map each inorder value to its index once. The first value of the current preorder slice is the root; everything left of it in inorder is the left subtree, the rest the right. Those lengths fix the next two recursive slices.

The first node preorder[0] in the pre-order sequence is the root node. We find the position k of the root node in the in-order sequence, which can divide the in-order sequence into the left subtree inorder[0..k] and the right subtree inorder[k+1..].

Through the intervals of the left and right subtrees, we can calculate the number of nodes in the left and right subtrees, assumed to be a and b. Then in the pre-order nodes, the a nodes after the root node are the left subtree, and the b nodes after that are the right subtree.

Therefore, we design a function dfs(i, j, n), where i and j represent the starting positions of the pre-order sequence and the in-order sequence, respectively, and n represents the number of nodes. The return value of the function is the binary tree constructed with preorder[i..i+n-1] as the pre-order sequence and inorder[j..j+n-1] as the in-order sequence.

The execution process of the function dfs(i, j, n) is as follows:

- If n ≤ 0, it means there are no nodes, return a null node.
- Take out the first node v = preorder[i] of the pre-order sequence as the root node, and then use the hash table d to find the position k of the root node in the in-order sequence. Then the number of nodes in the left subtree is k - j, and the number of nodes in the right subtree is n - k + j - 1.
- Recursively construct the left subtree l = dfs(i + 1, j, k - j) and the right subtree r = dfs(i + 1 + k - j, k + 1, n - k + j - 1).
- Finally, return the binary tree with v as the root node and l and r as the left and right subtrees, respectively.

The time complexity is O(n), and the space complexity is O(n). Here, n is the number of nodes in the binary tree.

Python 3

```python
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def buildTree(self, preorder: List[int], inorder: List[int]) -> Optional[TreeNode]:
        def dfs(i: int, j: int, n: int) -> Optional[TreeNode]:
            if n <= 0:
                return None
            v = preorder[i]
            k = d[v]
            l = dfs(i + 1, j, k - j)
            r = dfs(i + 1 + k - j, k + 1, n - k + j - 1)
            return TreeNode(v, l, r)

        d = {v: i for i, v in enumerate(inorder)}
        return dfs(0, 0, len(preorder))
```

Solution 2: Hash Table + Recursion (Duplicate Values)

> **How to think about it**
>
> Solution 1 needs unique values so one index locates the root. If values may repeat, a value can have several legal inorder positions. We store every index, try each one that falls in the current interval, recurse on both sides, and take the Cartesian product. This problem does not need that branch; it shows how to enumerate every feasible tree when duplicates are allowed.

This problem guarantees that node values are unique. If duplicates are allowed, the hash table should store every index of each value, and we enumerate every possible root position in the current range to build all valid binary trees.

The time and space complexities both depend on the number of valid trees (we build and store all of them) and are exponential in the worst case. The recursion stack uses O(n) extra space.

Python 3

```python
class Solution:
    def getBinaryTrees(self, preOrder: List[int], inOrder: List[int]) -> List[TreeNode]:
        def dfs(i: int, j: int, n: int) -> List[TreeNode]:
            if n <= 0:
                return [None]
            v = preOrder[i]
            ans = []
            for k in d[v]:
                if j <= k < j + n:
                    for l in dfs(i + 1, j, k - j):
                        for r in dfs(i + 1 + k - j, k + 1, n - 1 - (k - j)):
                            ans.append(TreeNode(v, l, r))
            return ans

        d = defaultdict(list)
        for i, x in enumerate(inOrder):
            d[x].append(i)
        return dfs(0, 0, len(preOrder))
```

            return False
        middle = position[value]
        return build(low, middle - 1) and build(middle + 1, high)

    return build(0, len(inorder) - 1) and index[0] == len(preorder)
```

114. Flatten Binary Tree to Linked List

Medium · Stack, Tree, Depth-First Search, Linked List, Binary Tree

leetcode.com/problems/flatten-binary-tree-to-linked-list

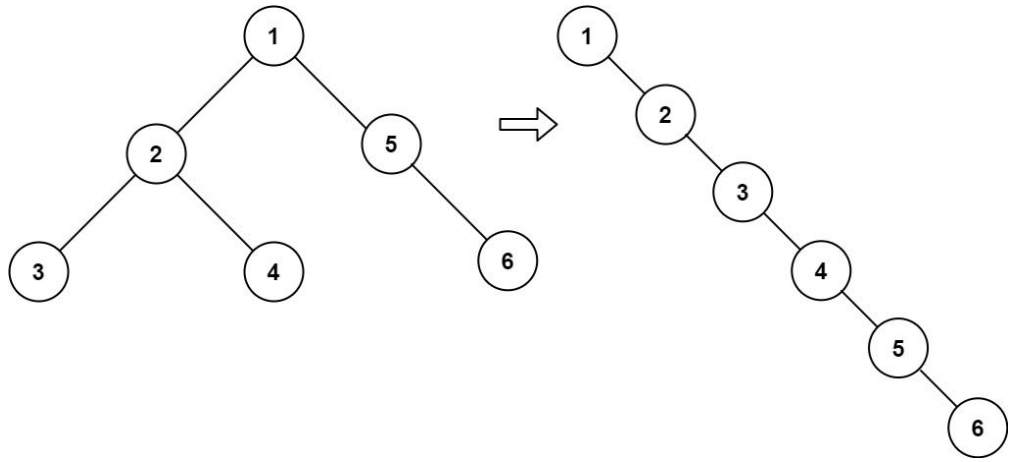
★ **TOP 10 PROBLEM** in Tree DFS (Preorder / Inorder / Postorder): master this one first

PROBLEM

Given the `root` of a binary tree, flatten the tree into a "linked list":

- The "linked list" should use the same `TreeNode` class where the `right` child pointer points to the next node in the list and the `left` child pointer is always `null`.
- The "linked list" should be in the same order as a **pre-order traversal** of the binary tree.

Example 1:



```
Input: root = [1,2,5,3,4,null,6]
Output: [1,null,2,null,3,null,4,null,5,null,6]
```

Example 2:

```
Input: root = []
Output: []
```

Example 3:

```
Input: root = [0]
Output: [0]
```

Constraints:

- The number of nodes in the tree is in the range `[0, 2000]`.
- `-100 <= Node.val <= 100`

Follow up:

Can you flatten the tree in-place (with

`O(1)`

extra space)?

SOLUTIONS (PYTHON 3)

Solution 1: Find Predecessor Node

> **How to think about it**
>
> A preorder flatten can build a new list with recursion or a stack, but the follow-up asks for O(1) extra space in place. n ≤ 2000. After the left subtree in preorder comes the original right subtree. The rightmost node of the left subtree is that predecessor: splice the old right onto it, move the left subtree to `right`, and clear `left`. Walk the right spine; no recursion stack is needed.

The visit order of preorder traversal is "root, left subtree, right subtree". After the last node of the left subtree is visited, the right subtree node of the root node will be visited next.

Therefore, for the current node, if its left child node is not null, we find the rightmost node of the left subtree as the predecessor node, and then assign the right child node of the current node to the right child node of the predecessor node. Then assign the left child node of the current node to the right child node of the current node, and set the left child node of the current node to null. Then take the right child node of the current node as the next node and continue processing until all nodes are processed.

The time complexity is O(n), where n is the number of nodes in the tree. The space complexity is O(1).

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def flatten(self, root: Optional[TreeNode]) -> None:
        """
        Do not return anything, modify root in-place instead.
        """
        while root:
            if root.left:
                pre = root.left
                while pre.right:
                    pre = pre.right
                pre.right = root.right
                root.right = root.left
                root.left = None
            root = root.right
```

Solution 2

> **How to think about it**
>
> Solution 1 already splices predecessors in O(1) space. This is the same idea with a different write-up: save both children, hang the left subtree on the right, attach the old right to its rightmost node, and step along `right`.

Python 3 (written for this guide: the doocs page has no Python 3 version of this solution)

```
class Solution:
    def flatten(self, root: Optional[TreeNode]) -> None:
        while root:
            left, right = root.left, root.right
            root.left = None
            if left:
                root.right = left
                while left.right:
                    left = left.right
                left.right = right
            root = root.right
```

        self.right = None
```

129. Sum Root to Leaf Numbers

Medium · Tree, Depth-First Search, Binary Tree

leetcode.com/problems/sum-root-to-leaf-numbers

PROBLEM

You are given the `root` of a binary tree containing digits from `0` to `9` only.

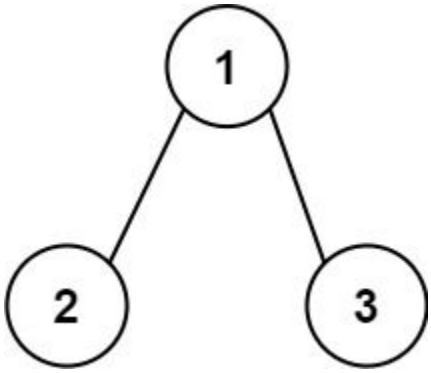
Each root-to-leaf path in the tree represents a number.

- For example, the root-to-leaf path `1 -> 2 -> 3` represents the number `123`.

Return *the total sum of all root-to-leaf numbers*. Test cases are generated so that the answer will fit in a **32-bit** integer.

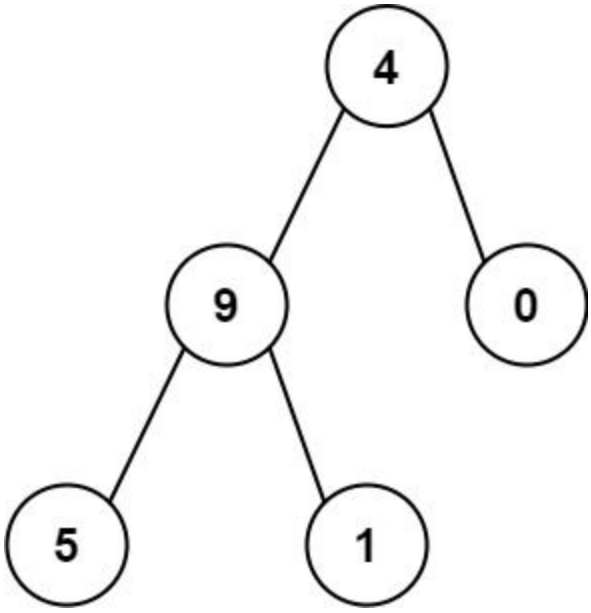
A **leaf** node is a node with no children.

Example 1:



```
Input: root = [1,2,3]
Output: 25
Explanation:
The root-to-leaf path 1->2 represents the number 12.
The root-to-leaf path 1->3 represents the number 13.
Therefore, sum = 12 + 13 = 25.
```

Example 2:



```
Input: root = [4,9,0,5,1]
Output: 1026
Explanation:
The root-to-leaf path 4->9->5 represents the number 495.
The root-to-leaf path 4->9->1 represents the number 491.
The root-to-leaf path 4->0 represents the number 40.
Therefore, sum = 495 + 491 + 40 = 1026.
```

Constraints:

- The number of nodes in the tree is in the range `[1, 1000]`.
- `0 <= Node.val <= 9`
- The depth of the tree will not exceed `10`.

SOLUTION (PYTHON 3)

Solution 1: DFS

> **How to think about it**
>
> Each root-to-leaf path is an integer; we want their sum. Depth is at most 10, so there are few paths, but we need not build strings. Walking down, accumulate s × 10 + val. At a leaf that number is the contribution; add the two subtrees.

We can design a function dfs(root, s), which represents the sum of all path numbers from the current node root to the leaf nodes, given that the current path number is s. The answer is dfs(root, 0).

The calculation of the function dfs(root, s) is as follows:

- If the current node root is null, return 0.
- Otherwise, add the value of the current node to s, i.e., s = s × 10 + root.val.
- If the current node is a leaf node, return s.
- Otherwise, return dfs(root.left, s) + dfs(root.right, s).

The time complexity is O(n), and the space complexity is O(log n). Here, n is the number of nodes in the binary tree.

Python 3

```python
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def sumNumbers(self, root: Optional[TreeNode]) -> int:
        def dfs(root, s):
            if root is None:
                return 0
            s = s * 10 + root.val
            if root.left is None and root.right is None:
                return s
            return dfs(root.left, s) + dfs(root.right, s)

        return dfs(root, 0)
```

```

1448. Count Good Nodes in Binary Tree

Medium · Tree, Depth-First Search, Breadth-First Search, Binary Tree

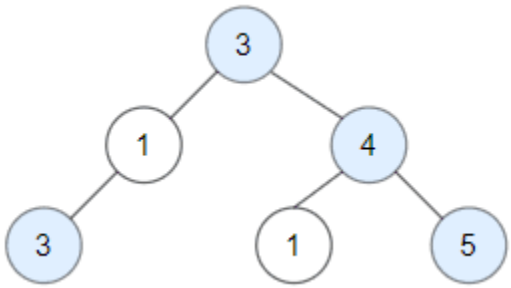
leetcode.com/problems/count-good-nodes-in-binary-tree

PROBLEM

Given a binary tree `root`, a node *X* in the tree is named **good** if in the path from root to *X* there are no nodes with a value *greater than* X.

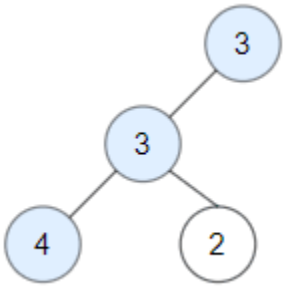
Return the number of **good** nodes in the binary tree.

Example 1:



```
Input: root = [3,1,4,3,null,1,5]
Output: 4
Explanation: Nodes in blue are good.
Root Node (3) is always a good node.
Node 4 -> (3,4) is the maximum value in the path starting from the root.
Node 5 -> (3,4,5) is the maximum value in the path
Node 3 -> (3,1,3) is the maximum value in the path.
```

Example 2:



```
Input: root = [3,3,null,4,2]
Output: 3
Explanation: Node 2 -> (3, 3, 2) is not good, because "3" is higher than it.
```

Example 3:

```
Input: root = [1]
Output: 1
Explanation: Root is considered as good.
```

Constraints:

- The number of nodes in the binary tree is in the range `[1, 10^5]`.
- Each node's value is between `[-10^4, 10^4]`.

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

A node is good if nothing larger appears on the path from the root. n≤ 10^5. DFS carries the path maximum mx; count the node when its value is at least mx, then update mx.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def goodNodes(self, root: TreeNode) -> int:
        def dfs(root: TreeNode, mx: int):
            if root is None:
                return
            nonlocal ans
            if mx <= root.val:
                ans += 1
                mx = root.val
            dfs(root.left, mx)
            dfs(root.right, mx)

        ans = 0
        dfs(root, -1000000)
        return ans
```

Complexity. Time: O(n). Space: O(h), h = height of the tree.

Solution 2: Explicit Stack

How to think about it

A node is good when no larger value appears on the path from the root. With n up to 10^5, one walk that carries the path maximum mx is enough: count the node when its value is at least mx, then update mx. The walk enters the left child first. A left chain can be n nodes long, so recursion overflows before the count is finished. Each node is compared only with the maximum on its own path, so the two children do not depend on each other. The nodes still to visit fit on an explicit stack together with the mx from above. After a pop, a value at least mx is counted and mx becomes that value; the right child is pushed, then the left child, both with this mx, so the left child is handled first. The initial mx is below the lower bound -10^4, so the root is always good. Each node is pushed once.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def goodNodes(self, root: TreeNode) -> int:
        ans = 0
        stk = [(root, -1000000)]
        while stk:
            node, mx = stk.pop()
            if node is None:
                continue
            if mx <= node.val:
                ans += 1
                mx = node.val
            stk.append((node.right, mx))
            stk.append((node.left, mx))
        return ans
```

Complexity. Time: O(n). Space: O(h).

    return good

# ============================================================
# FOLLOW-UP 2: A node is good only when it is STRICTLY
# greater than every node before it on the path
# ============================================================

# ---- follow-up 2: function ----
# Answer: Same walk, but the comparison is strict (the
# root is always good).
```

```python
# Time: O(n).  Space: O(h).
def count_strictly_good(root):
    def walk(node, biggest):
        if node is None:
            return 0
        count = 0
        if node.val > biggest:
            count = 1
            biggest = node.val
        return count + walk(node.left, biggest) + walk(node.right, biggest)

    if root is None:
        return 0
    return 1 + walk(root.left, root.val) + walk(root.right, root.val)
```

814. Binary Tree Pruning

Medium · Tree, Depth-First Search, Binary Tree

leetcode.com/problems/binary-tree-pruning

PROBLEM

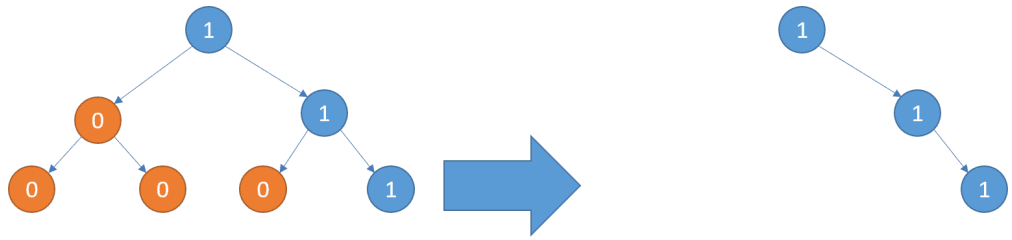
Given the `root` of a binary tree, return *the same tree where every subtree (of the given tree) not containing a* `1` *has been removed*.

A subtree of a node `node` is `node` plus every node that is a descendant of `node`.

Example 1:

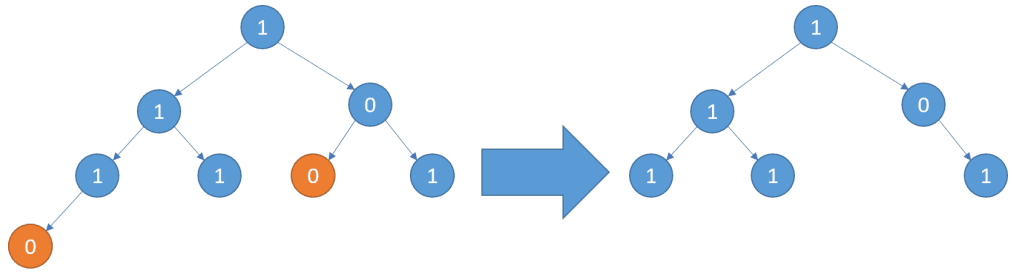
```
Input: root = [1,null,0,0,1]
Output: [1,null,0,null,1]
Explanation:
Only the red nodes satisfy the property "every subtree not containing a 1".
The diagram on the right represents the answer.
```

Example 2:



```
Input: root = [1,0,1,0,0,0,1]
Output: [1,null,1,null,1]
```

Example 3:



```
Input: root = [1,1,0,1,1,0,1,0]
Output: [1,1,0,1,1,null,1]
```

Constraints:

- The number of nodes in the tree is in the range `[1, 200]`.
- `Node.val` is either `0` or `1`.

SOLUTION (PYTHON 3)

Solution 1: Recursion

> **How to think about it**
>
> Every subtree that contains no 1 must be removed. A preorder walk cannot decide before seeing the children, so we prune left and right first, then drop the node if it became empty. After the recursive calls, a 0 with both children gone is deleted. The tree has at most 200 nodes, so one DFS suffices.

First, we check if the current node is null. If it is, we directly return the null node.

Otherwise, we recursively prune the left and right subtrees and reassign the pruned subtrees to the current node's left and right children. Then, we check if the current node's value is 0 and both its left and right children are null. If so, we return the null node; otherwise, we return the current node.

Time complexity is O(n), and space complexity is O(n). Here, n is the number of nodes in the binary tree.

Python 3

```python
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def pruneTree(self, root: Optional[TreeNode]) -> Optional[TreeNode]:
        if root is None:
            return root
        root.left = self.pruneTree(root.left)
        root.right = self.pruneTree(root.right)
        if root.val == 0 and root.left == root.right:
            return None
        return root
```

```

863. All Nodes Distance K in Binary Tree

Medium · Tree, Depth-First Search, Breadth-First Search, Hash Table, Binary Tree

leetcode.com/problems/all-nodes-distance-k-in-binary-tree

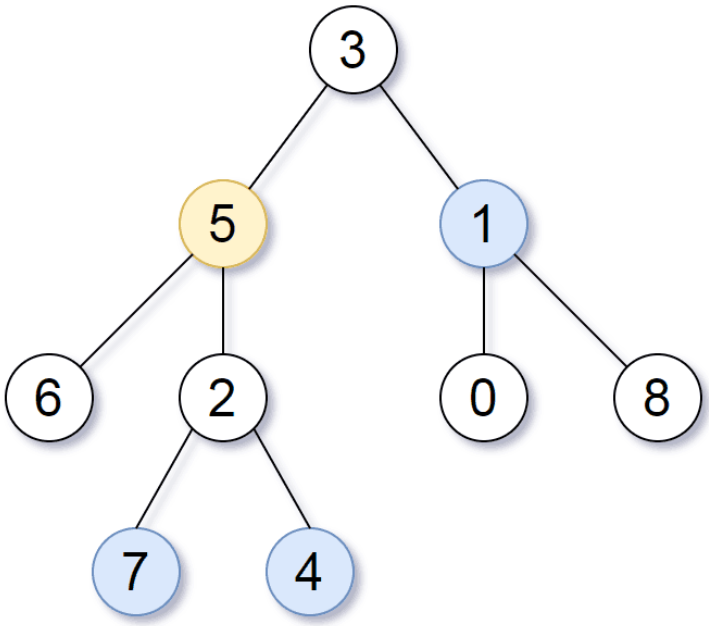
★ **TOP 10 PROBLEM** in Tree DFS (Preorder / Inorder / Postorder): master this one first

PROBLEM

Given the `root` of a binary tree, the value of a target node `target`, and an integer `k`, return *an array of the values of all nodes that have a distance* `k` *from the target node.*

You can return the answer in **any order**.

Example 1:



```
Input: root = [3,5,1,6,2,0,8,null,null,7,4], target = 5, k = 2
Output: [7,4,1]
Explanation: The nodes that are a distance 2 from the target node (with value 5) have values 7, 4, and
1.
```

Example 2:

```
Input: root = [1], target = 1, k = 3
Output: []
```

Constraints:

- The number of nodes in the tree is in the range `[1, 500]`.
- `0 <= Node.val <= 500`
- All the values `Node.val` are **unique**.
- `target` is the value of one of the nodes in the tree.
- `0 <= k <= 1000`

SOLUTION (PYTHON 3)

Solution 1: DFS + Hash Table

> **How to think about it**
>
> We want nodes at distance k from target. Child pointers alone cannot walk to a parent. With at most 500 nodes, record parents first, then walk k steps from target. The first DFS stores each parent; the second explores left, right, and parent, skipping the previous node, and collects values when the remaining distance is 0.

We first use DFS to traverse the entire tree and save each node's parent node in the hash table g.

Next, we use DFS again, starting from target, to search for nodes at a distance of k both upwards and downwards, and add them to the result array.

The time complexity is O(n), and the space complexity is O(n). Here, n is the number of nodes in the binary tree.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, x):
#         self.val = x
#         self.left = None
#         self.right = None

class Solution:
    def distanceK(self, root: TreeNode, target: TreeNode, k: int) -> List[int]:
        def dfs(root, fa):
            if root is None:
                return
            g[root] = fa
            dfs(root.left, root)
            dfs(root.right, root)

        def dfs2(root, fa, k):
            if root is None:

124. Binary Tree Maximum Path Sum

Hard · Tree, Depth-First Search, Dynamic Programming, Binary Tree, Tree DP

leetcode.com/problems/binary-tree-maximum-path-sum

★ **TOP 10 PROBLEM** in Tree DFS (Preorder / Inorder / Postorder): master this one first

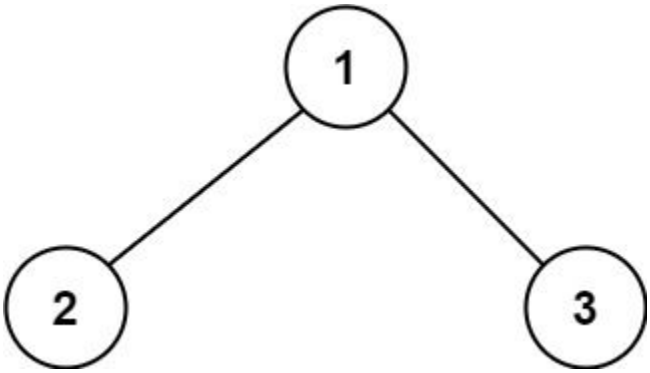
PROBLEM

A **path** in a binary tree is a sequence of nodes where each pair of adjacent nodes in the sequence has an edge connecting them. A node can only appear in the sequence **at most once**. Note that the path does not need to pass through the root.

The **path sum** of a path is the sum of the node's values in the path.

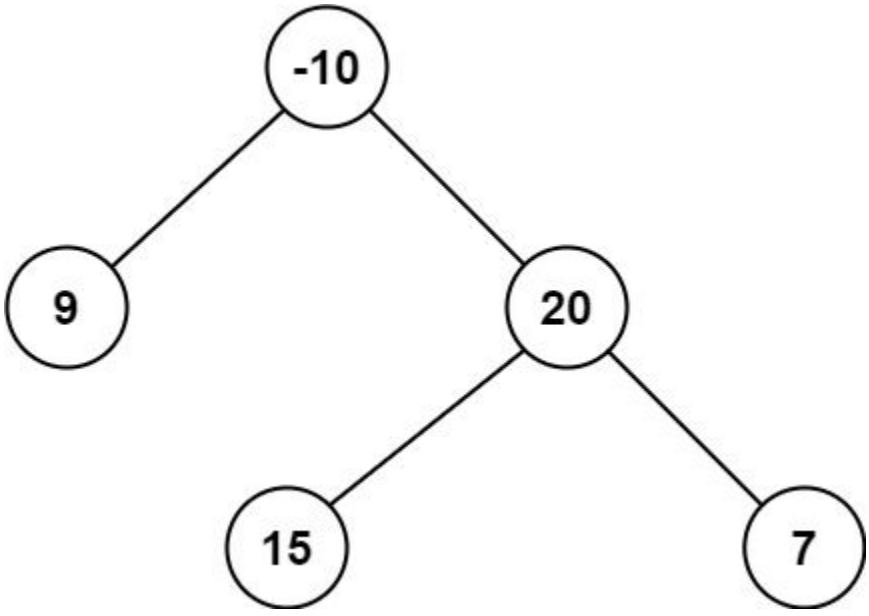
Given the `root` of a binary tree, return *the maximum **path sum** of any **non-empty** path*.

Example 1:



```
Input: root = [1,2,3]
Output: 6
Explanation: The optimal path is 2 -> 1 -> 3 with a path sum of 2 + 1 + 3 = 6.
```

Example 2:



```
Input: root = [-10,9,20,null,null,15,7]
Output: 42
Explanation: The optimal path is 15 -> 20 -> 7 with a path sum of 15 + 20 + 7 = 42.
```

Constraints:

- The number of nodes in the tree is in the range `[1, 3 * 10^4]`.
- `-1000 <= Node.val <= 1000`

SOLUTION (PYTHON 3)

Solution 1: Recursion

> **How to think about it**
>
> A path may start anywhere, need not pass the root, and may bend at a node to take both children. Enumerating paths is impossible at $n \le 3\times 10^4$. The value a node can pass upward is its value plus the better non-negative child chain. The sum that uses both children only updates the global answer and cannot propagate. Negative contributions are dropped by taking max(0,·) before returning.

When thinking about the classic routine of recursion problems in binary trees, we consider:

1. Termination condition (when to terminate recursion)
2. Recursively process the left and right subtrees
3. Merge the calculation results of the left and right subtrees

For this problem, we design a function dfs(root), which returns the maximum path sum of the binary tree with root as the root node.

The execution logic of the function dfs(root) is as follows:

If root does not exist, then dfs(root) returns 0;

Otherwise, we recursively calculate the maximum path sum of the left and right subtrees of root, denoted as left and right. If left is less than 0, then we set it to 0, similarly, if right is less than 0, then we set it to 0.

Then, we update the answer with root.val + left + right. Finally, the function returns root.val + max(left, right).

In the main function, we call dfs(root) to get the maximum path sum of each node, and the maximum value among them is the answer.

The time complexity is O(n), and the space complexity is O(n). Here, n is the number of nodes in the binary tree.

Python 3

```python
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def maxPathSum(self, root: Optional[TreeNode]) -> int:
        def dfs(root: Optional[TreeNode]) -> int:
            if root is None:
                return 0
            left = max(0, dfs(root.left))
            right = max(0, dfs(root.right))
            nonlocal ans
            ans = max(ans, root.val + left + right)
            return root.val + max(left, right)

        ans = -inf
        dfs(root)
        return ans
```

PATTERN 12 · TREE BFS (LEVEL ORDER) · PROBLEM 1 OF 20

637. Average of Levels in Binary Tree

Easy · Tree, Depth-First Search, Breadth-First Search, Binary Tree

leetcode.com/problems/average-of-levels-in-binary-tree

★ **TOP 10 PROBLEM** in Tree BFS (Level Order): master this one first

PROBLEM

Given the

`root`

of a binary tree, return

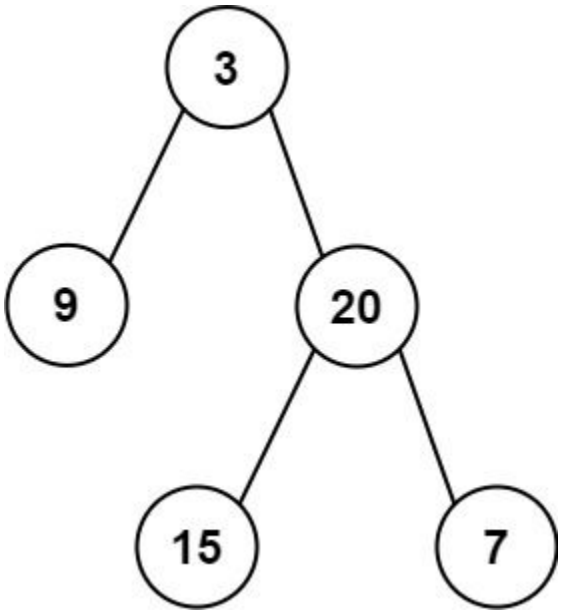
the average value of the nodes on each level in the form of an array

. Answers within

10^{-5}

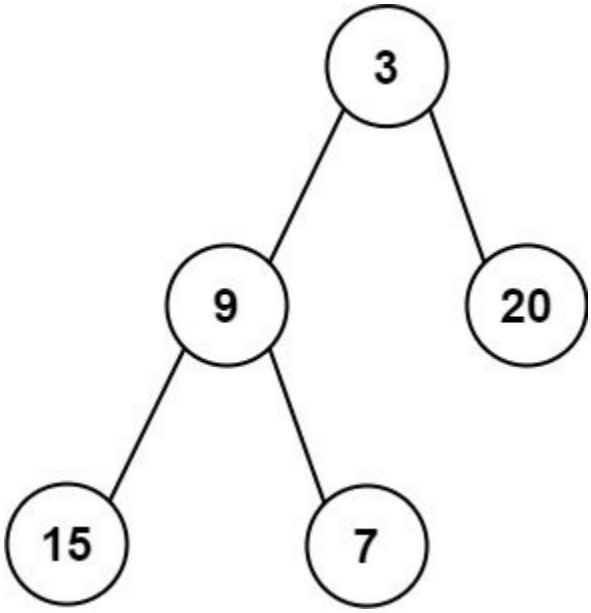
of the actual answer will be accepted.

Example 1:



```
Input: root = [3,9,20,null,null,15,7]
Output: [3.00000,14.50000,11.00000]
Explanation: The average value of nodes on level 0 is 3, on level 1 is 14.5, and on level 2 is 11.
Hence return [3, 14.5, 11].
```

Example 2:



```
Input: root = [3,9,20,15,7]
Output: [3.00000,14.50000,11.00000]
```

Constraints:

- The number of nodes in the tree is in the range $[1, 10^4]$.
- $-2^{31} <= Node.val <= 2^{31} - 1$

SOLUTIONS (PYTHON 3)

Solution 1: BFS

> **How to think about it**
>
> Level averages match a level-order walk. One BFS is enough for n≤ 10^4. Drain the current queue, divide the sum by its size, and enqueue children.

We can use the Breadth-First Search (BFS) method to traverse the nodes of each level and calculate the average value of each level.

Specifically, we define a queue q, initially adding the root node to the queue. Each time, we take out all the nodes in the queue, calculate their average value, add it to the answer array, and then add their child nodes to the queue. Repeat this process until the queue is empty.

The time complexity is O(n), and the space complexity is O(n). Here, n is the number of nodes in the binary tree.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def averageOfLevels(self, root: Optional[TreeNode]) -> List[float]:
        q = deque([root])
        ans = []
        while q:
            s, n = 0, len(q)
            for _ in range(n):
                root = q.popleft()
                s += root.val
                if root.left:
                    q.append(root.left)
                if root.right:
                    q.append(root.right)
            ans.append(s / n)
        return ans
```

Solution 2: DFS

> **How to think about it**
>
> BFS needs a queue. DFS can accumulate (sum, count) by depth and divide at the end, with the same result.

We can also use the Depth-First Search (DFS) method to calculate the average value of each level.

Specifically, we define an array s, where s[i] is a tuple representing the sum of node values and the number of nodes at the i-th level. We perform a depth-first search on the tree. For each node, we add the node's value to the corresponding s[i] and increment the node count by one. Finally, for each s[i], we calculate the average value and add it to the answer array.

The time complexity is O(n), and the space complexity is O(n). Here, n is the number of nodes in the binary tree.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def averageOfLevels(self, root: Optional[TreeNode]) -> List[float]:
        def dfs(root, i):
            if root is None:
                return
            if len(s) == i:
                s.append([root.val, 1])
            else:
                s[i][0] += root.val
                s[i][1] += 1
            dfs(root.left, i + 1)
            dfs(root.right, i + 1)

        s = []
        dfs(root, 0)
        return [a / b for a, b in s]
```

PATTERN 12 · TREE BFS (LEVEL ORDER) · PROBLEM 2 OF 20

111. Minimum Depth of Binary Tree

Easy · Tree, Depth-First Search, Breadth-First Search, Binary Tree

leetcode.com/problems/minimum-depth-of-binary-tree

★ **TOP 10 PROBLEM** in Tree BFS (Level Order): master this one first

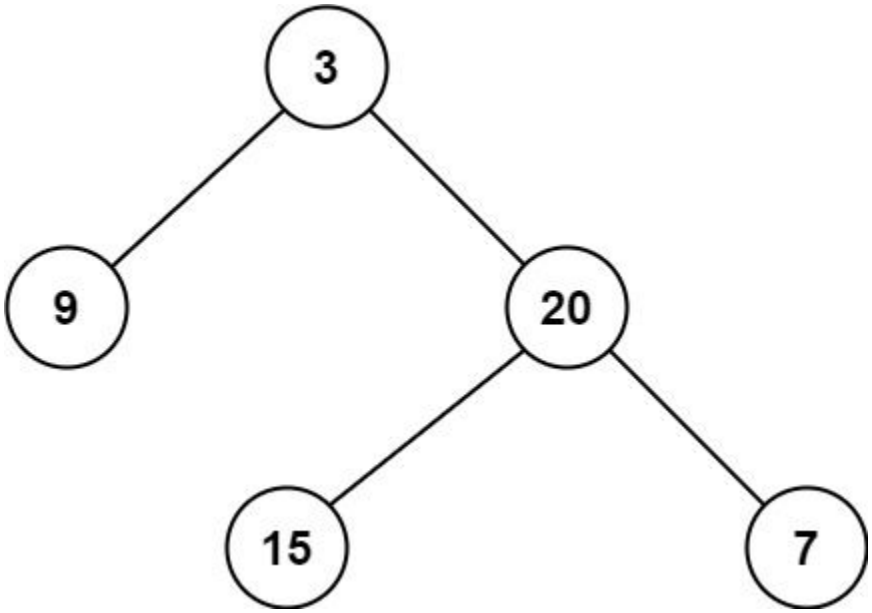
PROBLEM

Given a binary tree, find its minimum depth.

The minimum depth is the number of nodes along the shortest path from the root node down to the nearest leaf node.

Note: A leaf is a node with no children.

Example 1:



```
Input: root = [3,9,20,null,null,15,7]
Output: 2
```

Example 2:

```
Input: root = [2,null,3,null,4,null,5,null,6]
Output: 5
```

Constraints:

- The number of nodes in the tree is in the range `[0, 10^5]`.
- `-1000 <= Node.val <= 1000`

SOLUTIONS (PYTHON 3)

Solution 1: Recursion

How to think about it

Minimum depth is the number of nodes on the shortest root-to-leaf path. A node with only one child is not a leaf, so we must continue down the existing side; treating the missing child as depth 0 is wrong. $n \le 10^5$. Recursively: empty tree is 0; missing left means 1 plus the right minimum; missing right is symmetric; both children present means 1 plus the smaller of the two.

The termination condition for recursion is when the current node is null, at which point return 0. If one of the left or right subtrees of the current node is null, return the minimum depth of the non-null subtree plus 1. If neither the left nor right subtree of the current node is null, return the smaller value of the minimum depths of the left and right subtrees plus 1.

The time complexity is O(n), and the space complexity is O(n). Here, n is the number of nodes in the binary tree.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def minDepth(self, root: Optional[TreeNode]) -> int:
        if root is None:
            return 0
        if root.left is None:
            return 1 + self.minDepth(root.right)
        if root.right is None:
            return 1 + self.minDepth(root.left)
        return 1 + min(self.minDepth(root.left), self.minDepth(root.right))
```

Solution 2: BFS

> **How to think about it**
>
> Solution 1 may walk an entire deep branch before seeing the nearest leaf. Minimum depth is a shortest path, so BFS can stop at the first leaf. That is faster in practice on skewed trees.

Use a queue to implement breadth-first search, initially adding the root node to the queue. Each time, take a node from the queue. If this node is a leaf node, directly return the current depth. If this node is not a leaf node, add all non-null child nodes of this node to the queue. Continue to search the next layer of nodes until a leaf node is found.

The time complexity is O(n), and the space complexity is O(n). Here, n is the number of nodes in the binary tree.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def minDepth(self, root: Optional[TreeNode]) -> int:
        if root is None:
            return 0
        q = deque([root])
        ans = 0
        while 1:
            ans += 1
            for _ in range(len(q)):
                node = q.popleft()
                if node.left is None and node.right is None:
                    return ans
                if node.left:
                    q.append(node.left)
                if node.right:
                    q.append(node.right)
```

PATTERN 12 · TREE BFS (LEVEL ORDER) · PROBLEM 3 OF 20

993. Cousins in Binary Tree

Easy · Tree, Depth-First Search, Breadth-First Search, Binary Tree

leetcode.com/problems/cousins-in-binary-tree

★ **TOP 10 PROBLEM** in Tree BFS (Level Order): master this one first

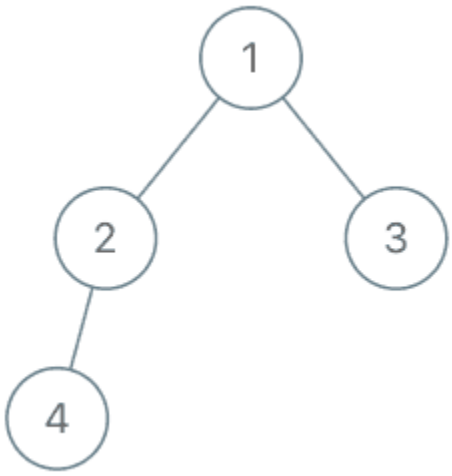
PROBLEM

Given the `root` of a binary tree with unique values and the values of two different nodes of the tree `x` and `y`, return `true` *if the nodes corresponding to the values* `x` *and* `y` *in the tree are* ***cousins****, or* `false` *otherwise.*

Two nodes of a binary tree are **cousins** if they have the same depth with different parents.

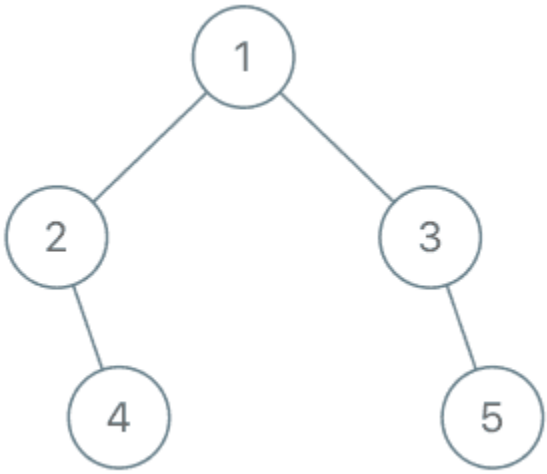
Note that in a binary tree, the root node is at the depth `0`, and children of each depth `k` node are at the depth `k + 1`.

Example 1:



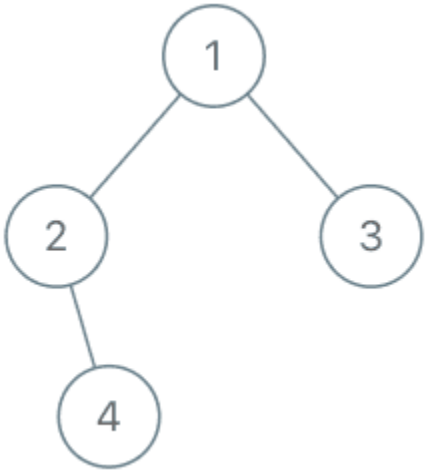
```
Input: root = [1,2,3,4], x = 4, y = 3
Output: false
```

Example 2:



```
Input: root = [1,2,3,null,4,null,5], x = 5, y = 4
Output: true
```

Example 3:



```
Input: root = [1,2,3,null,4], x = 2, y = 3
Output: false
```

Constraints:

- The number of nodes in the tree is in the range `[2, 100]`.
- `1 <= Node.val <= 100`
- Each node has a **unique** value.
- `x != y`
- `x` and `y` are exist in the tree.

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

Cousins share a depth and have different parents. Level-order the tree while carrying the parent; when x or y appears, record parent and depth, then compare after the walk.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def isCousins(self, root: Optional[TreeNode], x: int, y: int) -> bool:
        q = deque([(root, None)])
        depth = 0
        p1 = p2 = None
        d1 = d2 = None
        while q:
            for _ in range(len(q)):
                node, parent = q.popleft()
                if node.val == x:
                    p1, d1 = parent, depth
                elif node.val == y:
                    p2, d2 = parent, depth
                if node.left:
                    q.append((node.left, node))
                if node.right:
                    q.append((node.right, node))
            depth += 1
        return p1 != p2 and d1 == d2
```

Complexity. Time: O(n). Space: O(n).

Solution 2

> **How to think about it**
>
> BFS proceeds layer by layer. DFS works as well: pass the parent and depth, record them for x and y, and test the cousin condition.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def isCousins(self, root: Optional[TreeNode], x: int, y: int) -> bool:
        def dfs(root, parent, depth):
            if root is None:
                return
            if root.val == x:
                st[0] = (parent, depth)
            elif root.val == y:
                st[1] = (parent, depth)
            dfs(root.left, root, depth + 1)
            dfs(root.right, root, depth + 1)

        st = [None, None]
        dfs(root, None, 0)
        return st[0][0] != st[1][0] and st[0][1] == st[1][1]
```

Complexity. Time: O(n). Space: O(h).

    return are_siblings(root.left, x, y) or are_siblings(root.right, x, y)
```

429. N-ary Tree Level Order Traversal

Medium · Tree, Breadth-First Search

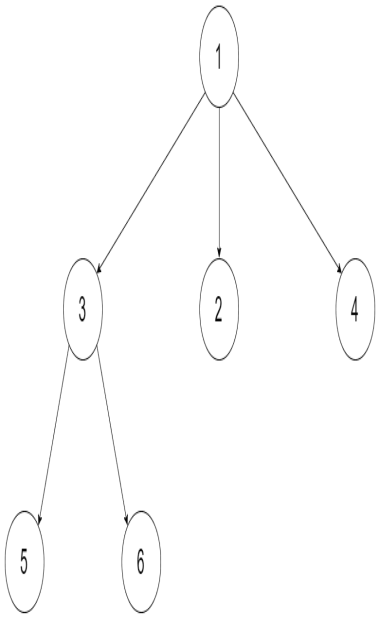
leetcode.com/problems/n-ary-tree-level-order-traversal

PROBLEM

Given an n-ary tree, return the *level order* traversal of its nodes' values.

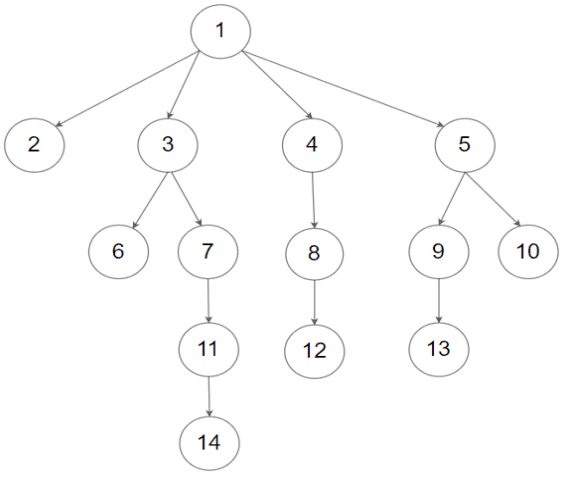
Nary-Tree input serialization is represented in their level order traversal, each group of children is separated by the null value (See examples).

Example 1:



```
Input: root = [1,null,3,2,4,null,5,6]
Output: [[1],[3,2,4],[5,6]]
```

Example 2:



```
Input: root =
[1,null,2,3,4,5,null,null,6,7,null,8,null,9,10,null,null,11,null,12,null,13,null,null,14]
Output: [[1],[2,3,4,5],[6,7,8,9,10],[11,12,13],[14]]
```

Constraints:

- The height of the n-ary tree is less than or equal to `1000`
- The total number of nodes is between `[0, 10^4]`

SOLUTIONS (PYTHON 3)

Solution 1: BFS

> **How to think about it**
>
> Level order groups values by depth. A depth-first walk without a layer index would mix levels. A queue holds the current layer: snapshot its length, pop that many nodes into a row, and enqueue their children. An empty root yields an empty list. The snapshot of the queue length isolates one layer and keeps left-to-right order.

First, we check if the root node is null. If it is, we return an empty list directly.

Otherwise, we create a queue q and initially add the root node to the queue.

When the queue is not empty, we loop through the following operations:

1. Create an empty list t to store the values of the current level nodes.
2. For each node in the queue, add its value to t and add its child nodes to the queue.
3. Add t to the result list ans.

Finally, return the result list ans.

The time complexity is O(n), and the space complexity is O(n). Here, n is the number of nodes in the N-ary tree.

Python 3

```
"""
# Definition for a Node.
class Node:
    def __init__(self, val=None, children=None):
        self.val = val
        self.children = children
"""

class Solution:
    def levelOrder(self, root: 'Node') -> List[List[int]]:
        ans = []
        if root is None:
            return ans
        q = deque([root])
        while q:
            t = []
            for _ in range(len(q)):
                root = q.popleft()
                t.append(root.val)
                q.extend(root.children)
            ans.append(t)
        return ans
```

Solution 2: DFS

> **How to think about it**
>
> Solution 1 needs a queue. Recursing with a depth i and appending to ans[i] (growing the list when needed) produces the same rows. The call stack carries the layer index; children are still written left to right.

We can use the Depth-First Search method to traverse the entire tree.

We define a helper function dfs(root, i), where root represents the current node, and i represents the current level.

In the dfs function, we first check if root is null. If it is, we return directly.

Otherwise, we check if the length of ans is less than or equal to i. If it is, it means that the current level has not been added to ans yet, so we need to add an empty list first. Then we add the value of root to ans[i].

Next, we traverse all child nodes of root. For each child node, we call dfs(child, i + 1).

In the main function, we call dfs(root, 0) and return ans.

The time complexity is O(n), and the space complexity is O(n). Here, n is the number of nodes in the N-ary tree.

Python 3

```
"""
# Definition for a Node.
class Node:
    def __init__(self, val=None, children=None):
        self.val = val
        self.children = children
"""

class Solution:
    def levelOrder(self, root: 'Node') -> List[List[int]]:
        def dfs(root, i):
            if root is None:
                return
            if len(ans) <= i:
                ans.append([])
            ans[i].append(root.val)
            for child in root.children:
                dfs(child, i + 1)

        ans = []
        dfs(root, 0)
        return ans
```

PATTERN 12 · TREE BFS (LEVEL ORDER) · PROBLEM 5 OF 20

102. Binary Tree Level Order Traversal

Medium · Tree, Breadth-First Search, Binary Tree

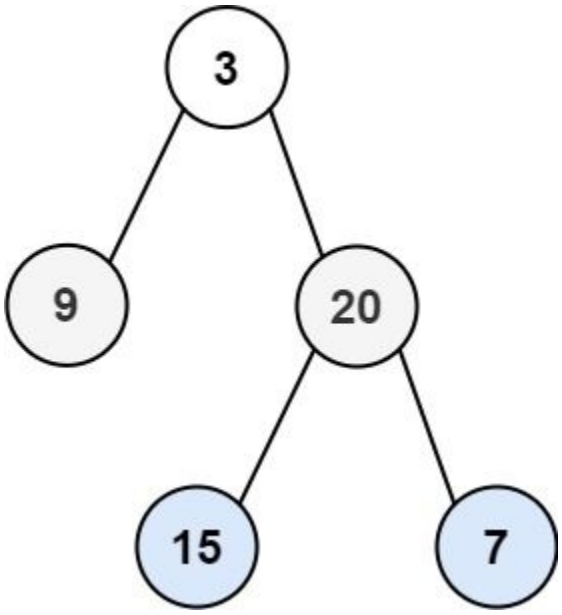
leetcode.com/problems/binary-tree-level-order-traversal

★ **TOP 10 PROBLEM** in Tree BFS (Level Order): master this one first

PROBLEM

Given the `root` of a binary tree, return *the level order traversal of its nodes' values*. (i.e., from left to right, level by level).

Example 1:



```
Input: root = [3,9,20,null,null,15,7]
Output: [[3],[9,20],[15,7]]
```

Example 2:

```
Input: root = [1]
Output: [[1]]
```

Example 3:

```
Input: root = []
Output: []
```

Constraints:

- The number of nodes in the tree is in the range `[0, 2000]`.
- `-1000 <= Node.val <= 1000`

SOLUTION (PYTHON 3)

Solution 1: BFS

How to think about it

We must emit values level by level. DFS can record depth and group later, but then left-to-right order needs extra work. n ≤ 2000, and a level holds at most O(n) nodes. BFS expands by level: the nodes currently in the queue are exactly one level. Dequeue them, collect values, and enqueue children to form the next level from left to right.

We can use the BFS method to solve this problem. First, enqueue the root node, then continuously perform the following operations until the queue is empty:

- Traverse all nodes in the current queue, store their values in a temporary array t, and then enqueue their child nodes.
- Store the temporary array t in the answer array.

Finally, return the answer array.

The time complexity is O(n), and the space complexity is O(n). Here, n is the number of nodes in the binary tree.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def levelOrder(self, root: Optional[TreeNode]) -> List[List[int]]:
        ans = []
        if root is None:
            return ans
        q = deque([root])
        while q:
            t = []
            for _ in range(len(q)):
                node = q.popleft()
                t.append(node.val)
                if node.left:
                    q.append(node.left)
                if node.right:
                    q.append(node.right)
            ans.append(t)
        return ans
```

```

PATTERN 12 · TREE BFS (LEVEL ORDER) · PROBLEM 6 OF 20

107. Binary Tree Level Order Traversal II

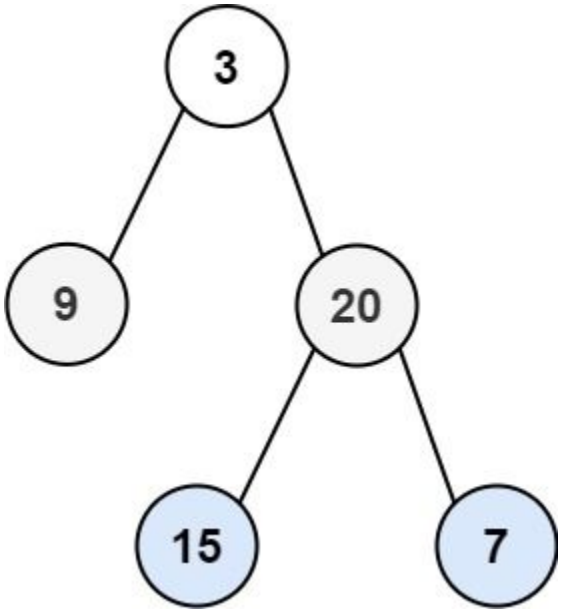
Medium · Tree, Breadth-First Search, Binary Tree

leetcode.com/problems/binary-tree-level-order-traversal-ii

PROBLEM

Given the `root` of a binary tree, return *the bottom-up level order traversal of its nodes' values*. (i.e., from left to right, level by level from leaf to root).

Example 1:



```
Input: root = [3,9,20,null,null,15,7]
Output: [[15,7],[9,20],[3]]
```

Example 2:

```
Input: root = [1]
Output: [[1]]
```

Example 3:

```
Input: root = []
Output: []
```

Constraints:

- The number of nodes in the tree is in the range `[0, 2000]`.
- `-1000 <= Node.val <= 1000`

SOLUTION (PYTHON 3)

Solution 1: BFS

How to think about it

This is ordinary level order, except the layers must be listed from the bottom up. Collect levels as usual and reverse the answer; there is no need to insert at the front while traversing. n ≤ 2000, so BFS by layer and a final reverse suffice.

We can use the BFS (Breadth-First Search) method to solve this problem. First, enqueue the root node, then continuously perform the following operations until the queue is empty:

- Traverse all nodes in the current queue, store their values in a temporary array t, and then enqueue their child nodes.
- Store the temporary array t in the answer array.

Finally, return the reversed answer array.

The time complexity is O(n), and the space complexity is O(n). Here, n is the number of nodes in the binary tree.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def levelOrderBottom(self, root: Optional[TreeNode]) -> List[List[int]]:
        ans = []
        if root is None:
            return ans
        q = deque([root])
        while q:
            t = []
            for _ in range(len(q)):
                node = q.popleft()
                t.append(node.val)
                if node.left:
                    q.append(node.left)
                if node.right:
                    q.append(node.right)
            ans.append(t)
        return ans[::-1]
```

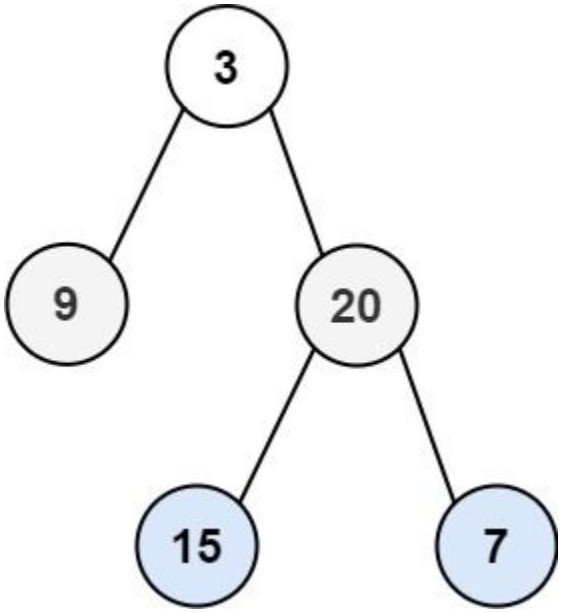
★ **TOP 10 PROBLEM** in Tree BFS (Level Order): master this one first

PROBLEM

Given the `root` of a binary tree, return *the zigzag level order traversal of its nodes' values*. (i.e., from left to right, then right to left for the next level and alternate between).

Example 1:



```
Input: root = [3,9,20,null,null,15,7]
Output: [[3],[20,9],[15,7]]
```

Example 2:

```
Input: root = [1]
Output: [[1]]
```

Example 3:

```
Input: root = []
Output: []
```

Constraints:

- The number of nodes in the tree is in the range `[0, 2000]`.
- `-100 <= Node.val <= 100`

SOLUTION (PYTHON 3)

Solution 1: BFS

How to think about it

Unlike ordinary level order, odd levels stay left-to-right and even levels go right-to-left. Building each level and reversing some of them is still O(n). n ≤ 2000 is fine. We keep BFS and add a direction flag. After a level is collected, reverse it when the flag says right-to-left, then flip the flag. Children are always enqueued left to right, so the next level's visitation order is unchanged.

To implement zigzag level order traversal, we need to add a flag `left` on the basis of level order traversal. This flag is used to mark the order of the node values in the current level. If `left` is `true`, the node values of the current level are stored in the result array `ans` from left to right. If `left` is `false`, the node values of the current level are stored in the result array `ans` from right to left.

The time complexity is O(n), and the space complexity is O(n). Here, n is the number of nodes in the binary tree.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def zigzagLevelOrder(self, root: Optional[TreeNode]) -> List[List[int]]:
        ans = []
        if root is None:
            return ans
        q = deque([root])
        ans = []
        left = 1
        while q:
            t = []
            for _ in range(len(q)):
                node = q.popleft()
                t.append(node.val)
                if node.left:
                    q.append(node.left)
                if node.right:
                    q.append(node.right)
            ans.append(t if left else t[::-1])
            left ^= 1
        return ans
```

    return levels
```

199. Binary Tree Right Side View

Medium · Tree, Depth-First Search, Breadth-First Search, Binary Tree

leetcode.com/problems/binary-tree-right-side-view

★ **TOP 10 PROBLEM** in Tree BFS (Level Order): master this one first

PROBLEM

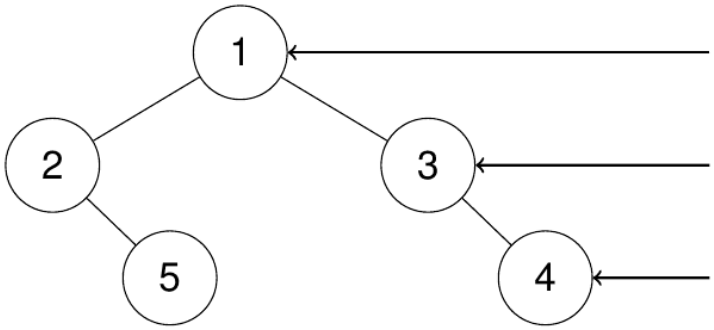
Given the `root` of a binary tree, imagine yourself standing on the **right side** of it, return *the values of the nodes you can see ordered from top to bottom*.

Example 1:

Input: root = [1,2,3,null,5,null,4]

Output: [1,3,4]

Explanation:

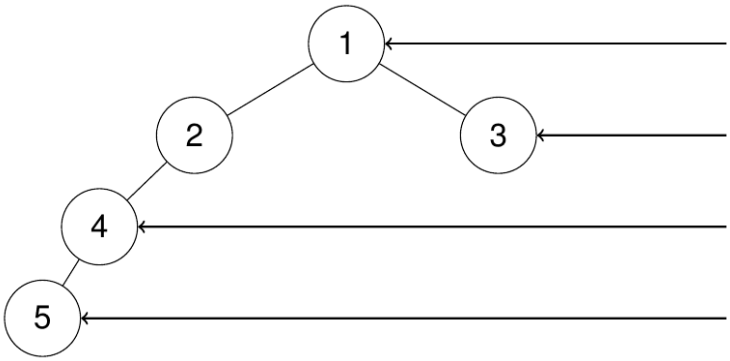


Example 2:

Input: root = [1,2,3,4,null,null,null,5]

Output: [1,3,4,5]

Explanation:



Example 3:

Input: root = [1,null,3]

Output: [1,3]

Example 4:

Input: root = []

Output: []

Constraints:

- The number of nodes in the tree is in the range `[0, 100]`.
- `-100 <= Node.val <= 100`

SOLUTIONS (PYTHON 3)

Solution 1: BFS

> **How to think about it**
>
> The right side view is the rightmost node of each level. n≤ 100. Enqueue the right child first so the front of the queue is that level's rightmost node; record it, then drain the level. No need to take the last element afterwards.

We can use breadth-first search (BFS) and define a queue q to store the nodes. We start by putting the root node into the queue. Each time, we take out all the nodes of the current level from the queue. For the current node, we first check if the right subtree exists; if it does, we put the right subtree into the queue. Then, we check if the left subtree exists; if it does, we put the left subtree into the queue. This way, the first node taken out from the queue each time is the rightmost node of that level.

The time complexity is O(n), and the space complexity is O(n). Here, n is the number of nodes in the binary tree.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def rightSideView(self, root: Optional[TreeNode]) -> List[int]:
        ans = []
        if root is None:
            return ans
        q = deque([root])
        while q:
            ans.append(q[0].val)
            for _ in range(len(q)):
                node = q.popleft()
                if node.right:
                    q.append(node.right)
                if node.left:
                    q.append(node.left)
        return ans
```

Solution 2: DFS

> **How to think about it**
>
> Solution 1 uses a queue. Recurse right then left with a depth: the first visit at that depth is the rightmost node. Space follows height rather than width.

Use DFS (depth-first search) to traverse the binary tree. Each time, traverse the right subtree first, then the left subtree. This way, the first node visited at each level is the rightmost node of that level.

The time complexity is O(n), and the space complexity is O(n). Here, n is the number of nodes in the binary tree.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def rightSideView(self, root: Optional[TreeNode]) -> List[int]:
        def dfs(root: Optional[TreeNode], depth: int) -> None:
            if root is None:
                return
            if len(ans) == depth:
                ans.append(root.val)
            dfs(root.right, depth + 1)
            dfs(root.left, depth + 1)

        ans = []
        dfs(root, 0)
        return ans
```

```

116. Populating Next Right Pointers in Each Node

Medium · Tree, Depth-First Search, Breadth-First Search, Linked List, Binary Tree

leetcode.com/problems/populating-next-right-pointers-in-each-node

PROBLEM

You are given a **perfect binary tree** where all leaves are on the same level, and every parent has two children. The binary tree has the following definition:

```
struct Node {
  int val;
  Node *left;
  Node *right;
  Node *next;
}
```

Populate each next pointer to point to its next right node. If there is no next right node, the next pointer should be set to `NULL`.

Initially, all next pointers are set to `NULL`.

Example 1:

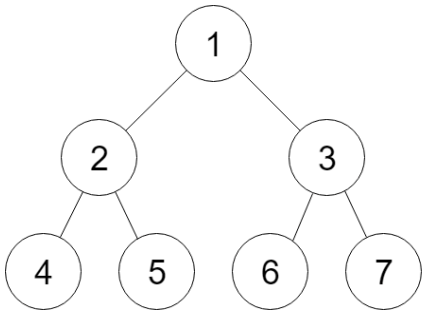

Figure A

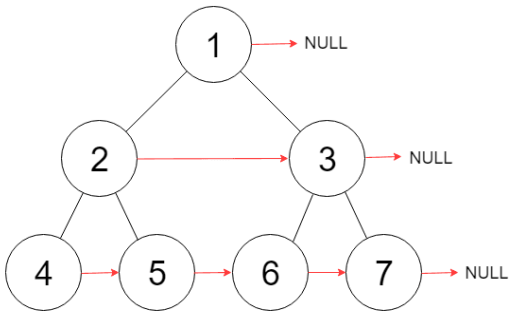

Figure B

```
Input: root = [1,2,3,4,5,6,7]
Output: [1,#,2,3,#,4,5,6,7,#]
Explanation: Given the above perfect binary tree (Figure A), your function should populate each next
pointer to point to its next right node, just like in Figure B. The serialized output is in level order
as connected by the next pointers, with '#' signifying the end of each level.
```

Example 2:

```
Input: root = []
Output: []
```

Constraints:

- The number of nodes in the tree is in the range `[0, 2^12 - 1]`.
- `-1000 <= Node.val <= 1000`

Follow-up:

- You may only use constant extra space.
- The recursive approach is fine. You may assume implicit stack space does not count as extra space for this problem.

SOLUTIONS (PYTHON 3)

Solution 1: BFS

> **How to think about it**
>
> The tree is perfect, so every level is full. BFS can wire next across each level. $n < 2^{12}$, and the queue is as wide as a level. The follow-up wants constant extra space; this method first gets the level-order linking right.

Use a queue for level order traversal, and each time you traverse a level, connect the nodes of the current level in order.

The time complexity is O(n), and the space complexity is O(n). Here, n is the number of nodes in the binary tree.

Python 3

```
"""
# Definition for a Node.
class Node:
    def __init__(self, val: int = 0, left: 'Node' = None, right: 'Node' = None, next: 'Node' = None):
        self.val = val
        self.left = left
        self.right = right
        self.next = next
"""

class Solution:
    def connect(self, root: "Optional[Node]") -> "Optional[Node]":
        if root is None:
            return root
        q = deque([root])
        while q:
            p = None
            for _ in range(len(q)):
                node = q.popleft()
                if p:
                    p.next = node
                p = node
                if node.left:
                    q.append(node.left)
                if node.right:
                    q.append(node.right)
        return root
```

Solution 2: DFS

> **How to think about it**
>
> Solution 1 stores a whole level in a queue. In a perfect tree, a node's two children are adjacent, and the right child is followed by the sibling's left child. Once the parent level is linked, those next pointers walk the next level, so recursion can wire children without a queue.

Use recursion for preorder traversal, and each time you traverse to a node, connect its left and right child nodes in order.

Specifically, we design a function dfs(left, right), which points the next pointer of the left node to the right node. In the function, we first check whether left and right are null. If both are not null, point left.next to right, and then recursively call dfs(left.left, left.right), dfs(left.right, right.left), dfs(right.left, right.right).

The time complexity is O(n), and the space complexity is O(n). Here, n is the number of nodes in the binary tree.

Python 3

```
"""
# Definition for a Node.
class Node:
    def __init__(self, val: int = 0, left: 'Node' = None, right: 'Node' = None, next: 'Node' = None):
        self.val = val
        self.left = left
        self.right = right
        self.next = next
"""

class Solution:
    def connect(self, root: 'Optional[Node]') -> 'Optional[Node]':
        def dfs(left, right):
            if left is None or right is None:
                return
            left.next = right
            dfs(left.left, left.right)
            dfs(left.right, right.left)
            dfs(right.left, right.right)

        if root:
            dfs(root.left, root.right)
        return root
```

117. Populating Next Right Pointers in Each Node II

Medium · Tree, Depth-First Search, Breadth-First Search, Linked List, Binary Tree

leetcode.com/problems/populating-next-right-pointers-in-each-node-ii

★ **TOP 10 PROBLEM** in Tree BFS (Level Order): master this one first

PROBLEM

Given a binary tree

```
struct Node {
  int val;
  Node *left;
  Node *right;
  Node *next;
}
```

Populate each next pointer to point to its next right node. If there is no next right node, the next pointer should be set to `NULL`.

Initially, all next pointers are set to `NULL`.

Example 1:

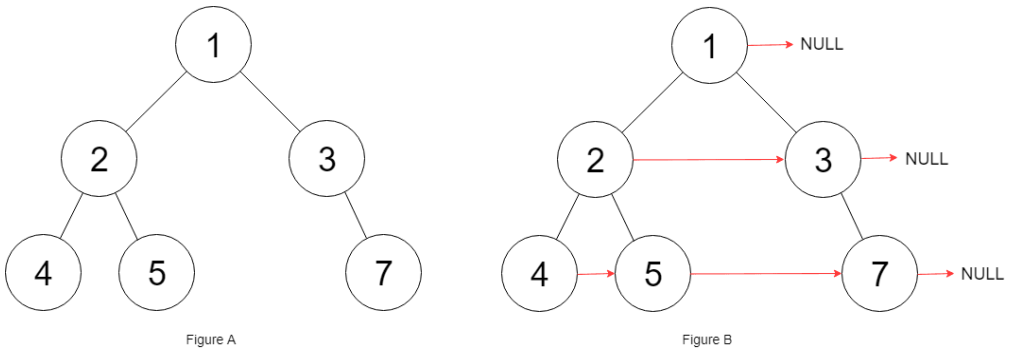

Figure A Figure B

```
Input: root = [1,2,3,4,5,null,7]
Output: [1,#,2,3,#,4,5,7,#]
Explanation: Given the above binary tree (Figure A), your function should populate each next pointer to point to its next right node, just like in Figure B. The serialized output is in level order as connected by the next pointers, with '#' signifying the end of each level.
```

Example 2:

```
Input: root = []
Output: []
```

Constraints:

- The number of nodes in the tree is in the range `[0, 6000]`.
- `-100 <= Node.val <= 100`

Follow-up:

- You may only use constant extra space.
- The recursive approach is fine. You may assume implicit stack space does not count as extra space for this problem.

SOLUTIONS (PYTHON 3)

Solution 1: BFS

> **How to think about it**
>
> Unlike the previous problem, the tree need not be perfect, so a left child does not always connect to a right child. Level-order is still correct: dequeue a level and link neighbors. n ≤ 6000.

We use a queue q for level order traversal. Each time we traverse a level, we connect the nodes of the current level in order.

The time complexity is O(n), and the space complexity is O(n). Here, n is the number of nodes in the binary tree.

Python 3

```
"""
# Definition for a Node.
class Node:
    def __init__(self, val: int = 0, left: 'Node' = None, right: 'Node' = None, next: 'Node' = None):
        self.val = val
        self.left = left
        self.right = right
        self.next = next
"""

class Solution:
    def connect(self, root: "Node") -> "Node":
        if root is None:
            return root
        q = deque([root])
        while q:
            p = None
            for _ in range(len(q)):
                node = q.popleft()
                if p:
                    p.next = node
                p = node
                if node.left:
                    q.append(node.left)
                if node.right:
                    q.append(node.right)
        return root
```

Solution 2: Space Optimization

> **How to think about it**
>
> Solution 1's queue is as wide as a level; the follow-up wants O(1) space. The current level is already a next list. While walking it we chain the next level's non-null children in order and remember that level's head, then step onto the new list. No queue.

The space complexity of Solution 1 is relatively high because it requires a queue to store the nodes of each level. We can implement it with constant space.

We define two pointers prev and next, which point to the previous node and the first node of the next level, respectively. When traversing the nodes of the current level, we string the nodes of the next level together and find the first node of the next level. After the current level is traversed, we assign the first node next of the next level to node and continue to traverse.

The time complexity is O(n), where n is the number of nodes in the binary tree. The space complexity is O(1).

Python 3

```
"""
# Definition for a Node.
class Node:
    def __init__(self, val: int = 0, left: 'Node' = None, right: 'Node' = None, next: 'Node' = None):
        self.val = val
        self.left = left
        self.right = right
        self.next = next
"""

class Solution:
    def connect(self, root: 'Node') -> 'Node':
        def modify(curr):
            nonlocal prev, next
            if curr is None:
                return
            next = next or curr
            if prev:
                prev.next = curr
            prev = curr

        node = root
        while node:
            prev = next = None
            while node:
                modify(node.left)
                modify(node.right)
                node = node.next
            node = next
        return root
```

PATTERN 12 · TREE BFS (LEVEL ORDER) · PROBLEM 11 OF 20

662. Maximum Width of Binary Tree

Medium · Tree, Depth-First Search, Breadth-First Search, Binary Tree

leetcode.com/problems/maximum-width-of-binary-tree

★ **TOP 10 PROBLEM** in Tree BFS (Level Order): master this one first

PROBLEM

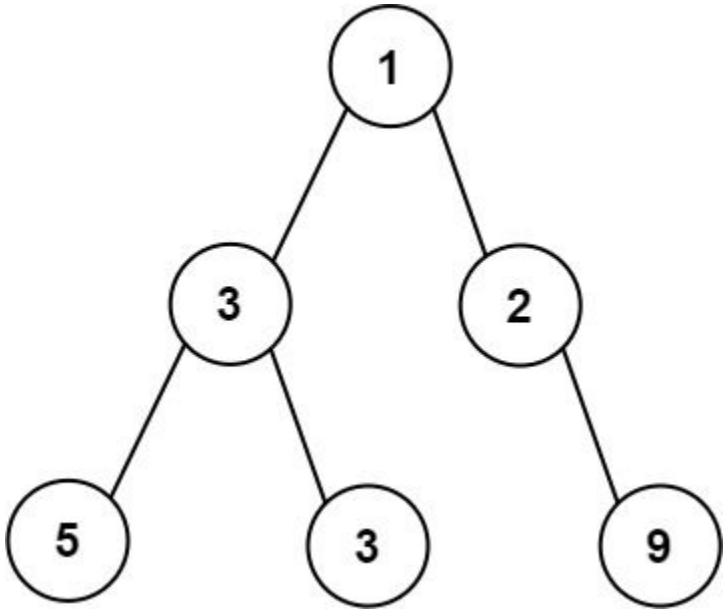
Given the `root` of a binary tree, return *the **maximum width** of the given tree*.

The **maximum width** of a tree is the maximum **width** among all levels.

The **width** of one level is defined as the length between the end-nodes (the leftmost and rightmost non-null nodes), where the null nodes between the end-nodes that would be present in a complete binary tree extending down to that level are also counted into the length calculation.

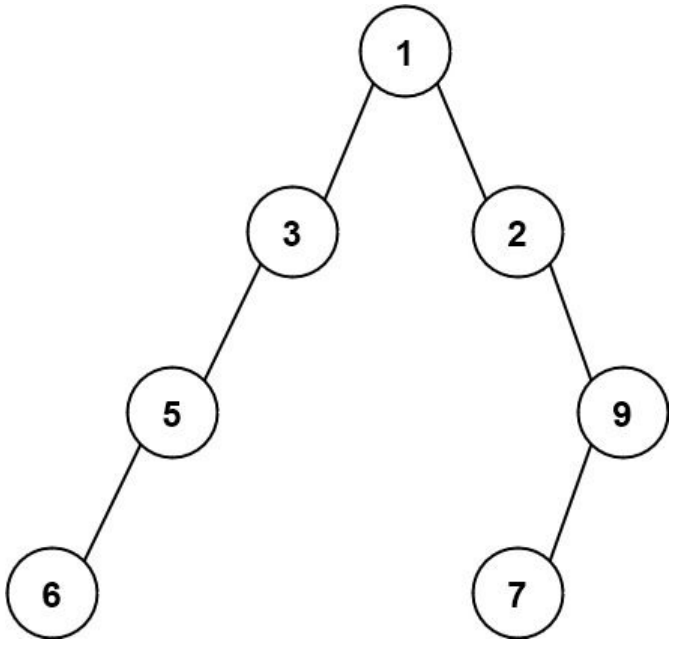
It is **guaranteed** that the answer will in the range of a **32-bit** signed integer.

Example 1:



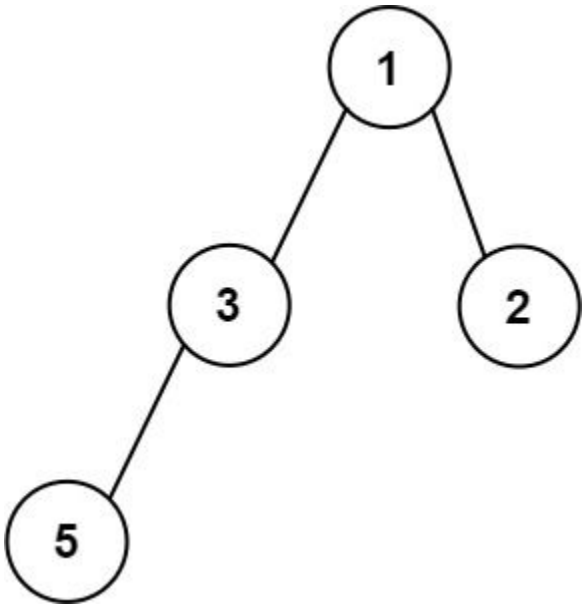
```
Input: root = [1,3,2,5,3,null,9]
Output: 4
Explanation: The maximum width exists in the third level with length 4 (5,3,null,9).
```

Example 2:



```
Input: root = [1,3,2,5,null,null,9,6,null,7]
Output: 7
Explanation: The maximum width exists in the fourth level with length 7
(6,null,null,null,null,null,7).
```

Example 3:



```
Input: root = [1,3,2,5]
Output: 2
Explanation: The maximum width exists in the second level with length 2 (3,2).
```

Constraints:

- The number of nodes in the tree is in the range `[1, 3000]`.
- `-100 <= Node.val <= 100`

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

Width is the span between the leftmost and rightmost positions on a level, counting holes. Storing nodes alone hides those holes. Number the root 1, left i≪ 1, right i≪ 1|1. In BFS the width is last index minus first plus one; keep the maximum.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def widthOfBinaryTree(self, root: Optional[TreeNode]) -> int:
        ans = 0
        q = deque([(root, 1)])
        while q:
            ans = max(ans, q[-1][1] - q[0][1] + 1)
            for _ in range(len(q)):
                root, i = q.popleft()
                if root.left:
                    q.append((root.left, i << 1))
                if root.right:
                    q.append((root.right, i << 1 | 1))
        return ans
```

Complexity. Time: O(n). Space: O(w), w = widest level.

Solution 2

How to think about it

BFS needs a queue. DFS records the first index seen at each depth and updates the width as i - t[depth] + 1 with the same numbering.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def widthOfBinaryTree(self, root: Optional[TreeNode]) -> int:
        def dfs(root, depth, i):
            if root is None:
                return
            if len(t) == depth:
                t.append(i)
            else:
                nonlocal ans
                ans = max(ans, i - t[depth] + 1)
            dfs(root.left, depth + 1, i << 1)
            dfs(root.right, depth + 1, i << 1 | 1)

        ans = 1
        t = []
        dfs(root, 0, 1)
        return ans
```

Complexity. Time: O(n). Space: O(h).

            best_level = level
        level += 1
    return best_level, best_width
```

PATTERN 12 · TREE BFS (LEVEL ORDER) · PROBLEM 12 OF 20

515. Find Largest Value in Each Tree Row

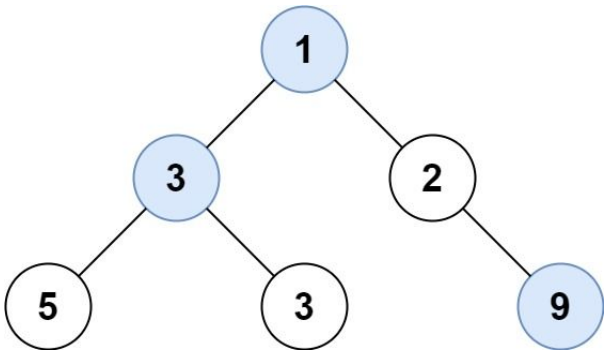
Medium · Tree, Depth-First Search, Breadth-First Search, Binary Tree

leetcode.com/problems/find-largest-value-in-each-tree-row

PROBLEM

Given the `root` of a binary tree, return *an array of the largest value in each row* of the tree **(0-indexed)**.

Example 1:



```
Input: root = [1,3,2,5,3,null,9]
Output: [1,3,9]
```

Example 2:

```
Input: root = [1,2,3]
Output: [1,3]
```

Constraints:

- The number of nodes in the tree will be in the range `[0, 10^4]`.
- `-2^31 <= Node.val <= 2^31 - 1`

SOLUTIONS (PYTHON 3)

Solution 1: BFS

> **How to think about it**
>
> The maximum of each level can be taken during a level-order walk. Enqueue the root, pop a whole level, track its maximum, and push children. Each finished level yields one answer. An empty tree returns an empty list. Time is linear in the number of nodes.

We define a queue q and put the root node into the queue. Each time, we take out all the nodes of the current level from the queue, find the maximum value, and then put all the nodes of the next level into the queue until the queue is empty.

The time complexity is O(n), and the space complexity is O(n). Here, n is the number of nodes in the binary tree.

Python 3

```python
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def largestValues(self, root: Optional[TreeNode]) -> List[int]:
        ans = []
        if root is None:
            return ans
        q = deque([root])
        while q:
            x = -inf
            for _ in range(len(q)):
                node = q.popleft()
                x = max(x, node.val)
                if node.left:
                    q.append(node.left)
                if node.right:
                    q.append(node.right)
            ans.append(x)
        return ans
```

Solution 2

How to think about it

BFS is the natural level scan but needs a queue. DFS can carry the depth: append when the depth equals the answer length, otherwise take a maximum. Preorder creates a slot the first time a depth is seen. Extra space is the recursion depth; the values match BFS.

Python 3

```python
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def largestValues(self, root: Optional[TreeNode]) -> List[int]:
        def dfs(root, curr):
            if root is None:
                return
            if curr == len(ans):
                ans.append(root.val)
            else:
                ans[curr] = max(ans[curr], root.val)
            dfs(root.left, curr + 1)
            dfs(root.right, curr + 1)

        ans = []
        dfs(root, 0)
        return ans
```

Complexity. Time: O(n). Space: O(h).

        walk(node.right, depth + 1)

    walk(root, 0)
    return best
```

513. Find Bottom Left Tree Value

Medium · Tree, Depth-First Search, Breadth-First Search, Binary Tree

leetcode.com/problems/find-bottom-left-tree-value

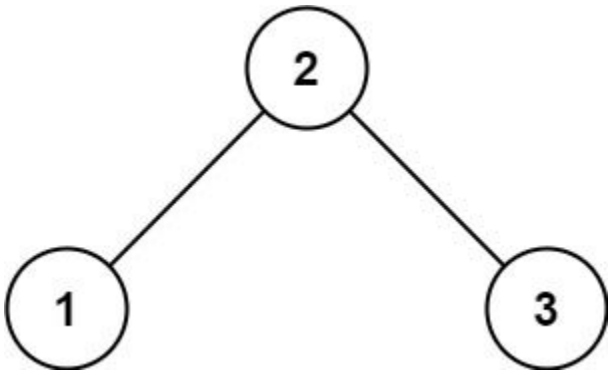
★ **TOP 10 PROBLEM** in Tree BFS (Level Order): master this one first

PROBLEM

You are given the `root` of a binary tree.

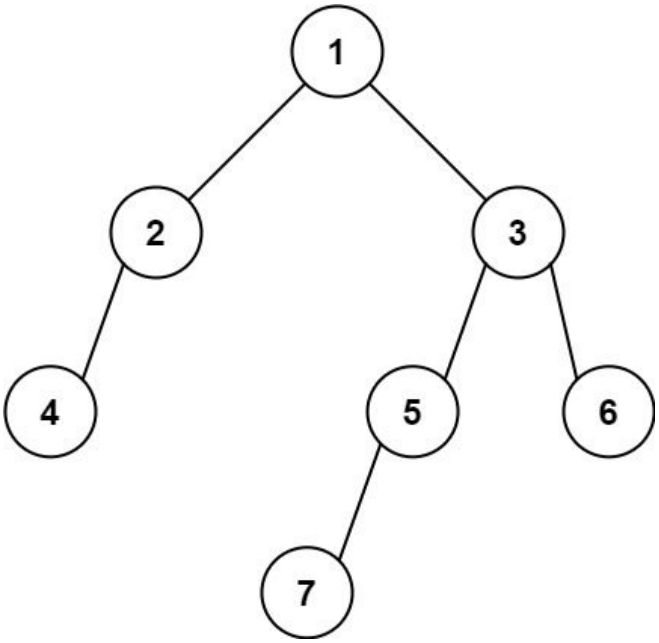
Return the **leftmost** value in the **last** row of the tree.

Example 1:



```
Input: root = [2,1,3]
Output: 1
Explanation: The last row is [1,3], so the leftmost value is 1.
```

Example 2:



```
Input: root = [1,2,3,4,null,5,6,null,null,7]
Output: 7
Explanation: The last row contains only the node 7.
```

Constraints:

- The number of nodes in the tree is in the range `[1, 10^4]`.

- -2^{31} <= Node.val <= 2^{31} - 1

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

The bottom-left value is the first node of the last level in a level-order walk. In BFS the queue front is the leftmost node of the current level. Record the front at the start of each level and enqueue children. When the queue drains, the last recorded value is the answer. Level order processes the deepest level last.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def findBottomLeftValue(self, root: Optional[TreeNode]) -> int:
        q = deque([root])
        ans = 0
        while q:
            ans = q[0].val
            for _ in range(len(q)):
                node = q.popleft()
                if node.left:
                    q.append(node.left)
                if node.right:
                    q.append(node.right)
        return ans
```

Complexity. Time: O(n). Space: O(w), w = widest level.

Solution 2

How to think about it

BFS uses an O(w) queue. DFS only needs to remember the first time a greater depth appears. A left-then-right preorder meets the leftmost node of each depth first; update the answer only when the depth is strictly larger. Extra space is the recursion stack, and the result matches level order.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def findBottomLeftValue(self, root: Optional[TreeNode]) -> int:
        def dfs(root, curr):
            if root is None:
                return
            dfs(root.left, curr + 1)
            dfs(root.right, curr + 1)
            nonlocal ans, mx
            if mx < curr:
                mx = curr
                ans = root.val

        ans = mx = 0
        dfs(root, 1)
        return ans
```

            if node.left:
                queue.append(node.left)
            if node.right:
                queue.append(node.right)
        depth += 1
    return None
```

623. Add One Row to Tree

Medium · Tree, Depth-First Search, Breadth-First Search, Binary Tree

leetcode.com/problems/add-one-row-to-tree

PROBLEM

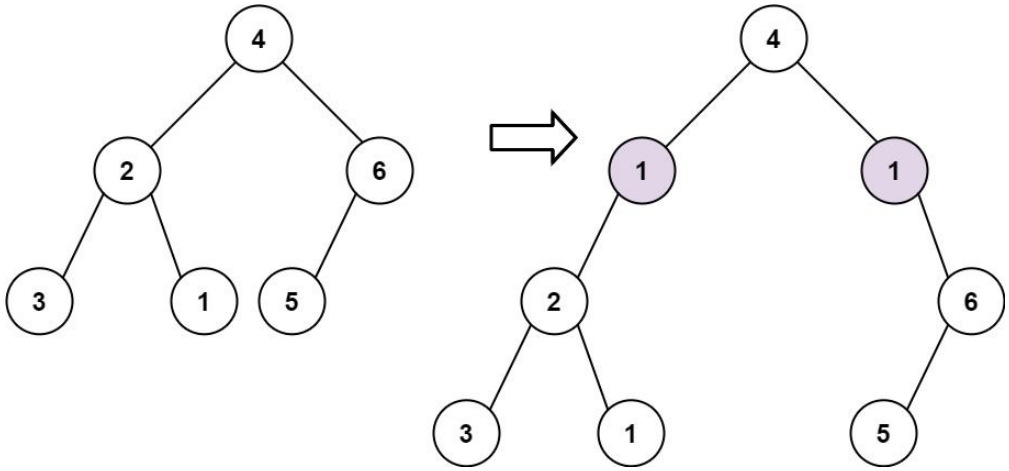
Given the `root` of a binary tree and two integers `val` and `depth`, add a row of nodes with value `val` at the given depth `depth`.

Note that the `root` node is at depth `1`.

The adding rule is:

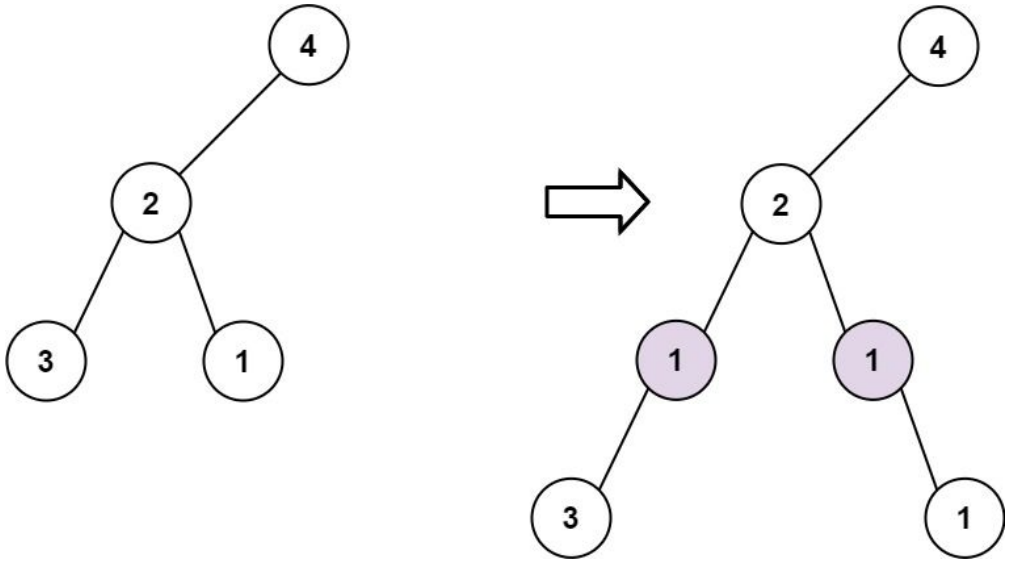
- Given the integer `depth`, for each not null tree node `cur` at the depth `depth - 1`, create two tree nodes with value `val` as `cur`'s left subtree root and right subtree root.
- `cur`'s original left subtree should be the left subtree of the new left subtree root.
- `cur`'s original right subtree should be the right subtree of the new right subtree root.
- If `depth == 1` that means there is no depth `depth - 1` at all, then create a tree node with value `val` as the new root of the whole original tree, and the original tree is the new root's left subtree.

Example 1:



```
Input: root = [4,2,6,3,1,5], val = 1, depth = 2
Output: [4,1,1,2,null,null,6,3,1,5]
```

Example 2:



```
Input: root = [4,2,null,3,1], val = 1, depth = 3
Output: [4,2,null,1,1,3,null,null,1]
```

Constraints:

- The number of nodes in the tree is in the range `[1, 10^4]`.
- The depth of the tree is in the range `[1, 10^4]`.
- `-100 <= Node.val <= 100`
- `-10^5 <= val <= 10^5`
- `1 <= depth <= the depth of tree + 1`

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

A new row must be inserted at depth depth, pushing the old nodes one level down. Rebuilding the whole tree is unnecessary. If depth=1, wrap the old root. Otherwise DFS to depth depth-1 and hang the previous children under the new nodes.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def addOneRow(
        self, root: Optional[TreeNode], val: int, depth: int
    ) -> Optional[TreeNode]:
        def dfs(root, d):
            if root is None:
                return
            if d == depth - 1:
                root.left = TreeNode(val, root.left, None)
                root.right = TreeNode(val, None, root.right)
                return
            dfs(root.left, d + 1)
            dfs(root.right, d + 1)

        if depth == 1:
            return TreeNode(val, root)
        dfs(root, 1)
        return root
```

Complexity. Time: O(n). Space: O(h).

Solution 2

> **How to think about it**
>
> DFS already attaches nodes at the parent layer. BFS reaches depth depth-1 with a queue and applies the same left/right splice, without recursion.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def addOneRow(
        self, root: Optional[TreeNode], val: int, depth: int
    ) -> Optional[TreeNode]:
        if depth == 1:
            return TreeNode(val, root)
        q = deque([root])
        i = 0
        while q:
            i += 1
            for _ in range(len(q)):
                node = q.popleft()
                if node.left:
                    q.append(node.left)
                if node.right:
                    q.append(node.right)
                if i == depth - 1:
                    node.left = TreeNode(val, node.left, None)
                    node.right = TreeNode(val, None, node.right)
        return root
```

Complexity. Time: O(n). Space: O(w), w = widest level.

1302. Deepest Leaves Sum

Medium · Tree, Depth-First Search, Breadth-First Search, Binary Tree

leetcode.com/problems/deepest-leaves-sum

PROBLEM

Given the

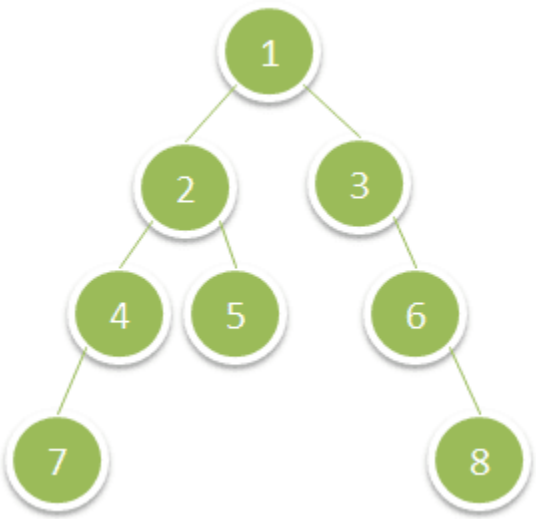
`root`

of a binary tree, return

the sum of values of its deepest leaves

.

Example 1:



```
Input: root = [1,2,3,4,5,null,6,7,null,null,null,null,8]
Output: 15
```

Example 2:

```
Input: root = [6,7,8,2,7,1,3,9,null,1,4,null,null,null,5]
Output: 19
```

Constraints:

- The number of nodes in the tree is in the range `[1, 10^4]`.
- `1 <= Node.val <= 100`

SOLUTIONS (PYTHON 3)

Solution 1: BFS

How to think about it

The sum of the deepest leaves can be obtained by a height pass plus a second walk, but two traversals are unnecessary. Level-order search already processes nodes by depth, so each layer's sum can be accumulated while dequeuing. The last nonempty layer is exactly the deepest one. We keep a queue of the current level and overwrite ans each time; when the queue is empty, ans is the answer.

We can use breadth-first search (BFS) to traverse the binary tree level by level, and calculate the sum of the node values at each level. After completing the traversal, return the sum of the node values at the last level.

The time complexity is O(n), and the space complexity is O(n). Here, n is the number of nodes in the tree.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def deepestLeavesSum(self, root: Optional[TreeNode]) -> int:
        q = deque([root])
        while q:
            ans = 0
            for _ in range(len(q)):
                node = q.popleft()
                ans += node.val
                if node.left:
                    q.append(node.left)
                if node.right:
                    q.append(node.right)
        return ans
```

Solution 2: DFS

> **How to think about it**
>
> BFS uses extra space proportional to the widest level. A recursive walk only needs the current depth: add the node when the depth matches the recorded maximum, and reset both the sum and the maximum when the depth is larger. One traversal then maintains the deepest-leaf sum.

We can use depth-first search (DFS) to recursively traverse the binary tree while keeping track of the current node's depth, the maximum depth, and the sum of the deepest leaf nodes. When visiting the current node, if the current node's depth equals the maximum depth, add the current node's value to the sum of the deepest leaf nodes. If the current node's depth is greater than the maximum depth, update the maximum depth to the current node's depth and update the sum of the deepest leaf nodes to the current node's value.

The time complexity is O(n), and the space complexity is O(n). Here, n is the number of nodes in the tree.

Python 3

```python
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def deepestLeavesSum(self, root: Optional[TreeNode]) -> int:
        def dfs(root, i):
            nonlocal ans, mx
            if root is None:
                return
            if i == mx:
                ans += root.val
            elif i > mx:
                ans = root.val
                mx = i
            dfs(root.left, i + 1)
            dfs(root.right, i + 1)

        ans = mx = 0
        dfs(root, 1)
        return ans
```

            if node.left:
                queue.append(node.left)
            if node.right:
                queue.append(node.right)
        depth += 1
    return 0
```

988. Smallest String Starting From Leaf

Medium · Tree, Depth-First Search, String, Backtracking, Binary Tree

leetcode.com/problems/smallest-string-starting-from-leaf

PROBLEM

You are given the `root` of a binary tree where each node has a value in the range `[0, 25]` representing the letters `'a'` to `'z'`.

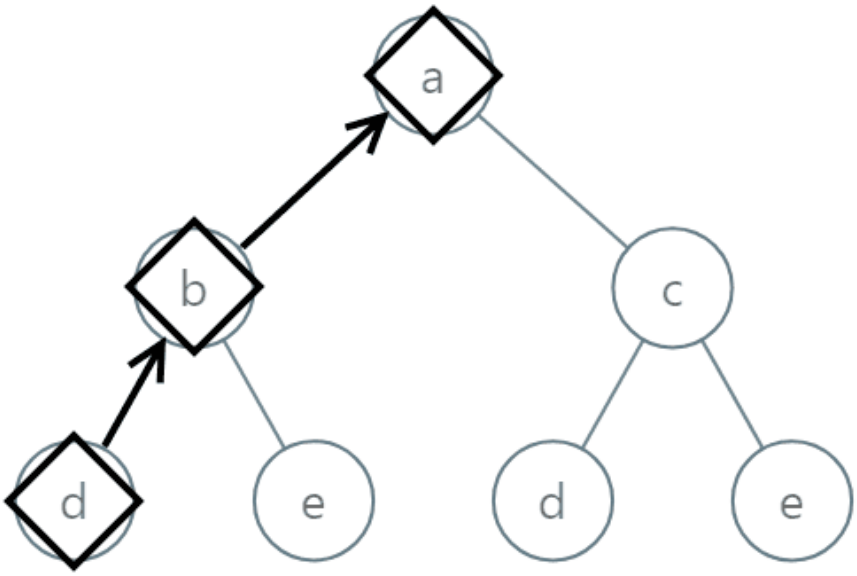
Return *the **lexicographically smallest** string that starts at a leaf of this tree and ends at the root*.

As a reminder, any shorter prefix of a string is **lexicographically smaller**.

- For example, `"ab"` is lexicographically smaller than `"aba"`.

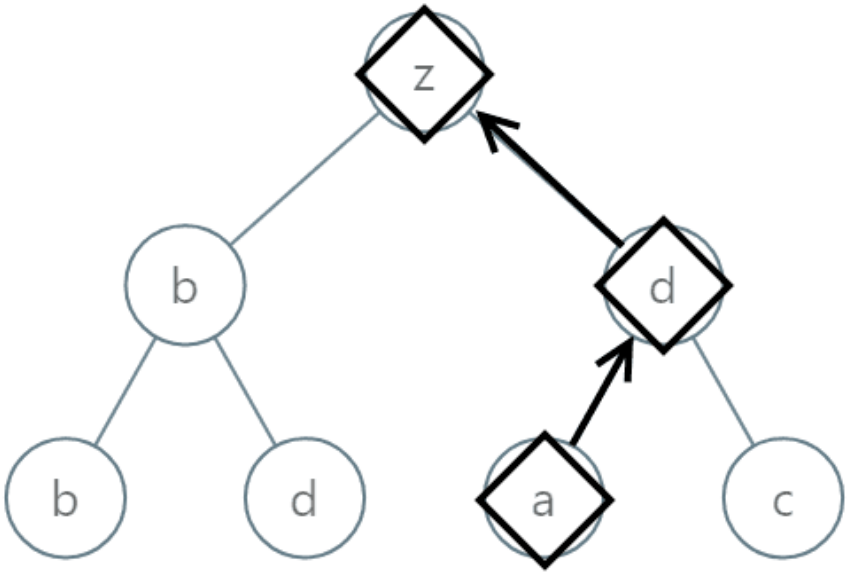
A leaf of a node is a node that has no children.

Example 1:



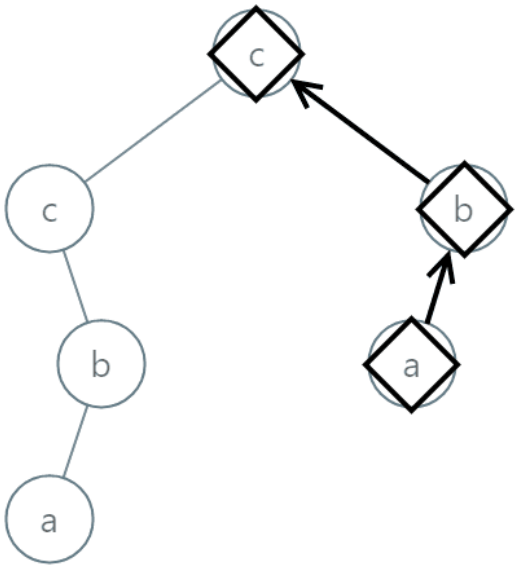
```
Input: root = [0,1,2,3,4,3,4]
Output: "dba"
```

Example 2:



```
Input: root = [25,1,3,1,3,0,2]
Output: "adz"
```

Example 3:



```
Input: root = [2,2,1,null,1,0,null,0]
Output: "abc"
```

Constraints:

- The number of nodes in the tree is in the range `[1, 8500]`.
- `0 <= Node.val <= 25`

SOLUTION (PYTHON 3)

Solution 1

How to think about it

A leaf-to-root path is a string; we want the lexicographically smallest. At most 8500 nodes, so every root-to-leaf path can be enumerated. DFS pushes letters, and at a leaf the reversed path is compared with the answer; then the letter is popped.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def smallestFromLeaf(self, root: TreeNode) -> str:
        ans = chr(ord('z') + 1)

        def dfs(root, path):
            nonlocal ans
            if root:
                path.append(chr(ord('a') + root.val))
                if root.left is None and root.right is None:
                    ans = min(ans, ''.join(reversed(path)))
                dfs(root.left, path)
                dfs(root.right, path)
                path.pop()

        dfs(root, [])
        return ans
```

Complexity. Time: O(n * h) (a string of length up to h is built at every leaf). Space: O(h).

```

```
    return best[0]
```

1145. Binary Tree Coloring Game

Medium · Tree, Depth-First Search, Binary Tree

leetcode.com/problems/binary-tree-coloring-game

PROBLEM

Two players play a turn based game on a binary tree. We are given the `root` of this binary tree, and the number of nodes `n` in the tree. `n` is odd, and each node has a distinct value from `1` to `n`.

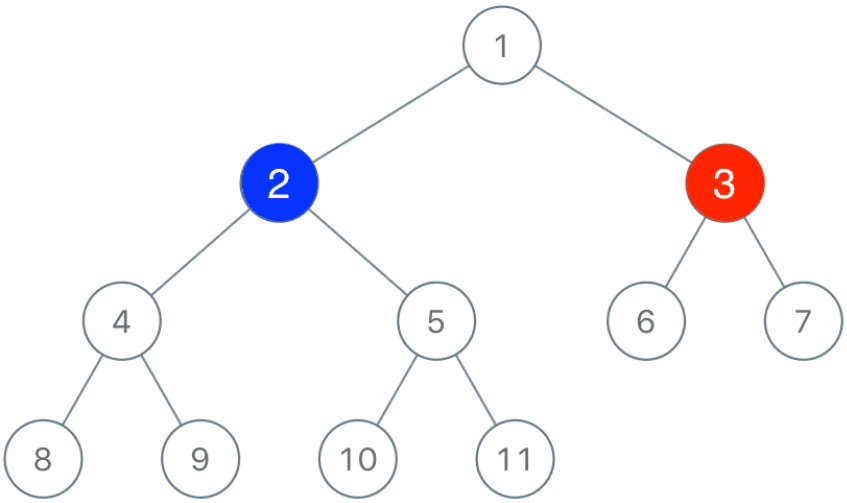
Initially, the first player names a value `x` with `1 <= x <= n`, and the second player names a value `y` with `1 <= y <= n` and `y != x`. The first player colors the node with value `x` red, and the second player colors the node with value `y` blue.

Then, the players take turns starting with the first player. In each turn, that player chooses a node of their color (red if player 1, blue if player 2) and colors an **uncolored** neighbor of the chosen node (either the left child, right child, or parent of the chosen node.)

If (and only if) a player cannot choose such a node in this way, they must pass their turn. If both players pass their turn, the game ends, and the winner is the player that colored more nodes.

You are the second player. If it is possible to choose such a `y` to ensure you win the game, return `true`. If it is not possible, return `false`.

Example 1:



```
Input: root = [1,2,3,4,5,6,7,8,9,10,11], n = 11, x = 3
Output: true
Explanation: The second player can choose the node with value 2.
```

Example 2:

```
Input: root = [1,2,3], n = 3, x = 1
Output: false
```

Constraints:

- The number of nodes in the tree is `n`.
- `1 <= x <= n <= 100`
- `n` is odd.
- 1 <= Node.val <= n

- All the values of the tree are **unique**.

SOLUTION (PYTHON 3)

Solution 1: DFS

> **How to think about it**
>
> After the first player takes x, the tree splits into the left subtree, the right subtree, and the parent side. The second player colors the root of the largest of the three and owns that component. More than n/2 nodes there is a win. Finding x and counting the two subtrees yields all three sizes.

First, we use DFS to find the node where player 1's colored point x is located, denoted as node.

Next, we count the number of nodes in the left and right subtrees of node, denoted as l and r respectively, and the number of nodes in the direction of node's parent node is n - l - r - 1. As long as max(l, r, n - l - r - 1) > n/2, player 2 has a winning strategy.

The time complexity is O(n), and the space complexity is O(n). Here, n is the total number of nodes.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def btreeGameWinningMove(self, root: Optional[TreeNode], n: int, x: int) -> bool:
        def dfs(root):
            if root is None or root.val == x:
                return root
            return dfs(root.left) or dfs(root.right)

        def count(root):
            if root is None:
                return 0
            return 1 + count(root.left) + count(root.right)

        node = dfs(root)
        l, r = count(node.left), count(node.right)
        return max(l, r, n - l - r - 1) > n // 2
```

2096. Step-By-Step Directions From a Binary Tree Node to Another

Medium · Tree, Depth-First Search, String, Binary Tree, Lowest Common Ancestor, Binary Lifting

leetcode.com/problems/step-by-step-directions-from-a-binary-tree-node-to-another

PROBLEM

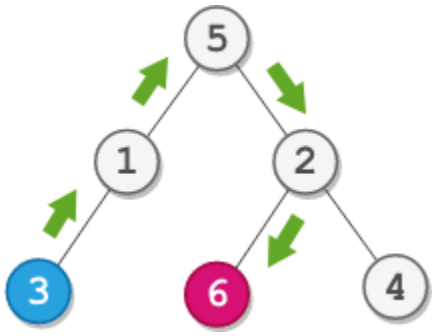
You are given the `root` of a **binary tree** with `n` nodes. Each node is uniquely assigned a value from `1` to `n`. You are also given an integer `startValue` representing the value of the start node `s`, and a different integer `destValue` representing the value of the destination node `t`.

Find the **shortest path** starting from node `s` and ending at node `t`. Generate step-by-step directions of such path as a string consisting of only the **uppercase** letters `'L'`, `'R'`, and `'U'`. Each letter indicates a specific direction:

- `'L'` means to go from a node to its **left child** node.
- `'R'` means to go from a node to its **right child** node.
- `'U'` means to go from a node to its **parent** node.

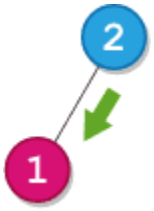
Return *the step-by-step directions of the **shortest path** from node `s` to node `t`.*

Example 1:



```
Input: root = [5,1,2,3,null,6,4], startValue = 3, destValue = 6
Output: "UURL"
Explanation: The shortest path is: 3 → 1 → 5 → 2 → 6.
```

Example 2:



```
Input: root = [2,1], startValue = 2, destValue = 1
Output: "L"
Explanation: The shortest path is: 2 → 1.
```

Constraints:

- The number of nodes in the tree is `n`.
- `2 <= n <= 10^5`
- `1 <= Node.val <= n`
- All the values in the tree are **unique**.
- `1 <= startValue, destValue <= n`

- `startValue != destValue`

SOLUTIONS (PYTHON 3)

Solution 1: Lowest Common Ancestor + DFS

> **How to think about it**
>
> The unique path goes through the LCA. Upward edges become `U`; the descent uses `L`/`R`. Three tree walks are fine for n ≤ 10^5. Find the LCA, DFS both directions from it, replace the start path by `U`s, and concatenate.

We can first find the lowest common ancestor of nodes startValue and destValue, denoted as node. Then, starting from node, we find the paths to startValue and destValue respectively. The path from startValue to node will consist of a number of Us, and the path from node to destValue will be the path. Finally, we concatenate these two paths.

The time complexity is O(n), and the space complexity is O(n). Here, n is the number of nodes in the binary tree.

Python 3

```python
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right

class Solution:
    def getDirections(
        self, root: Optional[TreeNode], startValue: int, destValue: int
    ) -> str:
        def lca(node: Optional[TreeNode], p: int, q: int):
            if node is None or node.val in (p, q):
                return node
            left = lca(node.left, p, q)
            right = lca(node.right, p, q)
            if left and right:
                return node
            return left or right

        def dfs(node: Optional[TreeNode], x: int, path: List[str]):
            if node is None:
                return False
            if node.val == x:
                return True
            path.append("L")
            if dfs(node.left, x, path):
                return True
            path[-1] = "R"
            if dfs(node.right, x, path):
                return True
            path.pop()
            return False

        node = lca(root, startValue, destValue)

        path_to_start = []
        path_to_dest = []

        dfs(node, startValue, path_to_start)
        dfs(node, destValue, path_to_dest)

        return "U" * len(path_to_start) + "".join(path_to_dest)
```

Solution 2: Lowest Common Ancestor + DFS (Optimized)

How to think about it

Solution 1 finds the LCA then walks twice more. Paths from the root share a prefix; stripping it is exactly “up to the LCA then down.” The extra LCA search disappears. Two DFS strings, skip the common prefix of length i, emit (|start|-i) `U`s plus the destination suffix.

We can start from root, find the paths to startValue and destValue, denoted as pathToStart and pathToDest, respectively. Then, remove the longest common prefix of pathToStart and pathToDest. At this point, the length of pathToStart is the number of Us in the answer, and the path of pathToDest is the path in the answer. We just need to concatenate these two paths.

The time complexity is O(n), and the space complexity is O(n). Here, n is the number of nodes in the binary tree.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right

class Solution:
    def getDirections(
        self, root: Optional[TreeNode], startValue: int, destValue: int
    ) -> str:
        def dfs(node: Optional[TreeNode], x: int, path: List[str]):
            if node is None:
                return False
            if node.val == x:
                return True
            path.append("L")
            if dfs(node.left, x, path):
                return True
            path[-1] = "R"
            if dfs(node.right, x, path):
                return True
            path.pop()
            return False

        path_to_start = []
        path_to_dest = []

        dfs(root, startValue, path_to_start)
        dfs(root, destValue, path_to_dest)
        i = 0
        while (
            i < len(path_to_start)
            and i < len(path_to_dest)
            and path_to_start[i] == path_to_dest[i]
        ):
            i += 1
        return "U" * (len(path_to_start) - i) + "".join(path_to_dest[i:])
```

Solution 3: Explicit-Stack Lowest Common Ancestor

How to think about it

The shortest path goes through the lowest common ancestor. Every step above that ancestor is `U`, and the descent from the ancestor to the destination is `L` or `R`. Three linear walks fit $n \le 10^5$. Both the ancestor search and the direction search enter the left child first. A left chain can be n nodes long, so recursion overflows before the direction string is finished. The ancestor is known only after both subtrees return: the current node is the ancestor when both sides found a target, otherwise the non-empty side is passed upward. An explicit stack separates “expand both children” from “both children have returned,” and the direction search pushes a backtrack marker before the left child. A failed left subtree rewrites the last step to `R` and searches the right child, stopping when the target is found. The length of the start path is the number of `U`s, concatenated with the path from the ancestor to the destination.

An explicit stack finds the lowest common ancestor of startValue and destValue, denoted as node. State 0 expands the two children, and state 1 decides the ancestor after both sides return: the current node when both sides are non-empty, otherwise the non-empty side. The same stack then walks from node, recording `L` to the left and rewriting that step to `R` when the left subtree misses the target. The number of steps from startValue back to node is the number of `U`s, followed by the direction string from node to destValue.

The time complexity is O(n), and the space complexity is O(n). Here, n is the number of nodes in the binary tree.

Python 3

```python
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right

class Solution:
    def getDirections(
        self, root: Optional[TreeNode], startValue: int, destValue: int
    ) -> str:
        def lca(root: Optional[TreeNode], p: int, q: int):
            ret = {}
            stk = [(root, 0)]
            while stk:
                node, state = stk.pop()
                if state == 0:
                    if node is None:
                        continue
                    if node.val in (p, q):
                        ret[id(node)] = node
                        continue
                    stk.append((node, 1))
                    stk.append((node.right, 0))
                    stk.append((node.left, 0))
                else:
                    left = ret.get(id(node.left)) if node.left is not None else None
                    right = ret.get(id(node.right)) if node.right is not None else None
                    if left and right:
                        ret[id(node)] = node
                    else:
                        ret[id(node)] = left or right
            return ret.get(id(root))

        def dfs(start: Optional[TreeNode], x: int, path: List[str]) -> bool:
            stk = [(start, 0)]
            while stk:
                node, state = stk.pop()
                if state == 0:
                    if node is None:
                        continue
                    if node.val == x:
                        return True
                    path.append('L')
                    stk.append((node, 1))
                    stk.append((node.left, 0))
                elif state == 1:
                    path[-1] = 'R'
                    stk.append((node, 2))
                    stk.append((node.right, 0))
                else:
                    path.pop()
            return False

        node = lca(root, startValue, destValue)
        path_to_start: List[str] = []
        path_to_dest: List[str] = []
        dfs(node, startValue, path_to_start)
        dfs(node, destValue, path_to_dest)
        return 'U' * len(path_to_start) + ''.join(path_to_dest)
```

Solution 4: Explicit-Stack Root Paths

How to think about it

Solution 1 still runs a separate ancestor search and then walks twice from that ancestor. Paths from the root share a prefix, and stripping it is the same as climbing back to the ancestor and then descending, so the dedicated ancestor search can be dropped. The two direction searches can still follow a chain of length n, so they use the same explicit stack: push a backtrack marker, then the left child, and rewrite the last step to `R` when the left subtree fails. After the common prefix of length i is removed, the answer is (|start|-i) `U`s plus the destination suffix.

An explicit stack walks from root to startValue and to destValue, producing pathToStart and pathToDest. A failed left subtree rewrites the last step to `R` before the right child is searched, so the strings match the previous depth-first order. After the longest common prefix is removed, the remaining length of pathToStart is the number of `U`s, and the remaining part of pathToDest is the downward path. Concatenate the two pieces.

The time complexity is O(n), and the space complexity is O(n). Here, n is the number of nodes in the binary tree.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right

class Solution:
    def getDirections(
        self, root: Optional[TreeNode], startValue: int, destValue: int
    ) -> str:
        def dfs(start: Optional[TreeNode], x: int, path: List[str]) -> bool:
            stk = [(start, 0)]
            while stk:
                node, state = stk.pop()
                if state == 0:
                    if node is None:
                        continue
                    if node.val == x:
                        return True
                    path.append('L')
                    stk.append((node, 1))
                    stk.append((node.left, 0))
                elif state == 1:
                    path[-1] = 'R'
                    stk.append((node, 2))
                    stk.append((node.right, 0))
                else:
                    path.pop()
            return False

        path_to_start: List[str] = []
        path_to_dest: List[str] = []
        dfs(root, startValue, path_to_start)
        dfs(root, destValue, path_to_dest)
        i = 0
        while (
            i < len(path_to_start)
            and i < len(path_to_dest)
            and path_to_start[i] == path_to_dest[i]
        ):
            i += 1
        return 'U' * (len(path_to_start) - i) + ''.join(path_to_dest[i:])
```

958. Check Completeness of a Binary Tree

Medium · Tree, Breadth-First Search, Binary Tree

leetcode.com/problems/check-completeness-of-a-binary-tree

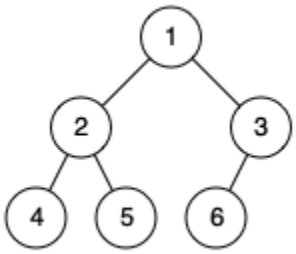
★ **TOP 10 PROBLEM** in Tree BFS (Level Order): master this one first

PROBLEM

Given the `root` of a binary tree, determine if it is a *complete binary tree*.

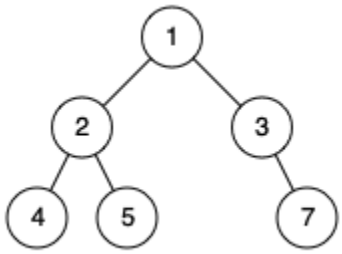
In a **complete binary tree**, every level, except possibly the last, is completely filled, and all nodes in the last level are as far left as possible. It can have between `1` and 2^h nodes inclusive at the last level `h`.

Example 1:



```
Input: root = [1,2,3,4,5,6]
Output: true
Explanation: Every level before the last is full (ie. levels with node-values {1} and {2, 3}), and all
nodes in the last level ({4, 5, 6}) are as far left as possible.
```

Example 2:



```
Input: root = [1,2,3,4,5,null,7]
Output: false
Explanation: The node with value 7 isn't as far left as possible.
```

Constraints:

- The number of nodes in the tree is in the range `[1, 100]`.
- `1 <= Node.val <= 1000`

SOLUTION (PYTHON 3)

Solution 1

> **How to think about it**
>
> In a complete tree, no non-null node may follow a null in level order. Enqueue null children as well; after the first null is popped, the rest of the queue must be null. The tree has at most 100 nodes, so one BFS decides it.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def isCompleteTree(self, root: TreeNode) -> bool:
        q = deque([root])
        while q:
            node = q.popleft()
            if node is None:
                break
            q.append(node.left)
            q.append(node.right)
        return all(node is None for node in q)
```

Complexity. Time: O(n). Space: O(n).

```

2641. Cousins in Binary Tree II

Medium · Tree, Depth-First Search, Breadth-First Search, Hash Table, Binary Tree

leetcode.com/problems/cousins-in-binary-tree-ii

PROBLEM

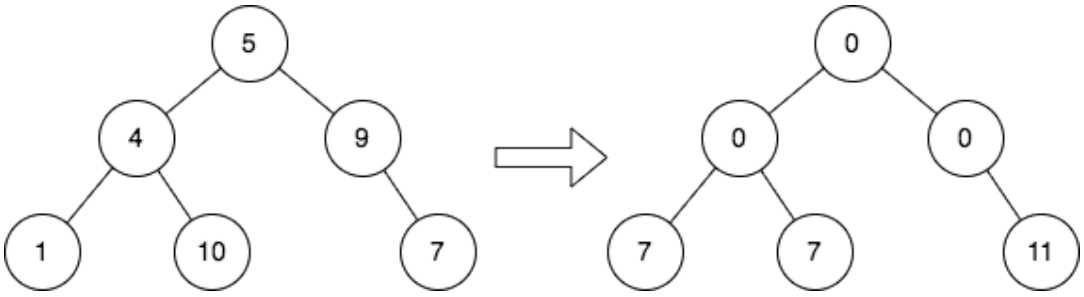
Given the `root` of a binary tree, replace the value of each node in the tree with the **sum of all its cousins' values**.

Two nodes of a binary tree are **cousins** if they have the same depth with different parents.

Return *the* `root` *of the modified tree*.

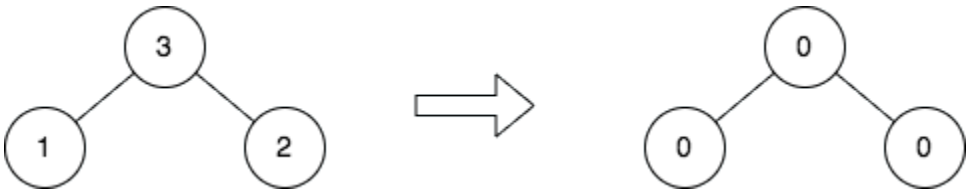
Note that the depth of a node is the number of edges in the path from the root node to it.

Example 1:



```
Input: root = [5,4,9,1,10,null,7]
Output: [0,0,0,7,7,null,11]
Explanation: The diagram above shows the initial binary tree and the binary tree after changing the
value of each node.
- Node with value 5 does not have any cousins so its sum is 0.
- Node with value 4 does not have any cousins so its sum is 0.
- Node with value 9 does not have any cousins so its sum is 0.
- Node with value 1 has a cousin with value 7 so its sum is 7.
- Node with value 10 has a cousin with value 7 so its sum is 7.
- Node with value 7 has cousins with values 1 and 10 so its sum is 11.
```

Example 2:



```
Input: root = [3,1,2]
Output: [0,0,0]
Explanation: The diagram above shows the initial binary tree and the binary tree after changing the
value of each node.
- Node with value 3 does not have any cousins so its sum is 0.
- Node with value 1 does not have any cousins so its sum is 0.
- Node with value 2 does not have any cousins so its sum is 0.
```

Constraints:

- The number of nodes in the tree is in the range $[1, 10^5]$.
- $1 <= Node.val <= 10^4$

SOLUTIONS (PYTHON 3)

Solution 1: Two DFS Traversals

> **How to think about it**
>
> Each node becomes the sum of its level minus itself and its sibling. Rescanning a level per node is too slow for $n \le 10^5$. The level sum depends only on depth, so it can be computed once. The first DFS fills s[depth]; the second writes, at the parent, the child-level total minus the two siblings. The root has no cousins and becomes 0.

We create a list s to record the sum of the node values at each level of the binary tree, where s[depth] represents the sum of the node values at the depth-th level (the root node is at level 0).

Next, we perform a DFS traversal to calculate the values in the array s. Then, we perform another DFS traversal to update the values of each node's children. The value of a child node is equal to the sum of the node values at its level minus the value of the child node and its sibling nodes.

The time complexity is O(n), and the space complexity is O(n). Here, n is the number of nodes in the binary tree.

Python 3

```python
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def replaceValueInTree(self, root: Optional[TreeNode]) -> Optional[TreeNode]:
        def dfs1(root: Optional[TreeNode], depth: int):
            if root is None:
                return
            if len(s) <= depth:
                s.append(0)
            s[depth] += root.val
            dfs1(root.left, depth + 1)
            dfs1(root.right, depth + 1)

        def dfs2(root: Optional[TreeNode], depth: int):
            sub = (root.left.val if root.left else 0) + (
                root.right.val if root.right else 0
            )
            depth += 1
            if root.left:
                root.left.val = s[depth] - sub
                dfs2(root.left, depth)
            if root.right:
                root.right.val = s[depth] - sub
                dfs2(root.right, depth)

        s = []
        dfs1(root, 0)
        root.val = 0
        dfs2(root, 0)
        return root
```

Solution 2: Breadth-First Search (BFS)

> **How to think about it**
>
> Solution 1 uses two recursive passes and stores every level sum. In a BFS the current layer is already queued, so we sum the next layer, then subtract sibling pairs at each parent, dropping the extra array and the second DFS.

First, we update the root node's value to 0, and use a queue q to store all nodes at each level, initially enqueueing the root node.

Then, we traverse the queue, calculate the sum s of all child nodes' values at each level, then calculate the sum sub of each child node and its sibling nodes' values, and then update each child node's value to s - sub.

After the traversal ends, we return the root node.

The time complexity is O(n), and the space complexity is O(n). Here, n is the number of nodes in the binary tree.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def replaceValueInTree(self, root: Optional[TreeNode]) -> Optional[TreeNode]:
        root.val = 0
        q = [root]
        while q:
            t = []
            s = 0
            for node in q:
                if node.left:
                    t.append(node.left)
                    s += node.left.val
                if node.right:
                    t.append(node.right)
                    s += node.right.val
            for node in q:
                sub = (node.left.val if node.left else 0) + (
                    node.right.val if node.right else 0
                )
                if node.left:
                    node.left.val = s - sub
                if node.right:
                    node.right.val = s - sub
            q = t
        return root
```

THE IDEA

The answer for position i depends on a few earlier positions. Define what dp[i] means in one sentence, write the recurrence, fill left to right, and often keep only the last two or three values.

Signals: climbing stairs, house robber, decode ways, maximum subarray, longest increasing subsequence, word break, coin change as counting.

A TEMPLATE TO KEEP IN YOUR HANDS (PYTHON)

```
dp = [0] * (n + 1)
dp[0] = 1                              # base case
for i in range(1, n + 1):
    dp[i] = dp[i - 1]                  # take one step
    if i >= 2:
        dp[i] += dp[i - 2]             # or two steps
return dp[n]
```

PATTERN 13 · DYNAMIC PROGRAMMING - 1D · PROBLEM 1 OF 20

70. Climbing Stairs

Easy · Memoization, Math, Dynamic Programming

leetcode.com/problems/climbing-stairs

★ **TOP 10 PROBLEM** in Dynamic Programming - 1D: master this one first

PROBLEM

You are climbing a staircase. It takes `n` steps to reach the top.

Each time you can either climb `1` or `2` steps. In how many distinct ways can you climb to the top?

Example 1:

```
Input: n = 2
Output: 2
Explanation: There are two ways to climb to the top.
1. 1 step + 1 step
2. 2 steps
```

Example 2:

```
Input: n = 3
Output: 3
Explanation: There are three ways to climb to the top.
1. 1 step + 1 step + 1 step
2. 1 step + 2 steps
3. 2 steps + 1 step
```

Constraints:

- `1 <= n <= 45`

SOLUTIONS (PYTHON 3)

Solution 1: Recursion

How to think about it

The first idea is recursion: the last step is 1 or 2, so f(n) = f(n-1) + f(n-2). n ≤ 45, and a naive recursion re-expands the same subproblems, which explodes. The bottleneck is overlap. This is the Fibonacci sequence, so we can compute it bottom-up. f[i] depends only on the previous two terms, so two rolling variables suffice: O(n) time and O(1) extra space.

We define f[i] to represent the number of ways to climb to the i-th step, then f[i] can be transferred from f[i - 1] and f[i - 2], that is:

$$f[i] = f[i - 1] + f[i - 2]$$

The initial conditions are f[0] = 1 and f[1] = 1, that is, the number of ways to climb to the 0th step is 1, and the number of ways to climb to the 1st step is also 1.

The answer is f[n].

Since f[i] is only related to f[i - 1] and f[i - 2], we can use two variables a and b to maintain the current number of ways, reducing the space complexity to O(1).

The time complexity is O(n), and the space complexity is O(1).

Python 3

```
class Solution:
    def climbStairs(self, n: int) -> int:
        a, b = 0, 1
        for _ in range(n):
            a, b = b, a + b
        return b
```

Solution 2: Matrix Quick Power to Accelerate Recursion

> **How to think about it**
>
> Solution 1 is already O(n), which is enough for n ≤ 45, but a linear recurrence is still slow when n grows. A linear homogeneous recurrence is matrix multiplication: F_n comes from F_{n-1} times a fixed 2 × 2 transition. Fast matrix exponentiation compresses n steps into O(log n). Constants are larger; use it when the same recurrence needs to be sped up.

We set Fib(n) to represent a 1 × 2 matrix bmatrix F_n & F_{n-1} bmatrix, where F_n and F_{n-1} are the n-th and (n - 1)-th Fibonacci numbers respectively.

We hope to derive Fib(n) based on Fib(n-1) = bmatrix F_{n-1} & F_{n-2} bmatrix. That is to say, we need a matrix base, so that Fib(n - 1) × base = Fib(n), that is:

$$\text{bmatrix } F_{n-1} \text{ \& } F_{n-2} \text{ bmatrix} \times \text{base} = \text{bmatrix } F_n \text{ \& } F_{n-1} \text{ bmatrix}$$

Since $F_n = F_{n-1} + F_{n-2}$, the first column of the matrix base is:

$$\text{bmatrix } 1 \backslash 1 \text{ bmatrix}$$

The second column is:

$$\text{bmatrix } 1 \backslash 0 \text{ bmatrix}$$

Therefore:

$$\text{bmatrix } F_{n-1} \text{ \& } F_{n-2} \text{ bmatrix} \times \text{bmatrix1 \& 1} \backslash 1 \text{ \& 0bmatrix} = \text{bmatrix } F_n \text{ \& } F_{n-1} \text{ bmatrix}$$

We define the initial matrix res = bmatrix 1 & 1 bmatrix, then F_n is equal to the first element of the first row of the result matrix of res multiplied by base^{n-1}. We can solve it using matrix quick power.

The time complexity is O(log n), and the space complexity is O(1).

Python 3

```
import numpy as np

class Solution:
    def climbStairs(self, n: int) -> int:
        res = np.asmatrix([(1, 1)], np.dtype("O"))
        factor = np.asmatrix([(1, 1), (1, 0)], np.dtype("O"))
        n -= 1
        while n:
            if n & 1:
                res *= factor
            factor *= factor
            n >>= 1
        return res[0, 0]
```

PATTERN 13 · DYNAMIC PROGRAMMING - 1D · PROBLEM 2 OF 20

198. House Robber

Medium · Array, Dynamic Programming

leetcode.com/problems/house-robber

★ **TOP 10 PROBLEM** in Dynamic Programming - 1D: master this one first

PROBLEM

You are a professional robber planning to rob houses along a street. Each house has a certain amount of money stashed, the only constraint stopping you from robbing each of them is that adjacent houses have security systems connected and **it will automatically contact the police if two adjacent houses were broken into on the same night**.

Given an integer array `nums` representing the amount of money of each house, return *the maximum amount of money you can rob tonight **without alerting the police***.

Example 1:

```
Input: nums = [1,2,3,1]
Output: 4
Explanation: Rob house 1 (money = 1) and then rob house 3 (money = 3).
Total amount you can rob = 1 + 3 = 4.
```

Example 2:

```
Input: nums = [2,7,9,3,1]
Output: 12
Explanation: Rob house 1 (money = 2), rob house 3 (money = 9) and rob house 5 (money = 1).
Total amount you can rob = 2 + 9 + 1 = 12.
```

Constraints:

- `1 <= nums.length <= 100`
- `0 <= nums[i] <= 400`

SOLUTIONS (PYTHON 3)

Solution 1: Memoization Search

How to think about it

Adjacent houses cannot both be robbed; maximize the take. Subset enumeration must enforce the gap, and overlapping suffixes repeat. From index i, rob and skip to i+2, or skip to i+1, and take the better. Memoization evaluates each index once.

We design a function dfs(i), which represents the maximum amount of money that can be stolen starting from the i-th house. Thus, the answer is dfs(0).

The execution process of the function dfs(i) is as follows:

- If i ≥ len(nums), it means all houses have been considered, and we directly return 0;
- Otherwise, consider stealing from the i-th house, then dfs(i) = nums[i] + dfs(i+2); if not stealing from the i-th house, then dfs(i) = dfs(i+1).
- Return max(nums[i] + dfs(i+2), dfs(i+1)).

To avoid repeated calculations, we use memoization search. The result of dfs(i) is saved in an array or hash table. Before each calculation, we first check if it has been calculated. If so, we directly return the result.

The time complexity is O(n), and the space complexity is O(n), where n is the length of the array.

Python 3

```python
class Solution:
    def rob(self, nums: List[int]) -> int:
        @cache
        def dfs(i: int) -> int:
            if i >= len(nums):
                return 0
            return max(nums[i] + dfs(i + 2), dfs(i + 1))

        return dfs(0)
```

Solution 2: Dynamic Programming

> **How to think about it**
>
> Solution 1 is recursive. f[i] is the best total among the first i houses: rob house i and add f[i-2], or take f[i-1]. Fill the table bottom-up.

We define f[i] as the maximum total amount that can be robbed from the first i houses, initially f[0]=0, f[1]=nums[0].

Consider the case where i > 1, the ith house has two options:

- Do not rob the ith house, the total amount of robbery is f[i-1];
- Rob the ith house, the total amount of robbery is f[i-2]+nums[i-1];

Therefore, we can get the state transition equation:

$$f[i]= \text{cases } 0, \& \ i=0 \ \backslash \ nums[0], \& \ i=1 \ \backslash \ \max(f[i-1],f[i-2]+nums[i-1]), \& \ i > 1 \text{ cases}$$

The final answer is f[n], where n is the length of the array.

The time complexity is O(n), and the space complexity is O(n). Where n is the length of the array.

Python 3

```python
class Solution:
    def rob(self, nums: List[int]) -> int:
        n = len(nums)
        f = [0] * (n + 1)
        f[1] = nums[0]
        for i in range(2, n + 1):
            f[i] = max(f[i - 1], f[i - 2] + nums[i - 1])
        return f[n]
```

Solution 3: Dynamic Programming (Space Optimization)

> **How to think about it**
>
> f[i] in Solution 2 depends only on the previous two values, so two rolling variables cut space to O(1).

We notice that when i > 2, f[i] is only related to f[i-1] and f[i-2]. Therefore, we can use two variables instead of an array to reduce the space complexity to O(1).

Python 3

```python
class Solution:
    def rob(self, nums: List[int]) -> int:
        f = g = 0
        for x in nums:
            f, g = max(f, g), f + x
        return max(f, g)
```

    return best[n]
```

213. House Robber II

Medium · Array, Dynamic Programming

leetcode.com/problems/house-robber-ii

PROBLEM

You are a professional robber planning to rob houses along a street. Each house has a certain amount of money stashed. All houses at this place are **arranged in a circle.** That means the first house is the neighbor of the last one. Meanwhile, adjacent houses have a security system connected, and **it will automatically contact the police if two adjacent houses were broken into on the same night**.

Given an integer array `nums` representing the amount of money of each house, return *the maximum amount of money you can rob tonight **without alerting the police***.

Example 1:

```
Input: nums = [2,3,2]
Output: 3
Explanation: You cannot rob house 1 (money = 2) and then rob house 3 (money = 2), because they are
adjacent houses.
```

Example 2:

```
Input: nums = [1,2,3,1]
Output: 4
Explanation: Rob house 1 (money = 1) and then rob house 3 (money = 3).
Total amount you can rob = 1 + 3 = 4.
```

Example 3:

```
Input: nums = [1,2,3]
Output: 3
```

Constraints:

- `1 <= nums.length <= 100`
- `0 <= nums[i] <= 1000`

SOLUTION (PYTHON 3)

Solution 1: Dynamic Programming

> **How to think about it**
>
> Houses form a circle, so the first and last cannot both be robbed, and the linear recurrence does not apply directly. We split into two linear instances—drop the first house, or drop the last—and take the better of the two. A single house is returned as-is.

The circular arrangement means that at most one of the first and last houses can be chosen for theft, so this circular arrangement problem can be reduced to two single-row house problems.

The time complexity is O(n), where n is the length of the array. The space complexity is O(1).

Python 3

```python
class Solution:
    def rob(self, nums: List[int]) -> int:
        def _rob(nums):
            f = g = 0
            for x in nums:
                f, g = max(f, g), f + x
            return max(f, g)

        if len(nums) == 1:
            return nums[0]
        return max(_rob(nums[1:]), _rob(nums[:-1]))
```

322. Coin Change

Medium · Breadth-First Search, Array, Dynamic Programming, Knapsack, Unbounded Knapsack

leetcode.com/problems/coin-change

★ **TOP 10 PROBLEM** in Dynamic Programming - 1D, Dynamic Programming - Knapsack Style: master this one first

Also appears in pattern 28 Dynamic Programming - Knapsack Style

PROBLEM

You are given an integer array `coins` representing coins of different denominations and an integer `amount` representing a total amount of money.

Return the **fewest** number of coins that you need to make up that amount. If that amount of money cannot be made up by any combination of the coins, return -1.

You may assume that you have an infinite number of each kind of coin.

Example 1:

```
Input: coins = [1,2,5], amount = 11
Output: 3
Explanation: 11 = 5 + 5 + 1
```

Example 2:

```
Input: coins = [2], amount = 3
Output: -1
```

Example 3:

```
Input: coins = [1], amount = 0
Output: 0
```

Constraints:

- `1 <= coins.length <= 12`
- `1 <= coins[i] <=` $2^{31} - 1$
- `0 <= amount <=` 10^4

SOLUTIONS (PYTHON 3)

Solution 1: Dynamic Programming (Complete Knapsack)

How to think about it

Each coin may be used any number of times; we want the fewest coins summing to amount. This is unbounded knapsack. A raw DFS repeats sub-amounts. Let f[i][j] be the fewest coins using the first i types to make j. Skip type i via f[i-1][j]; if j≥ x, take f[i][j-x]+1. f[0][0]=0, the rest are ∞; return -1 if impossible.

We define f[i][j] as the minimum number of coins needed to make up the amount j using the first i types of coins. Initially, f[0][0] = 0, and the values of other positions are all positive infinity.

We can enumerate the quantity k of the last coin used, then we have:

$$f[i][j] = \min(f[i - 1][j], f[i - 1][j - x] + 1, \ldots, f[i - 1][j - k \times x] + k)$$

where x represents the face value of the i-th type of coin.

Let j = j - x, then we have:

$$f[i][j - x] = \min(f[i - 1][j - x], f[i - 1][j - 2 \times x] + 1, \ldots, f[i - 1][j - k \times x] + k - 1)$$

Substituting the second equation into the first one, we can get the following state transition equation:

$$f[i][j] = \min(f[i - 1][j], f[i][j - x] + 1)$$

The final answer is f[m][n].

The time complexity is O(m × n), and the space complexity is O(m × n). Where m and n are the number of types of coins and the total amount, respectively.

Python 3

```python
class Solution:
    def coinChange(self, coins: List[int], amount: int) -> int:
        m, n = len(coins), amount
        f = [[inf] * (n + 1) for _ in range(m + 1)]
        f[0][0] = 0
        for i, x in enumerate(coins, 1):
            for j in range(n + 1):
                f[i][j] = f[i - 1][j]
                if j >= x:
                    f[i][j] = min(f[i][j], f[i][j - x] + 1)
        return -1 if f[m][n] >= inf else f[m][n]
```

Solution 2: Optimized Dynamic Programming

> **How to think about it**
>
> Method 1 only reads f[i-1][j] and f[i][j-x]. Collapse to one array and iterate amounts upward so f[j-x] already includes the current coin. Space becomes O(amount) with the same recurrence.

We notice that f[i][j] is only related to f[i - 1][j] and f[i][j - x]. Therefore, we can optimize the two-dimensional array into a one-dimensional array, reducing the space complexity to O(n). The time complexity remains O(m × n).

PATTERN 13 · DYNAMIC PROGRAMMING - 1D · PROBLEM 6 OF 20

300. Longest Increasing Subsequence

Medium · Array, Binary Search, Dynamic Programming, Longest Increasing Subsequence

leetcode.com/problems/longest-increasing-subsequence

★ **TOP 10 PROBLEM** in Dynamic Programming - 1D, Binary Indexed Tree (Fenwick Tree): master this one first

Also appears in pattern 41 Binary Indexed Tree (Fenwick Tree)

PROBLEM

Given an integer array `nums`, return *the length of the longest **strictly increasing subsequence***.

Example 1:

```
Input: nums = [10,9,2,5,3,7,101,18]
Output: 4
Explanation: The longest increasing subsequence is [2,3,7,101], therefore the length is 4.
```

Example 2:

```
Input: nums = [0,1,0,3,2,3]
Output: 4
```

Example 3:

```
Input: nums = [7,7,7,7,7,7,7]
Output: 1
```

Constraints:

- `1 <= nums.length <= 2500`
- -10^4 `<= nums[i] <=` 10^4

Follow up: Can you come up with an algorithm that runs in `O(n log(n))` time complexity?

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

A subsequence must keep relative order and increase strictly. Enumerating all subsequences explodes with n; n ≤ 2500 still allows an $O(n^2)$ transfer by ending index. The LIS ending at nums[i] depends only on smaller values to its left. Define f[i] as that length, and for each j < i with nums[j] < nums[i] take max(f[j]+1). A singleton has length 1, and the answer is max f.

Python 3

```python
class Solution:
    def lengthOfLIS(self, nums: List[int]) -> int:
        n = len(nums)
        f = [1] * n
        for i in range(1, n):
            for j in range(i):
                if nums[j] < nums[i]:
                    f[i] = max(f[i], f[j] + 1)
        return max(f)
```

Solution 2

How to think about it

Method 1 scans the left side linearly for the best f[j] below x, which costs O(n^2). After discretizing values, that query is a prefix maximum on ranks, which a Fenwick tree maintains in O(log n). Scan each x in original order: query the prefix max strictly below x, then write x. Only left-hand information is used, so the recurrence matches Method 1 in O(n log n) time.

Python 3

```python
class BinaryIndexedTree:
    def __init__(self, n: int):
        self.n = n
        self.c = [0] * (n + 1)

    def update(self, x: int, v: int):
        while x <= self.n:
            self.c[x] = max(self.c[x], v)
            x += x & -x

    def query(self, x: int) -> int:
        mx = 0
        while x:
            mx = max(mx, self.c[x])
            x -= x & -x
        return mx

class Solution:
    def lengthOfLIS(self, nums: List[int]) -> int:
        s = sorted(set(nums))
        m = len(s)
        tree = BinaryIndexedTree(m)
        for x in nums:
            x = bisect_left(s, x) + 1
            t = tree.query(x - 1) + 1
            tree.update(x, t)
        return tree.query(m)
```

PATTERN 13 · DYNAMIC PROGRAMMING - 1D · PROBLEM 9 OF 20

55. Jump Game

Medium · Greedy, Array, Dynamic Programming

leetcode.com/problems/jump-game

★ **TOP 10 PROBLEM** in Dynamic Programming - 1D, Greedy: master this one first

Also appears in pattern 21 Greedy

PROBLEM

You are given an integer array `nums`. You are initially positioned at the array's **first index**, and each element in the array represents your maximum jump length at that position.

Return `true` *if you can reach the last index, or* `false` *otherwise*.

Example 1:

```
Input: nums = [2,3,1,1,4]
Output: true
Explanation: Jump 1 step from index 0 to 1, then 3 steps to the last index.
```

Example 2:

```
Input: nums = [3,2,1,0,4]
Output: false
Explanation: You will always arrive at index 3 no matter what. Its maximum jump length is 0, which
makes it impossible to reach the last index.
```

Constraints:

- `1 <= nums.length <= 10^4`
- `0 <= nums[i] <= 10^5`

SOLUTION (PYTHON 3)

Solution 1: Greedy

How to think about it

The first idea is DFS/BFS over reachable indices, or DP for whether each index is reachable. Correct, but worst-case $O(n^2)$. $n \le 10^4$ is tight, and we only care about the last index, not the path. The waste is expanding every jump. Reachable indices form a prefix: maintain the farthest reachable mx; if some i > mx, we are cut off. So we scan left to right, update mx with i + nums[i], and finishing the scan means the end is reachable.

We use a variable mx to maintain the farthest index that can currently be reached, initially mx = 0.

We traverse the array from left to right. For each position i we traverse, if mx < i, it means that the current position cannot be reached, so we directly return `false`. Otherwise, the farthest position that we can reach by jumping from position i is i+nums[i], we use i+nums[i] to update the value of mx, that is, mx = max(mx, i + nums[i]).

At the end of the traversal, we directly return `true`.

The time complexity is O(n), where n is the length of the array. The space complexity is O(1).

PATTERN 13 · DYNAMIC PROGRAMMING - 1D · PROBLEM 10 OF 20

152. Maximum Product Subarray

Medium · Array, Dynamic Programming

leetcode.com/problems/maximum-product-subarray

★ **TOP 10 PROBLEM** in Dynamic Programming - 1D: master this one first

PROBLEM

Given an integer array `nums`, find a subarray that has the largest product, and return *the product*.

The test cases are generated so that the answer will fit in a **32-bit** integer.

Note that the product of an array with a single element is the value of that element.

Example 1:

```
Input: nums = [2,3,-2,4]
Output: 6
Explanation: [2,3] has the largest product 6.
```

Example 2:

```
Input: nums = [-2,0,-1]
Output: 0
Explanation: The result cannot be 2, because [-2,-1] is not a subarray.
```

Constraints:

- `1 <= nums.length <= 2 * 10^4`
- `-10 <= nums[i] <= 10`
- The product of any subarray of `nums` is **guaranteed** to fit in a **32-bit** integer.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Kadane works for sums; products flip when a negative appears, and a zero resets the run. n≤ 2× 10^4. Keep the max and min product ending here; the new value may multiply either or start a new segment. The answer is the best max seen.

Python 3

```python
class Solution:
    def maxProduct(self, nums: List[int]) -> int:
        ans = f = g = nums[0]
        for x in nums[1:]:
            ff, gg = f, g
            f = max(x, ff * x, gg * x)
            g = min(x, ff * x, gg * x)
            ans = max(ans, f)
        return ans
```

Complexity. Time: O(n). Space: O(1).

309. Best Time to Buy and Sell Stock with Cooldown

Medium · Array, Dynamic Programming

leetcode.com/problems/best-time-to-buy-and-sell-stock-with-cooldown

★ **TOP 10 PROBLEM** in Dynamic Programming - 1D: master this one first

PROBLEM

You are given an array `prices` where `prices[i]` is the price of a given stock on the i^{th} day.

Find the maximum profit you can achieve. You may complete as many transactions as you like (i.e., buy one and sell one share of the stock multiple times) with the following restrictions:

- After you sell your stock, you cannot buy stock on the next day (i.e., cooldown one day).

Note: You may not engage in multiple transactions simultaneously (i.e., you must sell the stock before you buy again).

Example 1:

```
Input: prices = [1,2,3,0,2]
Output: 3
Explanation: transactions = [buy, sell, cooldown, buy, sell]
```

Example 2:

```
Input: prices = [1]
Output: 0
```

Constraints:

- `1 <= prices.length <= 5000`
- `0 <= prices[i] <= 1000`

SOLUTIONS (PYTHON 3)

Solution 1: Memoization Search

How to think about it

We may trade many times, but a sell forces a one-day cooldown. A raw decision tree over day, holding, and cooldown revisits the same states. Compress to (i,j): starting at day i, whether we hold. Skip the day; if holding, sell and jump to i+2; if free, buy and start holding. Memoization evaluates each state once; the extra day after a sell is the cooldown.

We design a function dfs(i, j), which represents the maximum profit that can be obtained starting from the ith day with state j. The values of j are 0 and 1, respectively representing currently not holding a stock and holding a stock. The answer is dfs(0, 0).

The execution logic of the function dfs(i, j) is as follows:

If i ≥ n, it means that there are no more stocks to trade, so return 0;

Otherwise, we can choose not to trade, then dfs(i, j) = dfs(i + 1, j). We can also trade stocks. If j > 0, it means that we currently hold a stock and can sell it, then dfs(i, j) = prices[i] + dfs(i + 2, 0). If j = 0, it means that we currently do not hold a stock and can buy, then dfs(i, j) = -prices[i] + dfs(i + 1, 1). Take the maximum value as the return value of the function dfs(i, j).

The answer is dfs(0, 0).

To avoid repeated calculations, we use the method of memoization search, and use an array f to record the return value of dfs(i, j). If f[i][j] is not -1, it means that it has been calculated, and we can directly return f[i][j].

The time complexity is O(n), and the space complexity is O(n), where n is the length of the array prices.

Python 3

```python
class Solution:
    def maxProfit(self, prices: List[int]) -> int:
        @cache
        def dfs(i: int, j: int) -> int:
            if i >= len(prices):
                return 0
            ans = dfs(i + 1, j)
            if j:
                ans = max(ans, prices[i] + dfs(i + 2, 0))
            else:
                ans = max(ans, -prices[i] + dfs(i + 1, 1))
            return ans

        return dfs(0, 0)
```

Solution 2: Dynamic Programming

> **How to think about it**
>
> Solution 1 fills a suffix table from the end. The same choices can be written forward: f[i][0/1] is the best profit after day i, free or holding. Free comes from staying free or selling today; holding comes from staying put or buying after cooldown, i.e. from f[i-2][0]. Fill left to right; the answer is free on the last day. Time stays O(n).

We can also use dynamic programming to solve this problem.

We define f[i][j] to represent the maximum profit that can be obtained on the ith day with state j. The values of j are 0 and 1, respectively representing currently not holding a stock and holding a stock. Initially, f[0][0] = 0, f[0][1] = -prices[0].

When i ≥ 1, if we currently do not hold a stock, then f[i][0] can be obtained by transitioning from f[i - 1][0] and f[i - 1][1] + prices[i], i.e., f[i][0] = max(f[i - 1][0], f[i - 1][1] + prices[i]). If we currently hold a stock, then f[i][1] can be obtained by transitioning from f[i - 1][1] and f[i - 2][0] - prices[i], i.e., f[i][1] = max(f[i - 1][1], f[i - 2][0] - prices[i]). The final answer is f[n - 1][0].

The time complexity is O(n), and the space complexity is O(n), where n is the length of the array prices.

Python 3

```python
class Solution:
    def maxProfit(self, prices: List[int]) -> int:
        n = len(prices)
        f = [[0] * 2 for _ in range(n)]
        f[0][1] = -prices[0]
        for i in range(1, n):
            f[i][0] = max(f[i - 1][0], f[i - 1][1] + prices[i])
            f[i][1] = max(f[i - 1][1], f[i - 2][0] - prices[i])
        return f[n - 1][0]
```

Solution 3: Dynamic Programming (Space Optimization)

> **How to think about it**
>
> Method 2 only reads i-1 and i-2, so the full table is unnecessary. Three rolling variables (free two days ago, free yesterday, holding yesterday) implement the same transfers in O(1) space.

The transition only needs the previous two days, so three variables are enough and the space complexity is O(1).

Python 3

```python
class Solution:
    def maxProfit(self, prices: List[int]) -> int:
        f, f0, f1 = 0, 0, -prices[0]
        for x in prices[1:]:
            f, f0, f1 = f0, max(f0, f1 + x), max(f1, f - x)
        return f0
```

Solution 4: Dynamic Programming

How to think about it

We may trade many times, but a sell forces a one-day cooldown. n ≤ 5000, so a raw decision tree is far too large. The state is the day and whether we hold. Skipping always calls the next day before it returns, so the chain has length n and overflows the stack. Later days are known if we walk backward. Let f[i][j] be the best profit from day i with holding flag j, and fill i from n-1 down to 0. Selling lands on i+2, which is the cooldown.

Let f[i][j] be the maximum profit starting from day i in state j. The values of j are 0 and 1, meaning we do not hold a stock and we hold a stock. The answer is f[0][0]. Days past the end contribute 0, so f[n][j] = f[n + 1][j] = 0.

Fill i from n - 1 down to 0. Doing nothing keeps f[i + 1][j]. If j > 0, we hold a stock and may sell it, earning prices[i] + f[i + 2][0]. The extra day is the cooldown. If j = 0, we may buy, earning -prices[i] + f[i + 1][1]. Take the larger value:

$$f[i][j] = \max(f[i + 1][j], prices[i] + f[i + 2][0])$$

when j > 0, and

$$f[i][j] = \max(f[i + 1][j], -prices[i] + f[i + 1][1])$$

when j = 0.

The time complexity is O(n), and the space complexity is O(n), where n is the length of the array prices.

Python 3

```python
class Solution:
    def maxProfit(self, prices: List[int]) -> int:
        n = len(prices)
        f = [[0] * 2 for _ in range(n + 2)]
        for i in range(n - 1, -1, -1):
            for j in range(2):
                ans = f[i + 1][j]
                if j:
                    ans = max(ans, prices[i] + f[i + 2][0])
                else:
                    ans = max(ans, -prices[i] + f[i + 1][1])
                f[i][j] = ans
        return f[0][0]
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

416. Partition Equal Subset Sum

Medium · Array, Dynamic Programming, Knapsack, 0-1 Knapsack

leetcode.com/problems/partition-equal-subset-sum

★ **TOP 10 PROBLEM** in Dynamic Programming - 1D, Dynamic Programming - Knapsack Style: master this one first

Also appears in pattern 28 Dynamic Programming - Knapsack Style

PROBLEM

Given an integer array `nums`, return `true` *if you can partition the array into two subsets such that the sum of the elements in both subsets is equal or* `false` *otherwise*.

Example 1:

```
Input: nums = [1,5,11,5]
Output: true
Explanation: The array can be partitioned as [1, 5, 5] and [11].
```

Example 2:

```
Input: nums = [1,2,3,5]
Output: false
Explanation: The array cannot be partitioned into equal sum subsets.
```

Constraints:

- `1 <= nums.length <= 200`
- `1 <= nums[i] <= 100`

SOLUTIONS (PYTHON 3)

Solution 1: Dynamic Programming

How to think about it

Equal partition means a subset sums to half the total. An odd total is impossible. Subset enumeration is too large for n≤ 200. This is 0-1 knapsack with capacity m=s/2: f[i][j] is whether the first i numbers can make j, taking or skipping x. The n× m table fits the limits. Reject an odd sum first. The empty subset gives f[0][0]=true, which seeds the recurrence.

First, we calculate the total sum s of the array. If the total sum is odd, it cannot be divided into two subsets with equal sums, so we directly return `false`. If the total sum is even, we set the target subset sum to m = s/2. The problem is then transformed into: does there exist a subset whose element sum is m?

We define f[i][j] to represent whether it is possible to select several numbers from the first i numbers so that their sum is exactly j. Initially, f[0][0] = true and the rest f[i][j] = false. The answer is f[n][m].

Considering f[i][j], if we select the i-th number x, then f[i][j] = f[i - 1][j - x]. If we do not select the i-th number x, then f[i][j] = f[i - 1][j]. Therefore, the state transition equation is:

$$f[i][j] = f[i - 1][j] \text{ or } f[i - 1][j - x] \text{ if } j \geq x$$

The final answer is f[n][m].

The time complexity is O(m × n), and the space complexity is O(m × n). Where m and n are half of the total sum of the array and the length of the array, respectively.

Python 3

```python
class Solution:
    def canPartition(self, nums: List[int]) -> bool:
        m, mod = divmod(sum(nums), 2)
        if mod:
            return False
        n = len(nums)
        f = [[False] * (m + 1) for _ in range(n + 1)]
        f[0][0] = True
        for i, x in enumerate(nums, 1):
            for j in range(m + 1):
                f[i][j] = f[i - 1][j] or (j >= x and f[i - 1][j - x])
        return f[n][m]
```

Solution 2: Dynamic Programming (Space Optimization)

> **How to think about it**
>
> Row i depends only on row i-1, and an item must not be reused, so update j downward and keep a one-dimensional array. Space drops from O(nm) to O(m).

We notice that in Solution 1, f[i][j] is only related to f[i - 1][·]. Therefore, we can compress the two-dimensional array into a one-dimensional array.

The time complexity is O(n × m), and the space complexity is O(m). Where n is the length of the array, and m is half of the total sum of the array.

Python 3

```python
class Solution:
    def canPartition(self, nums: List[int]) -> bool:
        m, mod = divmod(sum(nums), 2)
        if mod:
            return False
        f = [True] + [False] * m
        for x in nums:
            for j in range(m, x - 1, -1):
                f[j] = f[j] or f[j - x]
        return f[m]
```

518. Coin Change II

Medium · Array, Dynamic Programming, Knapsack, Unbounded Knapsack

leetcode.com/problems/coin-change-ii

★ **TOP 10 PROBLEM** in Dynamic Programming - Knapsack Style: master this one first

Also appears in pattern 28 Dynamic Programming - Knapsack Style

PROBLEM

You are given an integer array `coins` representing coins of different denominations and an integer `amount` representing a total amount of money.

Return *the number of combinations that make up that amount*. If that amount of money cannot be made up by any combination of the coins, return `0`.

You may assume that you have an infinite number of each kind of coin.

The **final** answer is **guaranteed** to fit into a signed **32-bit** integer.

Example 1:

```
Input: amount = 5, coins = [1,2,5]
Output: 4
Explanation: there are four ways to make up the amount:
5=5
5=2+2+1
5=2+1+1+1
5=1+1+1+1+1
```

Example 2:

```
Input: amount = 3, coins = [2]
Output: 0
Explanation: the amount of 3 cannot be made up just with coins of 2.
```

Example 3:

```
Input: amount = 10, coins = [10]
Output: 1
```

Constraints:

- `1 <= coins.length <= 300`
- `1 <= coins[i] <= 5000`
- All the values of `coins` are **unique**.
- `0 <= amount <= 5000`

SOLUTIONS (PYTHON 3)

Solution 1: Dynamic Programming (Complete Knapsack)

How to think about it

We count combinations, not permutations. Generating sequences would overcount the same multiset. This is the unbounded-knapsack counting DP: iterate coins in the outer loop so each coin is added in one order. f[i][j] is the number of ways to make j with the first i coins: skip inherits f[i-1][j], take adds f[i][j-x]. f[0][0]=1 is the empty combination.

We define f[i][j] as the number of coin combinations to make up the amount j using the first i types of coins. Initially, f[0][0] = 1, and the values of other positions are all 0.

We can enumerate the quantity k of the last coin used, then we have equation one:

$$f[i][j] = f[i - 1][j] + f[i - 1][j - x] + f[i - 1][j - 2 \times x] + \ldots + f[i - 1][j - k \times x]$$

where x represents the face value of the i-th type of coin.

Let j = j - x, then we have equation two:

$$f[i][j - x] = f[i - 1][j - x] + f[i - 1][j - 2 \times x] + \ldots + f[i - 1][j - k \times x]$$

Substituting equation two into equation one, we can get the following state transition equation:

$$f[i][j] = f[i - 1][j] + f[i][j - x]$$

The final answer is f[m][n].

The time complexity is O(m × n), and the space complexity is O(m × n). Where m and n are the number of types of coins and the total amount, respectively.

Python 3

```python
class Solution:
    def change(self, amount: int, coins: List[int]) -> int:
        m, n = len(coins), amount
        f = [[0] * (n + 1) for _ in range(m + 1)]
        f[0][0] = 1
        for i, x in enumerate(coins, 1):
            for j in range(n + 1):
                f[i][j] = f[i - 1][j]
                if j >= x:
                    f[i][j] += f[i][j - x]
        return f[m][n]
```

Solution 2: Optimized Dynamic Programming

> **How to think about it**
>
> f[i][j] depends only on the previous row at j and the current row at j-x. A one-dimensional array, updated forward from x to `amount` for each coin, reuses the same coin's new states. Space drops to O(amount); the number of transitions is unchanged.

We notice that f[i][j] is only related to f[i - 1][j] and f[i][j - x]. Therefore, we can optimize the two-dimensional array into a one-dimensional array, reducing the space complexity to O(n). The time complexity remains O(m × n).

Python 3

```python
class Solution:
    def change(self, amount: int, coins: List[int]) -> int:
        n = amount
        f = [1] + [0] * n
        for x in coins:
            for j in range(x, n + 1):
                f[j] += f[j - x]
        return f[n]
```

    ways = [0] * (amount + 1)
    ways[0] = 1
    for coin in coins:
        for a in range(amount, coin - 1, -1):
            ways[a] += ways[a - coin]
    return ways[amount]
```

377. Combination Sum IV

Medium · Array, Dynamic Programming

leetcode.com/problems/combination-sum-iv

★ **TOP 10 PROBLEM** in Dynamic Programming - Knapsack Style: master this one first

Also appears in pattern 28 Dynamic Programming - Knapsack Style

PROBLEM

Given an array of **distinct** integers `nums` and a target integer `target`, return *the number of possible combinations that add up to* `target`.

The test cases are generated so that the answer can fit in a **32-bit** integer.

Example 1:

```
Input: nums = [1,2,3], target = 4
Output: 7
Explanation:
The possible combination ways are:
(1, 1, 1, 1)
(1, 1, 2)
(1, 2, 1)
(1, 3)
(2, 1, 1)
(2, 2)
(3, 1)
Note that different sequences are counted as different combinations.
```

Example 2:

```
Input: nums = [9], target = 3
Output: 0
```

Constraints:

- `1 <= nums.length <= 200`
- `1 <= nums[i] <= 1000`
- All the elements of `nums` are **unique**.
- `1 <= target <= 1000`

Follow up: What if negative numbers are allowed in the given array? How does it change the problem? What limitation we need to add to the question to allow negative numbers?

SOLUTION (PYTHON 3)

Solution 1: Dynamic Programming

How to think about it

Count ordered ways to sum to target. An outer loop over items (combinations) misses permutations. Enumerate the sum first, then the last addend. f[i] is the number of permutations summing to i, f[0]=1. For each i and each x≤ i, add f[i-x]. Same shape as 322, counting instead of minimizing coins.

We define f[i] as the number of combinations that sum up to i. Initially, f[0] = 1, and the rest f[i] = 0. The final answer is f[target].

For f[i], we can enumerate each element x in the array. If i ≥ x, then f[i] = f[i] + f[i - x].

Finally, return f[target].

The time complexity is O(n × target), and the space complexity is O(target), where n is the length of the array.

Python 3

```python
class Solution:
    def combinationSum4(self, nums: List[int], target: int) -> int:
        f = [1] + [0] * target
        for i in range(1, target + 1):
            for x in nums:
                if i >= x:
                    f[i] += f[i - x]
        return f[target]
```

    return total
```

PATTERN 13 · DYNAMIC PROGRAMMING - 1D · PROBLEM 15 OF 20

279. Perfect Squares

Medium · Breadth-First Search, Math, Dynamic Programming, Knapsack, Unbounded Knapsack

leetcode.com/problems/perfect-squares

★ **TOP 10 PROBLEM** in Dynamic Programming - Knapsack Style: master this one first

Also appears in pattern 28 Dynamic Programming - Knapsack Style

PROBLEM

Given an integer `n`, return *the least number of perfect square numbers that sum to* `n`.

A **perfect square** is an integer that is the square of an integer; in other words, it is the product of some integer with itself. For example, `1`, `4`, `9`, and `16` are perfect squares while `3` and `11` are not.

Example 1:

```
Input: n = 12
Output: 3
Explanation: 12 = 4 + 4 + 4.
```

Example 2:

```
Input: n = 13
Output: 2
Explanation: 13 = 4 + 9.
```

Constraints:

- `1 <= n <= 10^4`

SOLUTIONS (PYTHON 3)

Solution 1: Dynamic Programming (Complete Knapsack)

How to think about it

Perfect squares may be reused, so the fewest that sum to n is an unbounded knapsack with items $1^2,\ldots,m^2$ where m=floor(√n). f[i][j] is the fewest squares among the first i kinds that sum to j: skip i^2, or take one more copy.

Python 3

```python
class Solution:
    def numSquares(self, n: int) -> int:
        m = int(sqrt(n))
        f = [[inf] * (n + 1) for _ in range(m + 1)]
        f[0][0] = 0
        for i in range(1, m + 1):
            for j in range(n + 1):
                f[i][j] = f[i - 1][j]
                if j >= i * i:
                    f[i][j] = min(f[i][j], f[i][j - i * i] + 1)
        return f[m][n]
```

Complexity. Time: O(n * sqrt(n)). Space: O(n * sqrt(n)).

Solution 2: Optimized Dynamic Programming

> **How to think about it**
> f[i][j] depends only on f[i-1][j] and f[i][j-i^2], so a 1-D array updated in increasing j is enough.

f[i][j] depends only on f[i - 1][j] and f[i][j - i^2], so the table can be rolled into a 1D array of space O(n). The time complexity stays O(m × n).

Python 3

```
class Solution:
    def numSquares(self, n: int) -> int:
        m = int(sqrt(n))
        f = [0] + [inf] * n
        for i in range(1, m + 1):
            for j in range(i * i, n + 1):
                f[j] = min(f[j], f[j - i * i] + 1)
        return f[n]
```

376. Wiggle Subsequence

Medium · Greedy, Array, Dynamic Programming

leetcode.com/problems/wiggle-subsequence

Also appears in pattern 21 Greedy

PROBLEM

A **wiggle sequence** is a sequence where the differences between successive numbers strictly alternate between positive and negative. The first difference (if one exists) may be either positive or negative. A sequence with one element and a sequence with two non-equal elements are trivially wiggle sequences.

- For example, `[1, 7, 4, 9, 2, 5]` is a **wiggle sequence** because the differences `(6, -3, 5, -7, 3)` alternate between positive and negative.
- In contrast, `[1, 4, 7, 2, 5]` and `[1, 7, 4, 5, 5]` are not wiggle sequences. The first is not because its first two differences are positive, and the second is not because its last difference is zero.

A **subsequence** is obtained by deleting some elements (possibly zero) from the original sequence, leaving the remaining elements in their original order.

Given an integer array `nums`, return *the length of the longest **wiggle subsequence** of* `nums`.

Example 1:

```
Input: nums = [1,7,4,9,2,5]
Output: 6
Explanation: The entire sequence is a wiggle sequence with differences (6, -3, 5, -7, 3).
```

Example 2:

```
Input: nums = [1,17,5,10,13,15,10,5,16,8]
Output: 7
Explanation: There are several subsequences that achieve this length.
One is [1, 17, 10, 13, 10, 16, 8] with differences (16, -7, 3, -3, 6, -8).
```

Example 3:

```
Input: nums = [1,2,3,4,5,6,7,8,9]
Output: 2
```

Constraints:

- `1 <= nums.length <= 1000`
- `0 <= nums[i] <= 1000`

Follow up: Could you solve this in `O(n)` time?

SOLUTION (PYTHON 3)

Solution 1: Dynamic Programming

> **How to think about it**
>
> A wiggle subsequence alternates up and down. Enumerating subsequences is large. At an ending index we only distinguish a last up or last down. f[i] ends up, g[i] ends down. A smaller nums[j] extends a down into f; a larger one extends an up into g. The answer is the max of all f and g.

We define f[i] as the length of the wiggle sequence ending at the ith element with an upward trend, and g[i] as the length of the wiggle sequence ending at the ith element with a downward trend. Initially, f[0] = g[0] = 1 because when there is only one element, the length of the wiggle sequence is 1. Initialize the answer as 1.

For f[i], where i ≥ 1, we enumerate j in the range [0, i), if nums[j] < nums[i], it means that i can be appended after j to form an upward wiggle sequence, then f[i] = max(f[i], g[j] + 1); if nums[j] > nums[i], it means that i can be appended after j to form a downward wiggle sequence, then g[i] = max(g[i], f[j] + 1). Then we update the answer to max(f[i], g[i]).

Finally, we return the answer.

The time complexity is $O(n^2)$, and the space complexity is O(n). Where n is the length of the array nums.

Python 3

```python
class Solution:
    def wiggleMaxLength(self, nums: List[int]) -> int:
        n = len(nums)
        ans = 1
        f = [1] * n
        g = [1] * n
        for i in range(1, n):
            for j in range(i):
                if nums[j] < nums[i]:
                    f[i] = max(f[i], g[j] + 1)
                elif nums[j] > nums[i]:
                    g[i] = max(g[i], f[j] + 1)
            ans = max(ans, f[i], g[i])
        return ans
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

    return result
```

673. Number of Longest Increasing Subsequence

Medium · Binary Indexed Tree, Segment Tree, Array, Dynamic Programming, Longest Increasing Subsequence

leetcode.com/problems/number-of-longest-increasing-subsequence

Also appears in pattern 40 Segment Tree, 41 Binary Indexed Tree (Fenwick Tree)

PROBLEM

Given an integer array `nums`, return *the number of longest increasing subsequences.*

Notice that the sequence has to be **strictly** increasing.

Example 1:

```
Input: nums = [1,3,5,4,7]
Output: 2
Explanation: The two longest increasing subsequences are [1, 3, 4, 7] and [1, 3, 5, 7].
```

Example 2:

```
Input: nums = [2,2,2,2,2]
Output: 5
Explanation: The length of the longest increasing subsequence is 1, and there are 5 increasing
subsequences of length 1, so output 5.
```

Constraints:

- `1 <= nums.length <= 2000`
- -10^6 `<= nums[i] <=` 10^6
- The answer is guaranteed to fit inside a 32-bit integer.

SOLUTIONS (PYTHON 3)

Solution 1: Dynamic Programming

How to think about it

We need both the LIS length and how many such sequences exist. n≤ 2000 allows $O(n^2)$. f[i] and cnt[i] are the best length and count ending at i. Update or add when nums[j]<nums[i]. Sum cnt over positions that attain the global maximum length.

We define f[i] as the length of the longest increasing subsequence ending with nums[i], and cnt[i] as the number of longest increasing subsequences ending with nums[i]. Initially, f[i]=1, cnt[i]=1. Also, we define mx as the length of the longest increasing subsequence, and ans as the number of longest increasing subsequences.

For each nums[i], we enumerate all elements nums[j] in nums[0:i-1]. If nums[j] < nums[i], then nums[i] can be appended after nums[j] to form a longer increasing subsequence. If f[i] < f[j] + 1, it means the length of the longest increasing subsequence ending with nums[i] has increased, so we need to update f[i]=f[j]+1 and cnt[i]=cnt[j]. If f[i]=f[j]+1, it means we have found a longest increasing subsequence with the same length as before, so we need to increase cnt[i] by cnt[j]. Then, if mx < f[i], it means the length of the longest increasing subsequence has increased, so we need to update mx=f[i] and ans=cnt[i]. If mx=f[i], it means we have found a longest increasing subsequence with the same length as before, so we need to increase ans by cnt[i].

Finally, we return ans.

The time complexity is $O(n^2)$, and the space complexity is O(n). Here, n is the length of the array nums.

Python 3

```python
class Solution:
    def findNumberOfLIS(self, nums: List[int]) -> int:
        n = len(nums)
        f = [1] * n
        cnt = [1] * n
        mx = 0
        for i in range(n):
            for j in range(i):
                if nums[j] < nums[i]:
                    if f[i] < f[j] + 1:
                        f[i] = f[j] + 1
                        cnt[i] = cnt[j]
                    elif f[i] == f[j] + 1:
                        cnt[i] += cnt[j]
            if mx < f[i]:
                mx = f[i]
                ans = cnt[i]
            elif mx == f[i]:
                ans += cnt[i]
        return ans
```

Solution 2: Binary Indexed Tree

> **How to think about it**
>
> Scanning all previous indices is the bottleneck. After compressing values, a Fenwick tree stores the best length and count among smaller keys, so each step is O(log n).

We can use a binary indexed tree to maintain the length and count of the longest increasing subsequence in the prefix interval. We remove duplicates from the array nums and sort it to get the array arr. Then we enumerate each element x in nums, find the position i of x in the array arr by binary search, then query the length and count of the longest increasing subsequence in [1,i-1], denoted as v and cnt, then update the length and count of the longest increasing subsequence in [i] to v+1 and max(cnt,1). Finally, we query the length and count of the longest increasing subsequence in [1,m], where m is the length of the array arr, which is the answer.

The time complexity is O(n × log n), and the space complexity is O(n). Here, n is the length of the array nums.

Python 3

```python
class BinaryIndexedTree:
    __slots__ = ["n", "c", "d"]

    def __init__(self, n):
        self.n = n
        self.c = [0] * (n + 1)
        self.d = [0] * (n + 1)

    def update(self, x, v, cnt):
        while x <= self.n:
            if self.c[x] < v:
                self.c[x] = v
                self.d[x] = cnt
            elif self.c[x] == v:
                self.d[x] += cnt
            x += x & -x

    def query(self, x):
        v = cnt = 0
        while x:
            if self.c[x] > v:
                v = self.c[x]
                cnt = self.d[x]
            elif self.c[x] == v:
                cnt += self.d[x]
            x -= x & -x
        return v, cnt

class Solution:
    def findNumberOfLIS(self, nums: List[int]) -> int:
        arr = sorted(set(nums))
        m = len(arr)
        tree = BinaryIndexedTree(m)
        for x in nums:
            i = bisect_left(arr, x) + 1
            v, cnt = tree.query(i - 1)
            tree.update(i, v + 1, max(cnt, 1))
        return tree.query(m)[1]
```

983. Minimum Cost For Tickets

Medium · Array, Dynamic Programming

leetcode.com/problems/minimum-cost-for-tickets

PROBLEM

You have planned some train traveling one year in advance. The days of the year in which you will travel are given as an integer array `days`. Each day is an integer from `1` to `365`.

Train tickets are sold in **three different ways**:

- a **1-day** pass is sold for `costs[0]` dollars,
- a **7-day** pass is sold for `costs[1]` dollars, and
- a **30-day** pass is sold for `costs[2]` dollars.

The passes allow that many days of consecutive travel.

- For example, if we get a **7-day** pass on day `2`, then we can travel for `7` days: `2`, `3`, `4`, `5`, `6`, `7`, and `8`.

Return *the minimum number of dollars you need to travel every day in the given list of days*.

Example 1:

```
Input: days = [1,4,6,7,8,20], costs = [2,7,15]
Output: 11
Explanation: For example, here is one way to buy passes that lets you travel your travel plan:
On day 1, you bought a 1-day pass for costs[0] = $2, which covered day 1.
On day 3, you bought a 7-day pass for costs[1] = $7, which covered days 3, 4, ..., 9.
On day 20, you bought a 1-day pass for costs[0] = $2, which covered day 20.
In total, you spent $11 and covered all the days of your travel.
```

Example 2:

```
Input: days = [1,2,3,4,5,6,7,8,9,10,30,31], costs = [2,7,15]
Output: 17
Explanation: For example, here is one way to buy passes that lets you travel your travel plan:
On day 1, you bought a 30-day pass for costs[2] = $15 which covered days 1, 2, ..., 30.
On day 31, you bought a 1-day pass for costs[0] = $2 which covered day 31.
In total, you spent $17 and covered all the days of your travel.
```

Constraints:

- `1 <= days.length <= 365`
- `1 <= days[i] <= 365`
- `days` is in strictly increasing order.
- `costs.length == 3`
- `1 <= costs[i] <= 1000`

SOLUTIONS (PYTHON 3)

Solution 1: Memoization Search + Binary Search

How to think about it

Each travel day must be covered by a 1-, 7-, or 30-day pass at minimum cost. After buying a pass on trip i, the next uncovered trip is found by binary search. dfs(i) takes the best of the three options. There are at most 365 trips, so memoization is enough.

We define a function dfs(i), which represents the minimum cost required from the i-th trip to the last trip. Thus, the answer is dfs(0).

The execution process of the function dfs(i) is as follows:

- If i ≥ n, it means all trips have ended, return 0;
- Otherwise, we need to consider three types of purchases: buying a 1-day pass, buying a 7-day pass, and buying a 30-day pass. We calculate the cost for these three purchasing methods separately and use binary search to find the index j of the next trip, then recursively call dfs(j), and finally return the minimum cost among these three purchasing methods.

To avoid repeated calculations, we use memoization search to save the results that have already been calculated.

The time complexity is O(n × log n), and the space complexity is O(n). Here, n represents the number of trips.

Python 3

```python
class Solution:
    def mincostTickets(self, days: List[int], costs: List[int]) -> int:
        @cache
        def dfs(i: int) -> int:
            if i >= n:
                return 0
            ans = inf
            for c, v in zip(costs, valid):
                j = bisect_left(days, days[i] + v)
                ans = min(ans, c + dfs(j))
            return ans

        n = len(days)
        valid = [1, 7, 30]
        return dfs(0)
```

Solution 2: Dynamic Programming

> **How to think about it**
>
> Searching by trip index needs binary search. We can instead DP on calendar days: f[i] is the cheapest way to finish day i. A non-travel day copies f[i-1]; a travel day takes the min over the three pass starts. The last day is at most 365.

Let's denote the last day in the days array as m. We can define an array f of length m + 1, where f[i] represents the minimum cost from day 1 to day i.

We can calculate the value of f[i] in increasing order of the dates in the days array, starting from day 1. If day i is a travel day, we can consider three purchasing options: buying a 1-day pass, buying a 7-day pass, and buying a 30-day pass. We calculate the cost for these three purchasing methods separately and take the minimum cost among these three as the value of f[i]. If day i is not a travel day, then f[i] = f[i - 1].

The final answer is f[m].

The time complexity is O(m), and the space complexity is O(m). Here, m represents the last day of travel.

Python 3

```python
class Solution:
    def mincostTickets(self, days: List[int], costs: List[int]) -> int:
        m = days[-1]
        f = [0] * (m + 1)
        valid = [1, 7, 30]
        j = 0
        for i in range(1, m + 1):
            if i == days[j]:
                f[i] = inf
                for c, v in zip(costs, valid):
                    f[i] = min(f[i], f[max(0, i - v)] + c)
                j += 1
            else:
                f[i] = f[i - 1]
        return f[m]
```

    return best[0]
```

740. Delete and Earn

Medium · Array, Hash Table, Dynamic Programming

leetcode.com/problems/delete-and-earn

PROBLEM

You are given an integer array `nums`. You want to maximize the number of points you get by performing the following operation any number of times:

- Pick any `nums[i]` and delete it to earn `nums[i]` points. Afterwards, you must delete **every** element equal to `nums[i] - 1` and **every** element equal to `nums[i] + 1`.

Return *the **maximum number of points** you can earn by applying the above operation some number of times*.

Example 1:

```
Input: nums = [3,4,2]
Output: 6
Explanation: You can perform the following operations:
- Delete 4 to earn 4 points. Consequently, 3 is also deleted. nums = [2].
- Delete 2 to earn 2 points. nums = [].
You earn a total of 6 points.
```

Example 2:

```
Input: nums = [2,2,3,3,3,4]
Output: 9
Explanation: You can perform the following operations:
- Delete a 3 to earn 3 points. All 2's and 4's are also deleted. nums = [3,3].
- Delete a 3 again to earn 3 points. nums = [3].
- Delete a 3 once more to earn 3 points. nums = [].
You earn a total of 9 points.
```

Constraints:

- `1 <= nums.length <= 2 * 10^4`
- `1 <= nums[i] <= 10^4`

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Taking x earns every copy of x and forbids x-1 and x+1. n≤ 2× 10^4 and values ≤ 10^4, so searching each choice repeats work. Each value is all-or-nothing and neighbors conflict—the house-robber recurrence. Bucket scores into total[x], then walk the value line. Two rolling scalars are the best through i-2 and i-1; i takes max(first+total[i], second). Time follows the max value.

Python 3

```python
class Solution:
    def deleteAndEarn(self, nums: List[int]) -> int:
        mx = -inf
        for num in nums:
            mx = max(mx, num)
        total = [0] * (mx + 1)
        for num in nums:
            total[num] += num
        first = total[0]
        second = max(total[0], total[1])
        for i in range(2, mx + 1):
            cur = max(first + total[i], second)
            first = second
            second = cur
        return second
```

Complexity. Time: O(n + M), M = largest number. Space: O(M).

    taken.reverse()
    return taken
```

718. Maximum Length of Repeated Subarray

Medium · Array, Binary Search, Dynamic Programming, Sliding Window, Hash Function, Rolling Hash

leetcode.com/problems/maximum-length-of-repeated-subarray

PROBLEM

Given two integer arrays `nums1` and `nums2`, return *the maximum length of a subarray that appears in **both** arrays*.

Example 1:

```
Input: nums1 = [1,2,3,2,1], nums2 = [3,2,1,4,7]
Output: 3
Explanation: The repeated subarray with maximum length is [3,2,1].
```

Example 2:

```
Input: nums1 = [0,0,0,0,0], nums2 = [0,0,0,0,0]
Output: 5
Explanation: The repeated subarray with maximum length is [0,0,0,0,0].
```

Constraints:

- `1 <= nums1.length, nums2.length <= 1000`
- `0 <= nums1[i], nums2[i] <= 100`

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Find the longest common contiguous subarray. Lengths are 1000, so matching from every pair of starts is too slow, and LCS DP does not enforce contiguity. Contiguity means a suffix grows only when the current pair matches: it is one plus the suffix of the prefixes, otherwise zero. Let f[i][j] be the common suffix ending at nums1[i-1] and nums2[j-1]. Take the global maximum. Time O(mn).

Python 3

```python
class Solution:
    def findLength(self, nums1: List[int], nums2: List[int]) -> int:
        m, n = len(nums1), len(nums2)
        f = [[0] * (n + 1) for _ in range(m + 1)]
        ans = 0
        for i in range(1, m + 1):
            for j in range(1, n + 1):
                if nums1[i - 1] == nums2[j - 1]:
                    f[i][j] = f[i - 1][j - 1] + 1
                    ans = max(ans, f[i][j])
        return ans
```

108. Convert Sorted Array to Binary Search Tree

Easy · Tree, Binary Search Tree, Array, Divide and Conquer, Binary Tree

leetcode.com/problems/convert-sorted-array-to-binary-search-tree

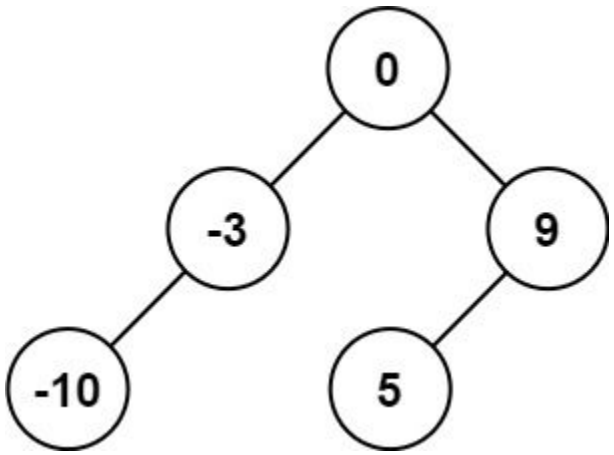
★ **TOP 10 PROBLEM** in Recursion / Divide and Conquer, Binary Search Tree (BST): master this one first

Also appears in pattern 26 Binary Search Tree (BST)

PROBLEM

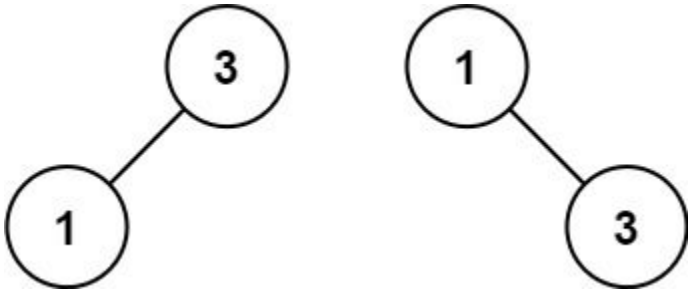
Given an integer array `nums` where the elements are sorted in **ascending order**, convert *it to a **height-balanced** binary search tree*.

Example 1:



```
Input: nums = [-10,-3,0,5,9]
Output: [0,-3,9,-10,null,5]
Explanation: [0,-10,5,null,-3,null,9] is also accepted:
```

Example 2:



```
Input: nums = [1,3]
Output: [3,1]
Explanation: [1,null,3] and [3,1] are both height-balanced BSTs.
```

Constraints:

- `1 <= nums.length <= 10^4`
- `-10^4 <= nums[i] <= 10^4`
- `nums` is sorted in a **strictly increasing** order.

SOLUTION (PYTHON 3)

Solution 1: Binary Search + Recursion

How to think about it

A sorted array is already the inorder sequence of some BST. Always picking the leftmost or rightmost value as the root yields a chain of height n, which is not height-balanced. $n \le 10^4$. The midpoint of an interval leaves the two sides differing by at most one element, so the height stays balanced. Take the mid of [l,r] as the root and recurse on both halves.

We design a recursive function dfs(l, r), which represents that the values of the nodes to be constructed in the current binary search tree are within the index range [l, r] of the array nums. This function returns the root node of the constructed binary search tree.

The execution process of the function dfs(l, r) is as follows:

1. If l > r, it means the current array is empty, so return `null`.
2. If l ≤ r, take the element at index mid = floor((l + r)/2) of the array as the root node of the current binary search tree, where floor(x) denotes the floor function of x.
3. Recursively construct the left subtree of the current binary search tree, with the root node's value being the element at index mid - 1 of the array. The values of the nodes in the left subtree are within the index range [l, mid - 1] of the array.
4. Recursively construct the right subtree of the current binary search tree, with the root node's value being the element at index mid + 1 of the array. The values of the nodes in the right subtree are within the index range [mid + 1, r] of the array.
5. Return the root node of the current binary search tree.

The answer is the return value of the function dfs(0, n - 1).

The time complexity is O(n), and the space complexity is O(log n). Here, n is the length of the array nums.

Python 3

```python
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def sortedArrayToBST(self, nums: List[int]) -> Optional[TreeNode]:
        def dfs(l: int, r: int) -> Optional[TreeNode]:
            if l > r:
                return None
            mid = (l + r) >> 1
            return TreeNode(nums[mid], dfs(l, mid - 1), dfs(mid + 1, r))

        return dfs(0, len(nums) - 1)
```

        if 2 * i + 2 < len(nums):
            nodes[i].right = nodes[2 * i + 2]
```

```
    return nodes[0] if nodes else None
```

PATTERN 14 · RECURSION / DIVIDE AND CONQUER · PROBLEM 2 OF 20

912. Sort an Array

Medium · Array, Divide and Conquer, Bucket Sort, Counting Sort, Radix Sort, Sorting, Heap (Priority Queue), Merge Sort

leetcode.com/problems/sort-an-array

★ **TOP 10 PROBLEM** in Recursion / Divide and Conquer, Sorting: master this one first

Also appears in pattern 23 Sorting

PROBLEM

Given an array of integers `nums`, sort the array in ascending order and return it.

You must solve the problem **without using any built-in** functions in `O(nlog(n))` time complexity and with the smallest space complexity possible.

Example 1:

```
Input: nums = [5,2,3,1]
Output: [1,2,3,5]
Explanation: After sorting the array, the positions of some numbers are not changed (for example, 2 and 3), while the positions of other numbers are changed (for example, 1 and 5).
```

Example 2:

```
Input: nums = [5,1,1,2,0,0]
Output: [0,0,1,1,2,5]
Explanation: Note that the values of nums are not necessarily unique.
```

Constraints:

- `1 <= nums.length <= 5 * 10^4`
- `-5 * 10^4 <= nums[i] <= 5 * 10^4`

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

n≤ 5× 10^4 needs an O(nlog n) sort; a naive quadratic pass is too slow. Three-way quicksort partitions around a random pivot into <, =, and > segments so duplicate keys do not degenerate, then recurses on the two sides.

Python 3

```python
class Solution:
    def sortArray(self, nums: List[int]) -> List[int]:
        def quick_sort(l, r):
            if l >= r:
                return
            x = nums[randint(l, r)]
            i, j, k = l - 1, r + 1, l
            while k < j:
                if nums[k] < x:
                    nums[i + 1], nums[k] = nums[k], nums[i + 1]
                    i, k = i + 1, k + 1
                elif nums[k] > x:
                    j -= 1
                    nums[j], nums[k] = nums[k], nums[j]
                else:
                    k = k + 1
            quick_sort(l, i)
            quick_sort(j, r)

        quick_sort(0, len(nums) - 1)
        return nums
```

Solution 2

> **How to think about it**
>
> Quicksort is fast on average but can unbalance and is not stable. Mergesort halves the range and merges in linear time, giving a guaranteed O(nlog n) bound at the cost of a linear buffer.

Python 3

```python
class Solution:
    def sortArray(self, nums: List[int]) -> List[int]:
        def merge_sort(l, r):
            if l >= r:
                return
            mid = (l + r) >> 1
            merge_sort(l, mid)
            merge_sort(mid + 1, r)
            i, j = l, mid + 1
            tmp = []
            while i <= mid and j <= r:
                if nums[i] <= nums[j]:
                    tmp.append(nums[i])
                    i += 1
                else:
                    tmp.append(nums[j])
                    j += 1
            if i <= mid:

PATTERN 14 · RECURSION / DIVIDE AND CONQUER · PROBLEM 3 OF 20

50. Pow(x, n)

Medium · Recursion, Math

leetcode.com/problems/powx-n

★ **TOP 10 PROBLEM** in Recursion / Divide and Conquer, Math / Number Theory: master this one first

Also appears in pattern 34 Math / Number Theory

PROBLEM

Implement pow(x, n), which calculates `x` raised to the power `n` (i.e., x^n).

Example 1:

```
Input: x = 2.00000, n = 10
Output: 1024.00000
```

Example 2:

```
Input: x = 2.10000, n = 3
Output: 9.26100
```

Example 3:

```
Input: x = 2.00000, n = -2
Output: 0.25000
Explanation: 2-2 = 1/22 = 1/4 = 0.25
```

Constraints:

- `-100.0 < x < 100.0`
- -2^{31} `<= n <=` $2^{31}-1$
- `n` is an integer.
- Either `x` is not zero or `n > 0`.
- -10^4 `<=` x^n `<=` 10^4

SOLUTION (PYTHON 3)

Solution 1: Mathematics (Fast Powering)

How to think about it

The first idea is multiply x by itself |n| times. |n| reaches 2^{31}, so a linear loop times out; negative n also needs a reciprocal. The bottleneck is multiplying by one x at a time. $x^{2k} = (x^k)^2$ and $x^{2k+1} = x \cdot (x^k)^2$ — the exponent halves each step. Walk the bits of n: square the base, and when a bit is 1 multiply into the answer. For negative n, compute the positive power then take the reciprocal. Fast powering drops O(|n|) to O(log |n|).

The core idea of the fast powering algorithm is to decompose the exponent n into the sum of 1s on several binary bits, and then transform the nth power of x into the product of several powers of x.

The time complexity is O(log n), and the space complexity is O(1). Here, n is the exponent.

Python 3

```python
class Solution:
    def myPow(self, x: float, n: int) -> float:
        def qpow(a: float, n: int) -> float:
            ans = 1
            while n:
                if n & 1:
                    ans *= a
                a *= a
                n >>= 1
            return ans

        return qpow(x, n) if n >= 0 else 1 / qpow(x, -n)
```

            result = multiply(result, base)
        base = multiply(base, base)
        n //= 2
    return result[0][1]
```

PATTERN 14 · RECURSION / DIVIDE AND CONQUER · PROBLEM 5 OF 20

241. Different Ways to Add Parentheses

Medium · Recursion, Memoization, Math, String, Dynamic Programming, Parentheses

leetcode.com/problems/different-ways-to-add-parentheses

★ **TOP 10 PROBLEM** in Recursion / Divide and Conquer: master this one first

PROBLEM

Given a string `expression` of numbers and operators, return *all possible results from computing all the different possible ways to group numbers and operators*. You may return the answer in **any order**.

The test cases are generated such that the output values fit in a 32-bit integer and the number of different results does not exceed 10^4.

Example 1:

```
Input: expression = "2-1-1"
Output: [0,2]
Explanation:
((2-1)-1) = 0
(2-(1-1)) = 2
```

Example 2:

```
Input: expression = "2*3-4*5"
Output: [-34,-14,-10,-10,10]
Explanation:
(2*(3-(4*5))) = -34
((2*3)-(4*5)) = -14
((2*(3-4))*5) = -10
(2*((3-4)*5)) = -10
(((2*3)-4)*5) = 10
```

Constraints:

- `1 <= expression.length <= 20`
- `expression` consists of digits and the operator `'+'`, `'-'`, and `'*'`.
- All the integer values in the input expression are in the range `[0, 99]`.
- The integer values in the input expression do not have a leading `'-'` or `'+'` denoting the sign.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Each parenthesization splits at some operator. Evaluating every split naively recomputes the same subexpressions. We cut at each operator, recurse for all left and right values, combine them, and memoize each substring.

Python 3

```python
class Solution:
    def diffWaysToCompute(self, expression: str) -> List[int]:
        @cache
        def dfs(exp):
            if exp.isdigit():
                return [int(exp)]
            ans = []
            for i, c in enumerate(exp):
                if c in '-+*':
                    left, right = dfs(exp[:i]), dfs(exp[i + 1 :])
                    for a in left:
                        for b in right:
                            if c == '-':
                                ans.append(a - b)
                            elif c == '+':
                                ans.append(a + b)
                            else:
                                ans.append(a * b)
            return ans

        return dfs(expression)
```

Complexity. Time: exponential: about O(4^n / sqrt(n)) (Catalan number of results). Space: the same order for the stored results.

PATTERN 14 · RECURSION / DIVIDE AND CONQUER · PROBLEM 6 OF 20

215. Kth Largest Element in an Array

Medium · Array, Divide and Conquer, Quickselect, Sorting, Heap (Priority Queue)

leetcode.com/problems/kth-largest-element-in-an-array

★ **TOP 10 PROBLEM** in Recursion / Divide and Conquer, Heap / Priority Queue, Sorting: master this one first

Also appears in pattern 19 Heap / Priority Queue, 23 Sorting, 38 K-way Merge

PROBLEM

Given an integer array `nums` and an integer `k`, return *the* k^{th} *largest element in the array*.

Note that it is the k^{th} largest element in the sorted order, not the k^{th} distinct element.

Can you solve it without sorting?

Example 1:

```
Input: nums = [3,2,1,5,6,4], k = 2
Output: 5
```

Example 2:

```
Input: nums = [3,2,3,1,2,4,5,5,6], k = 4
Output: 4
```

Constraints:

- `1 <= k <= nums.length <=` 10^5
- -10^4 `<= nums[i] <=` 10^4

SOLUTIONS (PYTHON 3)

Solution 1: Quick Select

How to think about it

Full sorting finds the k-th largest but orders every other position as well. Quickselect only needs the side that contains that rank. After partitioning around a pivot we recurse only into the interval that holds the target. The implementation converts " k-th largest" into " (n-k)-th smallest".

Quick Select is an algorithm for finding the k^{th} largest or smallest element in an unsorted array. Its basic idea is to select a pivot element each time, dividing the array into two parts: one part contains elements smaller than the pivot, and the other part contains elements larger than the pivot. Then, based on the position of the pivot, it decides whether to continue the search on the left or right side until the k^{th} largest element is found.

The time complexity is O(n), and the space complexity is O(log n). Here, n is the length of the array nums.

Python 3

```python
class Solution:
    def findKthLargest(self, nums: List[int], k: int) -> int:
        def quick_sort(l: int, r: int) -> int:
            if l == r:
                return nums[l]
            i, j = l - 1, r + 1
            x = nums[(l + r) >> 1]
            while i < j:
                while 1:
                    i += 1
                    if nums[i] >= x:
                        break
                while 1:
                    j -= 1
                    if nums[j] <= x:
                        break
                if i < j:
                    nums[i], nums[j] = nums[j], nums[i]
            if j < k:
                return quick_sort(j + 1, r)
            return quick_sort(l, j)

        n = len(nums)
        k = n - k
        return quick_sort(0, n - 1)
```

Solution 2: Priority Queue (Min Heap)

> **How to think about it**
>
> Quickselect is linear on average but quadratic in the worst case. A min-heap of size k is enough if we only need that order statistic. After one pass the heap stores the k largest values and its top is the answer, in O(nlog k) time.

We can maintain a min heap minQ of size k, and then iterate through the array nums, adding each element to the min heap. When the size of the min heap exceeds k, we pop the top element of the heap. This way, the final k elements in the min heap are the k largest elements in the array, and the top element of the heap is the k^{th} largest element.

The time complexity is O(nlog k), and the space complexity is O(k). Here, n is the length of the array nums.

Python 3

```python
class Solution:
    def findKthLargest(self, nums: List[int], k: int) -> int:
        return nlargest(k, nums)[-1]
```

Solution 3: Counting Sort

> **How to think about it**
>
> The heap still pays a log factor. With a bounded value range we count frequencies, then walk values from high to low until k occurrences are gathered. Time is linear in n plus the value range, with no comparison sort.

We can use the idea of counting sort, counting the occurrence of each element in the array nums and recording it in a hash table cnt. Then, we iterate over the elements i from largest to smallest, subtracting the occurrence count cnt[i] each time, until k is less than or equal to 0. At this point, the element i is the k^{th} largest element in the array.

The time complexity is O(n + m), and the space complexity is O(n). Here, n is the length of the array nums, and m is the maximum value among the elements in nums.

Python 3

```
class Solution:
    def findKthLargest(self, nums: List[int], k: int) -> int:
        cnt = Counter(nums)
        for i in count(max(cnt), -1):
            k -= cnt[i]
            if k <= 0:
                return i
```

```

PATTERN 14 · RECURSION / DIVIDE AND CONQUER · PROBLEM 8 OF 20

932. Beautiful Array

Medium · Array, Math, Divide and Conquer

leetcode.com/problems/beautiful-array

PROBLEM

An array `nums` of length `n` is **beautiful** if:

- `nums` is a permutation of the integers in the range `[1, n]`.
- For every `0 <= i < j < n`, there is no index `k` with `i < k < j` where `2 * nums[k] == nums[i] + nums[j]`.

Given the integer `n`, return *any* ***beautiful*** *array* `nums` *of length* `n`. There will be at least one valid answer for the given `n`.

Example 1:

```
Input: n = 4
Output: [2,1,4,3]
```

Example 2:

```
Input: n = 5
Output: [3,1,2,5,4]
```

Constraints:

- `1 <= n <= 1000`

SOLUTION (PYTHON 3)

Solution 1

How to think about it

A beautiful array forbids $2A_k = A_i + A_j$. The left side is even, so an odd/even pair A_i, A_j is always safe. Affine-map a smaller beautiful array into the odds and the evens and concatenate; the map preserves beauty, and divide-and-conquer builds 1..n.

Python 3

```python
class Solution:
    def beautifulArray(self, n: int) -> List[int]:
        if n == 1:
            return [1]
        left = self.beautifulArray((n + 1) >> 1)
        right = self.beautifulArray(n >> 1)
        left = [x * 2 - 1 for x in left]
        right = [x * 2 for x in right]
        return left + right
```

Complexity. Time: O(n log n). Space: O(n).

95. Unique Binary Search Trees II

Medium · Tree, Binary Search Tree, Dynamic Programming, Backtracking, Binary Tree

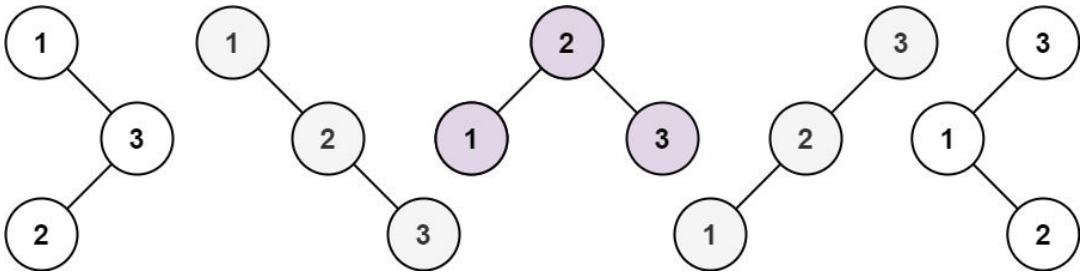
leetcode.com/problems/unique-binary-search-trees-ii

Also appears in pattern 26 Binary Search Tree (BST)

PROBLEM

Given an integer `n`, return *all the structurally unique **BST's** (binary search trees), which has exactly* `n` *nodes of unique values from* `1` *to* `n`. Return the answer in **any order**.

Example 1:



```
Input: n = 3
Output: [[1,null,2,null,3],[1,null,3,2],[2,1,3],[3,1,null,null,2],[3,2,null,1]]
```

Example 2:

```
Input: n = 1
Output: [[1]]
```

Constraints:

- `1 <= n <= 8`

SOLUTION (PYTHON 3)

Solution 1: DFS (Depth-First Search)

> **How to think about it**
>
> We need every BST on 1..n. Once the root is v, the left subtree uses only [1,v-1] and the right only [v+1,n]; the two sides are independent. Split by interval: enumerate the root, generate all left and right shapes, then take the Cartesian product. An empty interval is a null tree. n ≤ 8, Catalan numbers stay small, so search is enough.

We design a function dfs(i, j) that returns all feasible binary search trees composed of [i, j], so the answer is dfs(1, n).

The execution steps of the function dfs(i, j) are as follows:

1. If i > j, it means that there are no numbers to form a binary search tree at this time, so return a list consisting of a null node.
2. If i ≤ j, we enumerate the numbers v in [i, j] as the root node. The left subtree of the root node v is composed of [i, v - 1], and the right subtree is composed of [v + 1, j]. Finally, we take the Cartesian product of all combinations of the left and right subtrees, i.e., left × right, add the root node v, and get all binary search trees with v as the root node.

The time complexity is O(n × G(n)), and the space complexity is O(n × G(n)). Where G(n) is the Catalan number.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def generateTrees(self, n: int) -> List[Optional[TreeNode]]:
        def dfs(i: int, j: int) -> List[Optional[TreeNode]]:
            if i > j:
                return [None]
            ans = []
            for v in range(i, j + 1):
                left = dfs(i, v - 1)
                right = dfs(v + 1, j)
                for l in left:
                    for r in right:
                        ans.append(TreeNode(v, l, r))
            return ans

        return dfs(1, n)
```

1255. Maximum Score Words Formed by Letters

Hard · Bit Manipulation, Array, Hash Table, String, Dynamic Programming, Backtracking, Bitmask, Counting

leetcode.com/problems/maximum-score-words-formed-by-letters

PROBLEM

Given a list of `words`, list of single `letters` (might be repeating) and `score` of every character.

Return the maximum score of **any** valid set of words formed by using the given letters (`words[i]` cannot be used two or more times).

It is not necessary to use all characters in `letters` and each letter can only be used once. Score of letters `'a'`, `'b'`, `'c'`, ... ,`'z'` is given by `score[0]`, `score[1]`, ... , `score[25]` respectively.

Example 1:

```
Input: words = ["dog","cat","dad","good"], letters = ["a","a","c","d","d","d","g","o","o"], score =
[1,0,9,5,0,0,3,0,0,0,0,0,0,2,0,0,0,0,0,0,0,0,0,0]
Output: 23
Explanation:
Score a=1, c=9, d=5, g=3, o=2
Given letters, we can form the words "dad" (5+1+5) and "good" (3+2+2+5) with a score of 23.
Words "dad" and "dog" only get a score of 21.
```

Example 2:

```
Input: words = ["xxxz","ax","bx","cx"], letters = ["z","a","b","c","x","x","x"], score =
[4,4,4,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,5,0,10]
Output: 27
Explanation:
Score a=4, b=4, c=4, x=5, z=10
Given letters, we can form the words "ax" (4+5), "bx" (4+5) and "cx" (4+5) with a score of 27.
Word "xxxz" only get a score of 25.
```

Example 3:

```
Input: words = ["leetcode"], letters = ["l","e","t","c","o","d"], score =
[0,0,1,1,1,0,0,0,0,0,0,1,0,0,1,0,0,0,0,1,0,0,0,0,0,0]
Output: 0
Explanation:
Letter "e" can only be used once.
```

Constraints:

- `1 <= words.length <= 14`
- `1 <= words[i].length <= 15`
- `1 <= letters.length <= 100`
- `letters[i].length == 1`
- `score.length == 26`
- `0 <= score[i] <= 10`
- `words[i]`, `letters[i]` contains only lower case English letters.

SOLUTION (PYTHON 3)

Solution 1: Binary Enumeration

How to think about it

There are at most 14 words, so 2^{14} subsets are enumerable. A subset is legal iff it does not exceed the stock in letters. We count the letter bank, then for each nonempty mask concatenate the chosen words, check the counts, and score legal ones. The masks exhaust the choices; the count test enforces the bank.

Given the small data range in the problem, we can use binary enumeration to enumerate all word combinations for the given word list. Then, we check whether each word combination meets the requirements of the problem. If it does, we calculate its score and finally take the word combination with the highest score.

First, we use a hash table or array cnt to record the number of occurrences of each letter in the alphabet letters.

Next, we use binary enumeration to enumerate all word combinations. Each bit in the binary represents whether each word in the word list is selected. If the ith bit is 1, it means the ith word is selected; otherwise, the ith word is not selected.

Then, we count the number of occurrences of each letter in the current word combination and record it in the hash table or array cur. If the number of occurrences of each letter in cur is not greater than the corresponding letter in cnt, it means the current word combination meets the requirements of the problem. We calculate the score of the current word combination and take the word combination with the highest score.

The time complexity is $O(2^n \times n \times M)$, and the space complexity is $O(C)$. Where n and M are the number of words in the word set and the maximum length of the word, respectively; and C is the number of letters in the alphabet, in this problem, C=26.

Python 3

```python
class Solution:
    def maxScoreWords(
        self, words: List[str], letters: List[str], score: List[int]
    ) -> int:
        cnt = Counter(letters)
        n = len(words)
        ans = 0
        for i in range(1 << n):
            cur = Counter(''.join([words[j] for j in range(n) if i >> j & 1]))
            if all(v <= cnt[c] for c, v in cur.items()):
                t = sum(v * score[ord(c) - ord('a')] for c, v in cur.items())
                ans = max(ans, t)
        return ans
```

PATTERN 14 · RECURSION / DIVIDE AND CONQUER · PROBLEM 11 OF 20

372. Super Pow

Medium · Math, Divide and Conquer, Euler's Totient Function, Euler's Theorem

leetcode.com/problems/super-pow

Also appears in pattern 34 Math / Number Theory

PROBLEM

Your task is to calculate a^b mod `1337` where `a` is a positive integer and `b` is an extremely large positive integer given in the form of an array.

Example 1:

Input: a = 2, b = [3]

Output: 8

Explanation:

The array `b = [3]` represents the exponent 3. Therefore, $a^3 = 2^3 = 8$, so the result is 8.

Example 2:

Input: a = 2, b = [1,0]

Output: 1024

Explanation:

The array `b = [1, 0]` represents the exponent 10. Therefore, $a^{10} = 2^{10} = 1024$, so the result is 1024.

Example 3:

Input: a = 1, b = [4,3,3,8,5,2]

Output: 1

Explanation:

The array `b = [4, 3, 3, 8, 5, 2]` represents a positive exponent. Since `a = 1`, any positive power of 1 is 1. Therefore, the result is 1.

Constraints:

- `1 <= a <= 2^31 - 1`
- `1 <= b.length <= 2000`
- `0 <= b[i] <= 9`
- `b` does not contain leading zeros.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

a is raised to a huge decimal b given as digits; return a^b mod 1337. Building b as one integer is awkward. Write $b=\ldots+e_i \cdot 10^i$. From low digit to high: multiply by a^e, then replace the base with a^{10}. Modular fast pow keeps each step O(log e).

Python 3

```
class Solution:
    def superPow(self, a: int, b: List[int]) -> int:
        mod = 1337
        ans = 1
        for e in b[::-1]:
            ans = ans * pow(a, e, mod) % mod
            a = pow(a, 10, mod)
        return ans
```

PATTERN 14 · RECURSION / DIVIDE AND CONQUER · PROBLEM 12 OF 20

218. The Skyline Problem

Hard · Binary Indexed Tree, Segment Tree, Array, Divide and Conquer, Ordered Set, Sorting, Sweep Line, Heap (Priority Queue)

leetcode.com/problems/the-skyline-problem

★ **TOP 10 PROBLEM** in Recursion / Divide and Conquer, Segment Tree: master this one first

Also appears in pattern 40 Segment Tree

PROBLEM

A city's **skyline** is the outer contour of the silhouette formed by all the buildings in that city when viewed from a distance. Given the locations and heights of all the buildings, return *the **skyline** formed by these buildings collectively*.

The geometric information of each building is given in the array `buildings` where `buildings[i] = [left_i, right_i, height_i]`:

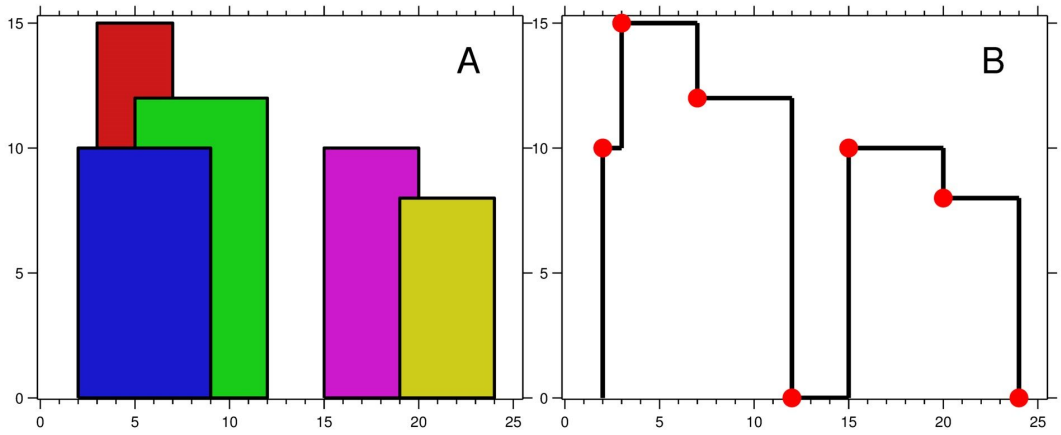
- `left_i` is the x coordinate of the left edge of the `i^th` building.
- `right_i` is the x coordinate of the right edge of the `i^th` building.
- `height_i` is the height of the `i^th` building.

You may assume all buildings are perfect rectangles grounded on an absolutely flat surface at height `0`.

The **skyline** should be represented as a list of "key points" **sorted by their x-coordinate** in the form `[[x_1,y_1],[x_2,y_2],...]`. Each key point is the left endpoint of some horizontal segment in the skyline except the last point in the list, which always has a y-coordinate `0` and is used to mark the skyline's termination where the rightmost building ends. Any ground between the leftmost and rightmost buildings should be part of the skyline's contour.

Note: There must be no consecutive horizontal lines of equal height in the output skyline. For instance, `[...,[2 3],[4 5],[7 5],[11 5],[12 7],...]` is not acceptable; the three lines of height 5 should be merged into one in the final output as such: `[...,[2 3],[4 5],[12 7],...]`

Example 1:



```
Input: buildings = [[2,9,10],[3,7,15],[5,12,12],[15,20,10],[19,24,8]]
Output: [[2,10],[3,15],[7,12],[12,0],[15,10],[20,8],[24,0]]
Explanation:
Figure A shows the buildings of the input.
Figure B shows the skyline formed by those buildings. The red points in figure B represent the key
points in the output list.
```

Example 2:

```
Input: buildings = [[0,2,3],[2,5,3]]
Output: [[0,3],[5,0]]
```

Constraints:

- `1 <= buildings.length <= 10^4`
- `0 <= left_i < right_i <= 2^31 - 1`
- `1 <= height_i <= 2^31 - 1`
- `buildings` is sorted by `left_i` in non-decreasing order.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Buildings occlude one another, so comparing every height at every x is not viable. The skyline can change only at left and right edges, which become sweep events. We sort those x-coordinates and keep a max-heap of buildings that still cover the sweep line. A key point is emitted when the height changes; adjacent equal heights are merged.

Python 3

```python
from queue import PriorityQueue

class Solution:
    def getSkyline(self, buildings: List[List[int]]) -> List[List[int]]:
        skys, lines, pq = [], [], PriorityQueue()
        for build in buildings:
            lines.extend([build[0], build[1]])
        lines.sort()
        city, n = 0, len(buildings)
        for line in lines:
            while city < n and buildings[city][0] <= line:
                pq.put([-buildings[city][2], buildings[city][0], buildings[city][1]])
                city += 1
            while not pq.empty() and pq.queue[0][2] <= line:
                pq.get()
            high = 0
            if not pq.empty():
                high = -pq.queue[0][0]
            if len(skys) > 0 and skys[-1][1] == high:
                continue
            skys.append([line, high])
        return skys
```

    for i in range(len(skyline) - 1):
        area += skyline[i][1] * (skyline[i + 1][0] - skyline[i][0])
    return area
```

PATTERN 14 · RECURSION / DIVIDE AND CONQUER · PROBLEM 13 OF 20

315. Count of Smaller Numbers After Self

Hard · Binary Indexed Tree, Segment Tree, Array, Binary Search, Divide and Conquer, Ordered Set, Treap, Merge Sort

leetcode.com/problems/count-of-smaller-numbers-after-self

★ **TOP 10 PROBLEM** in Recursion / Divide and Conquer, Segment Tree, Binary Indexed Tree (Fenwick Tree): master this one first

Also appears in pattern 40 Segment Tree, 41 Binary Indexed Tree (Fenwick Tree)

PROBLEM

Given an integer array `nums`, return *an integer array* `counts` *where* `counts[i]` *is the number of smaller elements to the right of* `nums[i]`.

Example 1:

```
Input: nums = [5,2,6,1]
Output: [2,1,1,0]
Explanation:
To the right of 5 there are 2 smaller elements (2 and 1).
To the right of 2 there is only 1 smaller element (1).
To the right of 6 there is 1 smaller element (1).
To the right of 1 there is 0 smaller element.
```

Example 2:

```
Input: nums = [-1]
Output: [0]
```

Example 3:

```
Input: nums = [-1,-1]
Output: [0,0]
```

Constraints:

- `1 <= nums.length <= 10^5`
- `-10^4 <= nums[i] <= 10^4`

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

Count how many later elements are smaller. A nested scan is $O(n^2)$. The count is a prefix frequency over values already seen to the right. Walk right to left: discretize, insert the current rank into a Fenwick tree, then query ranks strictly below it. Insert-then-query x-1 still ignores equals. Reverse the answers to restore order.

Python 3

```python
class BinaryIndexedTree:
    def __init__(self, n):
        self.n = n
        self.c = [0] * (n + 1)

    @staticmethod
    def lowbit(x):
        return x & -x

    def update(self, x, delta):
        while x <= self.n:
            self.c[x] += delta
            x += BinaryIndexedTree.lowbit(x)

    def query(self, x):
        s = 0
        while x > 0:
            s += self.c[x]
            x -= BinaryIndexedTree.lowbit(x)
        return s

class Solution:
    def countSmaller(self, nums: List[int]) -> List[int]:
        alls = sorted(set(nums))
        m = {v: i for i, v in enumerate(alls, 1)}
        tree = BinaryIndexedTree(len(m))
        ans = []
        for v in nums[::-1]:
            x = m[v]
            tree.update(x, 1)
            ans.append(tree.query(x - 1))
        return ans[::-1]
```

Solution 2

> **How to think about it**
>
> The Fenwick tree is a prefix sum on the value domain. A segment tree splits that domain, supports point increment and range [1,x-1], and matches Method 1 with explicit interval nodes.

Python 3

```python
class Node:
    def __init__(self):
        self.l = 0
        self.r = 0
        self.v = 0

class SegmentTree:
    def __init__(self, n):
        self.tr = [Node() for _ in range(n << 2)]
        self.build(1, 1, n)

    def build(self, u, l, r):
        self.tr[u].l = l
        self.tr[u].r = r
        if l == r:
            return
        mid = (l + r) >> 1
        self.build(u << 1, l, mid)
        self.build(u << 1 | 1, mid + 1, r)

    def modify(self, u, x, v):
        if self.tr[u].l == x and self.tr[u].r == x:
            self.tr[u].v += v
            return
        mid = (self.tr[u].l + self.tr[u].r) >> 1
        if x <= mid:
            self.modify(u << 1, x, v)
        else:
            self.modify(u << 1 | 1, x, v)
        self.pushup(u)

    def query(self, u, l, r):
        if self.tr[u].l >= l and self.tr[u].r <= r:
            return self.tr[u].v
        mid = (self.tr[u].l + self.tr[u].r) >> 1
        v = 0
        if l <= mid:
            v += self.query(u << 1, l, r)
        if r > mid:
            v += self.query(u << 1 | 1, l, r)
        return v

    def pushup(self, u):
        self.tr[u].v = self.tr[u << 1].v + self.tr[u << 1 | 1].v

class Solution:
    def countSmaller(self, nums: List[int]) -> List[int]:
        s = sorted(set(nums))
        m = {v: i for i, v in enumerate(s, 1)}
        tree = SegmentTree(len(s))
        ans = []
        for v in nums[::-1]:
            x = m[v]
            ans.append(tree.query(1, 1, x - 1))
            tree.modify(1, x, 1)
        return ans[::-1]
```

Complexity. Time: O(n log n). Space: O(n).

Solution 3: Merge Sort

> **How to think about it**
>
> The first two methods need discretization and an extra tree. During merge, when a left value is ≤ the current right value, exactly j consumed right elements are smaller and later; add j to that index. No value tree is required; time stays O(nlog n).

During the merge phase of merge sort, when a left element left[i] ≤ right[j], it means exactly j elements on the right side are smaller than left[i], so we accumulate j into the count of left[i].

Once all right elements are exhausted, all right elements are smaller than each remaining left element, so we accumulate the right array's full length into each remaining left element's count.

Note: In C++, merge sort on very large arrays may suffer Memory Limit Exceeded. Use a buffer array to avoid excessive memory allocations.

Complexity

- Time complexity: O(n log n), the standard time complexity for merge sort.
- Space complexity: O(n), the standard space complexity of recursion stack.

Python 3

```python
class Solution:
    def countSmaller(self, nums: list[int]) -> list[int]:
        self.right_smaller_counts = [0] * len(nums)

        nums_indices = [(num, idx) for idx, num in enumerate(nums)]
        self.merge_sort(nums_indices)

        return self.right_smaller_counts

    def combine_arrays(
        self,
        left_nums_indices: list[tuple[int, int]],
        right_nums_indices: list[tuple[int, int]],
    ) -> list[tuple[int, int]]:
        merged_nums_indices: list[tuple[int, int]] = []
        left_idx, right_idx = 0, 0

        while left_idx < len(left_nums_indices) and right_idx < len(right_nums_indices):
            if left_nums_indices[left_idx][0] <= right_nums_indices[right_idx][0]:
                # Iterated left side element finalizes its right smaller count.
                left_num_idx = left_nums_indices[left_idx][1]
                self.right_smaller_counts[left_num_idx] += right_idx

                merged_nums_indices.append(left_nums_indices[left_idx])
                left_idx += 1
                continue

            merged_nums_indices.append(right_nums_indices[right_idx])
            right_idx += 1

        while left_idx < len(left_nums_indices):
            # Iterated left side element finalizes its right smaller count.
            left_num_idx = left_nums_indices[left_idx][1]
            self.right_smaller_counts[left_num_idx] += len(right_nums_indices)

            merged_nums_indices.append(left_nums_indices[left_idx])
            left_idx += 1

        while right_idx < len(right_nums_indices):
            merged_nums_indices.append(right_nums_indices[right_idx])
            right_idx += 1

        return merged_nums_indices

    def merge_sort(self, nums_indices: list[tuple[int, int]]) -> list[tuple[int, int]]:
        if len(nums_indices) == 1:
            return nums_indices  # Single element.

        split_idx = len(nums_indices) // 2

        left_nums_indices = self.merge_sort(nums_indices[:split_idx])
        right_nums_indices = self.merge_sort(nums_indices[split_idx:])

        return self.combine_arrays(left_nums_indices, right_nums_indices)
```

PATTERN 14 · RECURSION / DIVIDE AND CONQUER · PROBLEM 15 OF 20

493. Reverse Pairs

Hard · Binary Indexed Tree, Segment Tree, Array, Binary Search, Divide and Conquer, Ordered Set, Treap, Merge Sort

leetcode.com/problems/reverse-pairs

★ **TOP 10 PROBLEM** in Recursion / Divide and Conquer, Segment Tree, Binary Indexed Tree (Fenwick Tree): master this one first

Also appears in pattern 40 Segment Tree, 41 Binary Indexed Tree (Fenwick Tree)

PROBLEM

Given an integer array `nums`, return *the number of **reverse pairs** in the array*.

A **reverse pair** is a pair `(i, j)` where:

- `0 <= i < j < nums.length` and
- `nums[i] > 2 * nums[j]`.

Example 1:

```
Input: nums = [1,3,2,3,1]
Output: 2
Explanation: The reverse pairs are:
(1, 4) --> nums[1] = 3, nums[4] = 1, 3 > 2 * 1
(3, 4) --> nums[3] = 3, nums[4] = 1, 3 > 2 * 1
```

Example 2:

```
Input: nums = [2,4,3,5,1]
Output: 3
Explanation: The reverse pairs are:
(1, 4) --> nums[1] = 4, nums[4] = 1, 4 > 2 * 1
(2, 4) --> nums[2] = 3, nums[4] = 1, 3 > 2 * 1
(3, 4) --> nums[3] = 5, nums[4] = 1, 5 > 2 * 1
```

Constraints:

- $1 <= nums.length <= 5 * 10^4$
- $-2^{31} <= nums[i] <= 2^{31} - 1$

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

A reverse pair is i<j and nums[i]>2 nums[j]. A double loop is O(n^2). During mergesort both halves are sorted, so cross pairs can be counted before merging. Recurse on both halves, then for each right value advance a left pointer until nums[i]>2 nums[j]; the leftover left side all form pairs. Merge by raw value afterwards. Counting and merging stay separate: the count compares against 2 nums[j], the merge compares the original values.

Python 3

```python
class Solution:
    def reversePairs(self, nums: List[int]) -> int:
        def merge_sort(l, r):
            if l >= r:
                return 0
            mid = (l + r) >> 1
            ans = merge_sort(l, mid) + merge_sort(mid + 1, r)
            t = []
            i, j = l, mid + 1
            while i <= mid and j <= r:
                if nums[i] <= 2 * nums[j]:
                    i += 1
                else:
                    ans += mid - i + 1
                    j += 1
            i, j = l, mid + 1
            while i <= mid and j <= r:
                if nums[i] <= nums[j]:
                    t.append(nums[i])
                    i += 1
                else:
                    t.append(nums[j])
                    j += 1
            t.extend(nums[i : mid + 1])
            t.extend(nums[j : r + 1])
            nums[l : r + 1] = t
            return ans

        return merge_sort(0, len(nums) - 1)
```

Solution 2

How to think about it

Solution 1 rewrites the array. After discretizing nums and 2 nums, walk right to left, insert 2 nums[j] into a Fenwick tree, and query how many inserted values are less than nums[i]. The relative order of the original array is not needed beyond the right-to-left scan; the tree stores the 2 nums already seen.

Python 3

```python
class BinaryIndexedTree:
    def __init__(self, n):
        self.n = n
        self.c = [0] * (n + 1)

    @staticmethod
    def lowbit(x):
        return x & -x

    def update(self, x, delta):
        while x <= self.n:
            self.c[x] += delta
            x += BinaryIndexedTree.lowbit(x)

    def query(self, x):
        s = 0
        while x > 0:
            s += self.c[x]
            x -= BinaryIndexedTree.lowbit(x)
        return s

class Solution:
    def reversePairs(self, nums: List[int]) -> int:
        s = set()
        for num in nums:
            s.add(num)
            s.add(num * 2)
        alls = sorted(s)
        m = {v: i for i, v in enumerate(alls, 1)}
        ans = 0
        tree = BinaryIndexedTree(len(m))
        for num in nums[::-1]:
            ans += tree.query(m[num] - 1)
            tree.update(m[num * 2], 1)
        return ans
```

Complexity. Time: O(n log n). Space: O(n).

Solution 3

> **How to think about it**
>
> Replace the Fenwick tree with a segment tree: same discretization, insert 2 nums from the right, query the count below nums[i]. Same algebra, with explicit interval nodes.

Python 3

```python
class Node:
    def __init__(self):
        self.l = 0
        self.r = 0
        self.v = 0

class SegmentTree:
    def __init__(self, n):
        self.tr = [Node() for _ in range(4 * n)]
        self.build(1, 1, n)

    def build(self, u, l, r):
        self.tr[u].l = l
        self.tr[u].r = r
        if l == r:
            return
        mid = (l + r) >> 1
        self.build(u << 1, l, mid)
        self.build(u << 1 | 1, mid + 1, r)

    def modify(self, u, x, v):
        if self.tr[u].l == x and self.tr[u].r == x:
            self.tr[u].v += 1
            return
        mid = (self.tr[u].l + self.tr[u].r) >> 1
        if x <= mid:
            self.modify(u << 1, x, v)
        else:
            self.modify(u << 1 | 1, x, v)
        self.pushup(u)

    def pushup(self, u):
        self.tr[u].v = self.tr[u << 1].v + self.tr[u << 1 | 1].v

    def query(self, u, l, r):
        if self.tr[u].l >= l and self.tr[u].r <= r:
            return self.tr[u].v
        mid = (self.tr[u].l + self.tr[u].r) >> 1
        v = 0
        if l <= mid:
            v += self.query(u << 1, l, r)
        if r > mid:
            v += self.query(u << 1 | 1, l, r)
        return v

class Solution:
    def reversePairs(self, nums: List[int]) -> int:
        s = set()
        for num in nums:
            s.add(num)
            s.add(num * 2)
        alls = sorted(s)
        m = {v: i for i, v in enumerate(alls, 1)}
        tree = SegmentTree(len(m))
        ans = 0
        for v in nums[::-1]:
            x = m[v]
            ans += tree.query(1, 1, x - 1)
            tree.modify(1, m[v * 2], 1)
        return ans
```

Complexity. Time: O(n log n). Space: O(n).

```

PATTERN 14 · RECURSION / DIVIDE AND CONQUER · PROBLEM 16 OF 20

282. Expression Add Operators

Hard · Math, String, Backtracking

leetcode.com/problems/expression-add-operators

★ **TOP 10 PROBLEM** in Recursion / Divide and Conquer: master this one first

PROBLEM

Given a string `num` that contains only digits and an integer `target`, return ***all possibilities*** *to insert the binary operators* `'+'`, `'-'`, *and/or* `'*'` *between the digits of* `num` *so that the resultant expression evaluates to the* `target` *value.*

Note that operands in the returned expressions **should not** contain leading zeros.

Note that a number can contain multiple digits.

Example 1:

```
Input: num = "123", target = 6
Output: ["1*2*3","1+2+3"]
Explanation: Both "1*2*3" and "1+2+3" evaluate to 6.
```

Example 2:

```
Input: num = "232", target = 8
Output: ["2*3+2","2+3*2"]
Explanation: Both "2*3+2" and "2+3*2" evaluate to 8.
```

Example 3:

```
Input: num = "3456237490", target = 9191
Output: []
Explanation: There are no expressions that can be created from "3456237490" to evaluate to 9191.
```

Constraints:

- `1 <= num.length <= 10`
- `num` consists of only digits.
- -2^{31} `<= target <=` $2^{31} - 1$

SOLUTION (PYTHON 3)

Solution 1

How to think about it

We insert +, -, * or concatenate digits. Multiplication binds tighter than addition, and concatenated numbers may not have leading zeros. DFS keeps the last operand prev and the value curr. Plus and minus update curr directly; multiply rewinds the last term via curr-prev+prev×next.

Python 3

```python
class Solution:
    def addOperators(self, num: str, target: int) -> List[str]:
        ans = []

        def dfs(u, prev, curr, path):
            if u == len(num):
                if curr == target:
                    ans.append(path)
                return
            for i in range(u, len(num)):
                if i != u and num[u] == '0':
                    break
                next = int(num[u : i + 1])
                if u == 0:
                    dfs(i + 1, next, next, path + str(next))
                else:
                    dfs(i + 1, next, curr + next, path + "+" + str(next))
                    dfs(i + 1, -next, curr - next, path + "-" + str(next))
                    dfs(
                        i + 1,
                        prev * next,
                        curr - prev + prev * next,
                        path + "*" + str(next),
                    )

        dfs(0, 0, 0, "")
        return ans
```

Complexity. Time: O(n * 4^n). Space: O(n) recursion depth (plus the answers).

    go(0, 0, "")
    return results
```

664. Strange Printer

Hard · String, Dynamic Programming

leetcode.com/problems/strange-printer

PROBLEM

There is a strange printer with the following two special properties:

- The printer can only print a sequence of **the same character** each time.
- At each turn, the printer can print new characters starting from and ending at any place and will cover the original existing characters.

Given a string `s`, return *the minimum number of turns the printer needed to print it*.

Example 1:

```
Input: s = "aaabbb"
Output: 2
Explanation: Print "aaa" first and then print "bbb".
```

Example 2:

```
Input: s = "aba"
Output: 2
Explanation: Print "aaa" first and then print "b" from the second place of the string, which will cover the existing character 'a'.
```

Constraints:

- `1 <= s.length <= 100`
- `s` consists of lowercase English letters.

SOLUTION (PYTHON 3)

Solution 1: Dynamic Programming

> **How to think about it**
>
> One print paints a contiguous segment with the same letter. n≤ 100 suits interval DP. f[i][j] is the fewest prints for s[i..j]. Equal endpoints reuse the last stroke; otherwise try every split. Fill shorter intervals first.

We define f[i][j] as the minimum operations to print s[i..j], with the initial value f[i][j]=∞, and the answer is f[0][n-1], where n is the length of string s.

Consider f[i][j], if s[i] = s[j], we can print s[j] when print s[i], so we can ignore s[j] and continue to print s[i+1..j-1]. If s[i] ≠ s[j], we need to print the substring separately, i.e. s[i..k] and s[k+1..j], where k ∈ [i,j). So we can have the following transition equation:

$$f[i][j]= \text{cases } 1, \& \text{ if } i=j \setminus f[i][j-1], \& \text{ if } s[i]=s[j] \setminus \min_{i \le k < j} \{f[i][k]+f[k+1][j]\}, \& \text{ otherwise cases}$$

We can enumerate i from large to small and j from small to large, so that we can ensure that f[i][j-1], f[i][k] and f[k+1][j] have been calculated when we calculate f[i][j].

The time complexity is $O(n^3)$ and the space complexity is $O(n^2)$. Where n is the length of string s.

Python 3

```python
class Solution:
    def strangePrinter(self, s: str) -> int:
        n = len(s)
        f = [[inf] * n for _ in range(n)]
        for i in range(n - 1, -1, -1):
            f[i][i] = 1
            for j in range(i + 1, n):
                if s[i] == s[j]:
                    f[i][j] = f[i][j - 1]
                else:
                    for k in range(i, j):
                        f[i][j] = min(f[i][j], f[i][k] + f[k + 1][j])
        return f[0][-1]
```

        memo[(i, j)] = best
        return best

    return turns(0, len(letters) - 1)
```

1000. Minimum Cost to Merge Stones

Hard · Array, Dynamic Programming, Prefix Sum

leetcode.com/problems/minimum-cost-to-merge-stones

PROBLEM

There are `n` piles of `stones` arranged in a row. The i^{th} pile has `stones[i]` stones.

A move consists of merging exactly `k` **consecutive** piles into one pile, and the cost of this move is equal to the total number of stones in these `k` piles.

Return *the minimum cost to merge all piles of stones into one pile*. If it is impossible, return `-1`.

Example 1:

```
Input: stones = [3,2,4,1], k = 2
Output: 20
Explanation: We start with [3, 2, 4, 1].
We merge [3, 2] for a cost of 5, and we are left with [5, 4, 1].
We merge [4, 1] for a cost of 5, and we are left with [5, 5].
We merge [5, 5] for a cost of 10, and we are left with [10].
The total cost was 20, and this is the minimum possible.
```

Example 2:

```
Input: stones = [3,2,4,1], k = 3
Output: -1
Explanation: After any merge operation, there are 2 piles left, and we can't merge anymore. So the
task is impossible.
```

Example 3:

```
Input: stones = [3,5,1,2,6], k = 3
Output: 25
Explanation: We start with [3, 5, 1, 2, 6].
We merge [5, 1, 2] for a cost of 8, and we are left with [3, 8, 6].
We merge [3, 8, 6] for a cost of 17, and we are left with [17].
The total cost was 25, and this is the minimum possible.
```

Constraints:

- `n == stones.length`
- `1 <= n <= 30`
- `1 <= stones[i] <= 100`
- `2 <= k <= 30`

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Enumerating every merge order is correct, but with n ≤ 30 the number of valid partitions grows too quickly to search. Each move only merges K consecutive piles, so the cost is determined by subproblems of the form “turn a contiguous segment into a given number of piles,” and the same interval is reached by many orders. Each merge reduces the pile count by K-1, so a single pile exists only when (n-1) mod (K-1)=0; otherwise the answer is -1. When it is feasible, merging [i,j] into k piles means some prefix becomes 1 pile and the suffix becomes k-1 piles; merging into 1 pile means first obtaining K piles and then paying the sum of that interval. We therefore fill f[i][j][k] by increasing interval length and keep a prefix sum s for O(1) range sums. The split h always uses f[i][h][1] on the left, matching the consecutive-merge constraint. The answer is f[1][n][1].

Python 3

```python
class Solution:
    def mergeStones(self, stones: List[int], K: int) -> int:
        n = len(stones)
        if (n - 1) % (K - 1):
            return -1
        s = list(accumulate(stones, initial=0))
        f = [[[inf] * (K + 1) for _ in range(n + 1)] for _ in range(n + 1)]
        for i in range(1, n + 1):
            f[i][i][1] = 0
        for l in range(2, n + 1):
            for i in range(1, n - l + 2):
                j = i + l - 1
                for k in range(1, K + 1):
                    for h in range(i, j):
                        f[i][j][k] = min(f[i][j][k], f[i][h][1] + f[h + 1][j][k - 1])
                f[i][j][1] = f[i][j][K] + s[j] - s[i - 1]
        return f[1][n][1]
```

```

312. Burst Balloons

Hard · Array, Dynamic Programming

leetcode.com/problems/burst-balloons

★ **TOP 10 PROBLEM** in Recursion / Divide and Conquer: master this one first

PROBLEM

You are given `n` balloons, indexed from `0` to `n - 1`. Each balloon is painted with a number on it represented by an array `nums`. You are asked to burst all the balloons.

If you burst the i^{th} balloon, you will get `nums[i - 1] * nums[i] * nums[i + 1]` coins. If `i - 1` or `i + 1` goes out of bounds of the array, then treat it as if there is a balloon with a `1` painted on it.

Return *the maximum coins you can collect by bursting the balloons wisely*.

Example 1:

```
Input: nums = [3,1,5,8]
Output: 167
Explanation:
nums = [3,1,5,8] --> [3,5,8] --> [3,8] --> [8] --> []
coins = 3*1*5 + 3*5*8 + 1*3*8 + 1*8*1 = 167
```

Example 2:

```
Input: nums = [1,5]
Output: 10
```

Constraints:

- `n == nums.length`
- `1 <= n <= 300`
- `0 <= nums[i] <= 100`

SOLUTION (PYTHON 3)

Solution 1: Dynamic Programming

How to think about it

The burst order changes neighbors, so searching by burst sequence revisits the same open intervals. Padding 1 at both ends fixes the multipliers on the boundary. If k is the last balloon burst in the open interval (i,j), the two sides do not interact and we add arr[i]· arr[k]· arr[j]. Let f[i][j] be the best score of clearing (i,j); fill by increasing width (i decreasing, j increasing). The answer is f[0][n+1].

Let's denote the length of the array `nums` as n. According to the problem description, we can add a 1 to both ends of the array `nums`, denoted as `arr`.

Then, we define f[i][j] as the maximum number of coins we can get by bursting all the balloons in the interval [i, j]. Therefore, the answer is f[0][n+1].

For f[i][j], we enumerate all positions k in the interval [i, j]. Suppose k is the last balloon to burst, then we can get the following state transition equation:

$$f[i][j] = \max(f[i][j], f[i][k] + f[k][j] + arr[i] \times arr[k] \times arr[j])$$

In implementation, since the state transition equation of f[i][j] involves f[i][k] and f[k][j], where i < k < j, we need to traverse i from large to small and j from small to large. This ensures that when calculating f[i][j], f[i][k] and f[k][j] have already been calculated.

Finally, we return f[0][n+1].

The time complexity is $O(n^3)$, and the space complexity is $O(n^2)$. Where n is the length of the array `nums`.

Python 3

```
class Solution:
    def maxCoins(self, nums: List[int]) -> int:
        n = len(nums)
        arr = [1] + nums + [1]
        f = [[0] * (n + 2) for _ in range(n + 2)]
        for i in range(n - 1, -1, -1):
            for j in range(i + 2, n + 2):
                for k in range(i + 1, j):
                    f[i][j] = max(f[i][j], f[i][k] + f[k][j] + arr[i] * arr[k] * arr[j])
        return f[0][-1]
```

PATTERN 14 · RECURSION / DIVIDE AND CONQUER · PROBLEM 20 OF 20

327. Count of Range Sum

Hard · Binary Indexed Tree, Segment Tree, Array, Binary Search, Divide and Conquer, Ordered Set, Treap, Merge Sort

leetcode.com/problems/count-of-range-sum

★ **TOP 10 PROBLEM** in Segment Tree, Binary Indexed Tree (Fenwick Tree): master this one first

Also appears in pattern 40 Segment Tree, 41 Binary Indexed Tree (Fenwick Tree)

PROBLEM

Given an integer array `nums` and two integers `lower` and `upper`, return *the number of range sums that lie in* `[lower, upper]` *inclusive*.

Range sum `S(i, j)` is defined as the sum of the elements in `nums` between indices `i` and `j` inclusive, where `i <= j`.

Example 1:

```
Input: nums = [-2,5,-1], lower = -2, upper = 2
Output: 3
Explanation: The three ranges are: [0,0], [2,2], and [0,2] and their respective sums are: -2, -1, 2.
```

Example 2:

```
Input: nums = [0], lower = 0, upper = 0
Output: 1
```

Constraints:

- `1 <= nums.length <= 10^5`
- `-2^31 <= nums[i] <= 2^31 - 1`
- `-10^5 <= lower <= upper <= 10^5`
- The answer is **guaranteed** to fit in a **32-bit** integer.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Count subarrays whose sum lies in [lower,upper]. A sum is a prefix difference; a double loop is O(n^2). For prefix x we need how many earlier prefixes fall in [x-upper,x-lower]. Discretize all x, x-lower, and x-upper. A Fenwick tree stores frequencies of seen prefixes: query the interval, then insert x, so only earlier prefixes count.

Python 3

```python
class BinaryIndexedTree:
    def __init__(self, n):
        self.n = n
        self.c = [0] * (n + 1)

    def update(self, x, v):
        while x <= self.n:
            self.c[x] += v
            x += x & -x

    def query(self, x):
        s = 0
        while x > 0:
            s += self.c[x]
            x -= x & -x
        return s

class Solution:
    def countRangeSum(self, nums: List[int], lower: int, upper: int) -> int:
        s = list(accumulate(nums, initial=0))
        arr = sorted(set(v for x in s for v in (x, x - lower, x - upper)))
        tree = BinaryIndexedTree(len(arr))
        ans = 0
        for x in s:
            l = bisect_left(arr, x - upper) + 1
            r = bisect_left(arr, x - lower) + 1
            ans += tree.query(r) - tree.query(l - 1)
            tree.update(bisect_left(arr, x) + 1, 1)
        return ans
```

78. Subsets

Medium · Bit Manipulation, Array, Backtracking

leetcode.com/problems/subsets

★ **TOP 10 PROBLEM** in Backtracking / Subsets / Combinations / Permutations, Bit Manipulation: master this one first

Also appears in pattern 27 Bit Manipulation

PROBLEM

Given an integer array `nums` of **unique** elements, return *all possible subsets (the power set)*.

The solution set **must not** contain duplicate subsets. Return the solution in **any order**.

Example 1:

```
Input: nums = [1,2,3]
Output: [[],[1],[2],[1,2],[3],[1,3],[2,3],[1,2,3]]
```

Example 2:

```
Input: nums = [0]
Output: [[],[0]]
```

Constraints:

- `1 <= nums.length <= 10`
- `-10 <= nums[i] <= 10`
- All the numbers of `nums` are **unique**.

SOLUTIONS (PYTHON 3)

Solution 1: DFS (Backtracking)

How to think about it

A subset is a choose/skip for each element, 2^n of them. n ≤ 10, so listing all is fine. We could rebuild from each mask, or recurse. Recursion is the direct picture: from index i, skip nums[i] then take it and pop. At i=n copy the path into the answer. Distinct elements mean no duplicate subsets.

We design a function dfs(i), which represents starting the search from the ith element of the array for all subsets. The execution logic of the function dfs(i) is as follows:

- If i = n, it means the current search has ended. Add the current subset t to the answer array ans, and then return.
- Otherwise, we can choose not to select the current element and directly execute dfs(i + 1); or we can choose the current element, i.e., add the current element nums[i] to the subset t, and then execute dfs(i + 1). Note that we need to remove nums[i] from the subset t after executing dfs(i + 1) (backtracking).

In the main function, we call dfs(0), i.e., start searching all subsets from the first element of the array. Finally, return the answer array ans.

The time complexity is $O(n \times 2^n)$, and the space complexity is O(n). Here, n is the length of the array. There are a total of 2^n subsets, and each subset takes O(n) time to construct.

Python 3

```python
class Solution:
    def subsets(self, nums: List[int]) -> List[List[int]]:
        def dfs(i: int):
            if i == len(nums):
                ans.append(t[:])
                return
            dfs(i + 1)
            t.append(nums[i])
            dfs(i + 1)
            t.pop()

        ans = []
        t = []
        dfs(0)
        return ans
```

Solution 2: Binary Enumeration

> **How to think about it**
>
> Method 1 expands choose/skip on the call stack. n is tiny, so each subset can be a mask in $[0,2^n)$: bit i includes nums[i]. No recursion; the same $O(n \times 2^n)$ work.

We can also use the method of binary enumeration to get all subsets.

We can use 2^n binary numbers to represent all subsets of n elements. For the current binary number mask, if the ith bit is 1, it means that the ith element is selected, otherwise it means that the ith element is not selected.

The time complexity is $O(n \times 2^n)$, and the space complexity is $O(n)$. Here, n is the length of the array. There are a total of 2^n subsets, and each subset takes $O(n)$ time to construct.

Python 3

```python
class Solution:
    def subsets(self, nums: List[int]) -> List[List[int]]:
        ans = []
        for mask in range(1 << len(nums)):
            t = [x for i, x in enumerate(nums) if mask >> i & 1]
            ans.append(t)
        return ans
```

def subsets_of_size(nums, k):
    result = []

    def go(start, current):
        if len(current) == k:
            result.append(list(current))
            return
        for i in range(start, len(nums)):
            if len(nums) - i < k - len(current):
                break
            current.append(nums[i])
            go(i + 1, current)
            current.pop()

    go(0, [])
    return result
```

784. Letter Case Permutation

Medium · Bit Manipulation, String, Backtracking

leetcode.com/problems/letter-case-permutation

PROBLEM

Given a string `s`, you can transform every letter individually to be lowercase or uppercase to create another string.

Return *a list of all possible strings we could create*. Return the output in **any order**.

Example 1:

```
Input: s = "a1b2"
Output: ["a1b2","a1B2","A1b2","A1B2"]
```

Example 2:

```
Input: s = "3z4"
Output: ["3z4","3Z4"]
```

Constraints:

- `1 <= s.length <= 12`
- `s` consists of lowercase English letters, uppercase English letters, and digits.

SOLUTIONS (PYTHON 3)

Solution 1: DFS

> **How to think about it**
>
> Each letter may flip case. The string is short, so DFS enumerates. At a letter, first continue unchanged, then xor 32 and continue; digits have one branch. Collect at the end.

Since each letter in s can be converted to uppercase or lowercase, we can use the DFS (Depth-First Search) method to enumerate all possible cases.

Specifically, traverse the string s from left to right. For each letter encountered, you can choose to convert it to uppercase or lowercase, and then continue to traverse the subsequent letters. When you reach the end of the string, you get a conversion scheme and add it to the answer.

The method of converting case can be implemented using bitwise operations. For a letter, the difference between the ASCII codes of its lowercase and uppercase forms is 32, so we can achieve case conversion by XORing the ASCII code of the letter with 32.

The time complexity is $O(n \times 2^n)$, where n is the length of the string s. For each letter, we can choose to convert it to uppercase or lowercase, so there are 2^n conversion schemes in total. For each conversion scheme, we need $O(n)$ time to generate a new string.

Python 3

```python
class Solution:
    def letterCasePermutation(self, s: str) -> List[str]:
        def dfs(i: int) -> None:
            if i >= len(t):
                ans.append("".join(t))
                return
            dfs(i + 1)
            if t[i].isalpha():
                t[i] = chr(ord(t[i]) ^ 32)
                dfs(i + 1)

        t = list(s)
        ans = []
        dfs(0)
        return ans
```

Solution 2: Binary Enumeration

> **How to think about it**
>
> There are exactly 2^n strings if n letters appear. A bitmask can pick lower/upper for the j-th letter. For each mask, rewrite letters by that bit and copy digits.

For a letter, we can convert it to uppercase or lowercase. Therefore, for each letter, we can use a binary bit to represent its conversion scheme, where 1 represents lowercase and 0 represents uppercase.

First, we count the number of letters in the string s, denoted as n. Then, there are 2^n conversion schemes in total. We can use each bit of a binary number to represent the conversion scheme of each letter, enumerating from 0 to 2^n-1.

Specifically, we can use a variable i to represent the current binary number being enumerated, where the j-th bit of i represents the conversion scheme of the j-th letter. That is, the j-th bit of i being 1 means the j-th letter is converted to lowercase, and 0 means the j-th letter is converted to uppercase.

The time complexity is $O(n \times 2^n)$, where n is the length of the string s. For each letter, we can choose to convert it to uppercase or lowercase, so there are 2^n conversion schemes in total. For each conversion scheme, we need $O(n)$ time to generate a new string.

Python 3

```python
class Solution:
    def letterCasePermutation(self, s: str) -> List[str]:
        ans = []
        n = sum(c.isalpha() for c in s)
        for i in range(1 << n):
            j, t = 0, []
            for c in s:
                if c.isalpha():
                    c = c.lower() if (i >> j) & 1 else c.upper()
                    j += 1
                t.append(c)
            ans.append(''.join(t))
        return ans
```

```

77. Combinations

Medium · Backtracking

leetcode.com/problems/combinations

PROBLEM

Given two integers `n` and `k`, return *all possible combinations of* `k` *numbers chosen from the range* `[1, n]`.

You may return the answer in **any order**.

Example 1:

```
Input: n = 4, k = 2
Output: [[1,2],[1,3],[1,4],[2,3],[2,4],[3,4]]
Explanation: There are 4 choose 2 = 6 total combinations.
Note that combinations are unordered, i.e., [1,2] and [2,1] are considered to be the same combination.
```

Example 2:

```
Input: n = 1, k = 1
Output: [[1]]
Explanation: There is 1 choose 1 = 1 total combination.
```

Constraints:

- `1 <= n <= 20`
- `1 <= k <= n`

SOLUTIONS (PYTHON 3)

Solution 1: Backtracking (Two Ways)

How to think about it

The first idea is all 2^n subsets of {1,…,n}, keep those of length k. n ≤ 20 might pass, but most subsets have the wrong size. Order does not matter; each number is in or out, and we can stop a path once its length is k. So dfs(i) handles i: push, recurse i+1, pop, then skip. Enumerating the next j among leftovers is the other tree; both yield the same combinations. The code below is the first form.

We design a function dfs(i), which represents starting the search from number i, with the current search path as t, and the answer as ans.

The execution logic of the function dfs(i) is as follows:

- If the length of the current search path t equals k, then add the current search path to the answer and return.
- If i > n, it means the search has ended, return.
- Otherwise, we can choose to add the number i to the search path t, and then continue the search, i.e., execute dfs(i + 1), and then remove the number i from the search path t; or we do not add the number i to the search path t, and directly execute dfs(i + 1).

The above method is actually enumerating whether to select the current number or not, and then recursively searching the next number. We can also enumerate the next number j to be selected, where i ≤ j ≤ n. If the next number to be selected is j, then we add the number j to the search path t, and then continue the search, i.e., execute dfs(j + 1), and then remove the number j from the search path t.

In the main function, we start the search from number 1, i.e., execute dfs(1).

The time complexity is $O(C_n^k \times k)$, and the space complexity is O(k). Here, C_n^k represents the combination number.

Similar problems:

- 39. Combination Sum

- 40. Combination Sum II
- 216. Combination Sum III

Python 3

```python
class Solution:
    def combine(self, n: int, k: int) -> List[List[int]]:
        def dfs(i: int):
            if len(t) == k:
                ans.append(t[:])
                return
            if i > n:
                return
            t.append(i)
            dfs(i + 1)
            t.pop()
            dfs(i + 1)

        ans = []
        t = []
        dfs(1)
        return ans
```

Solution 2

How to think about it

Method 1 walks a choose/skip tree of depth n; skip branches still scan the rest of the numbers. Method 2 enumerates the next chosen j ∈ [i,n], so recursion depth equals how many we have picked, and the tree matches combinations of length k more closely. Same answers; the loop just expands the remaining candidates.

Python 3

```python
class Solution:
    def combine(self, n: int, k: int) -> List[List[int]]:

39. Combination Sum

Medium · Array, Backtracking

leetcode.com/problems/combination-sum

★ **TOP 10 PROBLEM** in Backtracking / Subsets / Combinations / Permutations: master this one first

PROBLEM

Given an array of **distinct** integers `candidates` and a target integer `target`, return *a list of all **unique combinations** of* `candidates` *where the chosen numbers sum to* `target`. You may return the combinations in **any order**.

The **same** number may be chosen from `candidates` an **unlimited number of times**. Two combinations are unique if the frequency of at least one of the chosen numbers is different.

The test cases are generated such that the number of unique combinations that sum up to `target` is less than `150` combinations for the given input.

Example 1:

```
Input: candidates = [2,3,6,7], target = 7
Output: [[2,2,3],[7]]
Explanation:
2 and 3 are candidates, and 2 + 2 + 3 = 7. Note that 2 can be used multiple times.
7 is a candidate, and 7 = 7.
These are the only two combinations.
```

Example 2:

```
Input: candidates = [2,3,5], target = 8
Output: [[2,2,2,2],[2,3,3],[3,5]]
```

Example 3:

```
Input: candidates = [2], target = 1
Output: []
```

Constraints:

- `1 <= candidates.length <= 30`
- `2 <= candidates[i] <= 40`
- All elements of `candidates` are **distinct**.
- `1 <= target <= 40`

SOLUTIONS (PYTHON 3)

Solution 1: Sorting + Pruning + Backtracking

How to think about it

The first idea is to use each number any number of times and collect every sequence that sums to target. With n ≤ 30 and target ≤ 40, an unpruned search wastes paths that already exceed the target, and different orders of the same multiset would be counted twice. A combination ignores order, so each multiset should appear once. Sort first, and only take candidates from the current index rightward. After sorting, if the remainder s is already smaller than candidates[i], everything after is larger and the branch dies. dfs(i,s) enumerates j from i, and the recursive call stays at j so the same value may be reused.

We can first sort the array to facilitate pruning.

Next, we design a function dfs(i, s), which means starting the search from index i with a remaining target value of s. Here, i and s are both non-negative integers, the current search path is t, and the answer is ans.

In the function dfs(i, s), we first check whether s is 0. If it is, we add the current search path t to the answer ans, and then return. If s < candidates[i], it means that the elements of the current index and the following indices are all greater than the remaining target value s, and the path is invalid, so we return directly. Otherwise, we start the search from index i, and the search index range is $j \in [i, n)$, where n is the length of the array candidates. During the search, we add the element of the current index to the search path t, recursively call the function dfs(j, s - candidates[j]), and after the recursion ends, we remove the element of the current index from the search path t.

In the main function, we just need to call the function dfs(0, target) to get the answer.

The time complexity is $O(2^n \times n)$, and the space complexity is O(n). Here, n is the length of the array candidates. Due to pruning, the actual time complexity is much less than $O(2^n \times n)$.

- 77. Combinations
- 216. Combination Sum III

Python 3

```python
class Solution:
    def combinationSum(self, candidates: List[int], target: int) -> List[List[int]]:
        def dfs(i: int, s: int):
            if s == 0:
                ans.append(t[:])
                return
            if s < candidates[i]:
                return
            for j in range(i, len(candidates)):
                t.append(candidates[j])
                dfs(j, s - candidates[j])
                t.pop()

        candidates.sort()
        t = []
        ans = []
        dfs(0, target)
        return ans
```

Solution 2: Sorting + Pruning + Backtracking(Another Form)

> **How to think about it**
>
> Method 1 already prunes correctly by looping over “who is next”. The other writing is choose-or-skip at the current index: skip goes to i+1; take stays at i so the same value may be reused. The search tree looks different; the answers do not. It is the same algorithm unfolded as a binary tree.

We can also change the implementation logic of the function dfs(i, s) to another form. In the function dfs(i, s), we first check whether s is 0. If it is, we add the current search path t to the answer ans, and then return. If $i \geq n$ or s < candidates[i], the path is invalid, so we return directly. Otherwise, we consider two situations, one is not selecting the element of the current index, that is, recursively calling the function dfs(i + 1, s), and the other is selecting the element of the current index, that is, recursively calling the function dfs(i, s - candidates[i]).

The time complexity is $O(2^n \times n)$, and the space complexity is O(n). Here, n is the length of the array candidates. Due to pruning, the actual time complexity is much less than $O(2^n \times n)$.

Python 3

```
class Solution:
    def combinationSum(self, candidates: List[int], target: int) -> List[List[int]]:
        def dfs(i: int, s: int):
            if s == 0:
                ans.append(t[:])
                return
            if i >= len(candidates) or s < candidates[i]:
                return
            dfs(i + 1, s)
            t.append(candidates[i])
            dfs(i, s - candidates[i])
            t.pop()

        candidates.sort()
        t = []
        ans = []
        dfs(0, target)
        return ans
```

★ **TOP 10 PROBLEM** in Backtracking / Subsets / Combinations / Permutations: master this one first

PROBLEM

Given an integer array `nums` that may contain duplicates, return *all possible subsets (the power set)*.

The solution set **must not** contain duplicate subsets. Return the solution in **any order**.

Example 1:

```
Input: nums = [1,2,2]
Output: [[],[1],[1,2],[1,2,2],[2],[2,2]]
```

Example 2:

```
Input: nums = [0]
Output: [[],[0]]
```

Constraints:

- `1 <= nums.length <= 10`
- `-10 <= nums[i] <= 10`

SOLUTIONS (PYTHON 3)

Solution 1: Sorting + DFS

How to think about it

The first idea is the same DFS as Subsets: take or skip each index. Correct, but duplicates make [1, 2] appear twice. n ≤ 10 is small, yet the solution set must be unique. The bottleneck is treating equal values at different indices as distinct choices. Sort so equals sit together; skip the same value on the “not take” branch so each multiset is generated once. After sorting, DFS: take i, then on the skip path jump over every later equal nums[i]. How many copies we take is decided by recursion depth, never as two identical subsets side by side.

We can first sort the array nums to facilitate deduplication.

Then, we design a function dfs(i), which represents the current search for subsets starting from the i-th element. The execution logic of the function dfs(i) is as follows:

If i ≥ n, it means all elements have been searched, add the current subset to the answer array, and end the recursion.

If i < n, add the i-th element to the subset, execute dfs(i + 1), then remove the i-th element from the subset. Next, we check if the i-th element is the same as the next element. If they are the same, skip the element in a loop until we find the first element different from the i-th element, then execute dfs(i + 1).

Finally, we only need to call dfs(0) and return the answer array.

The time complexity is $O(n \times 2^n)$, and the space complexity is $O(n)$. Here, n is the length of the array nums.

Python 3

```python
class Solution:
    def subsetsWithDup(self, nums: List[int]) -> List[List[int]]:
        def dfs(i: int):
            if i == len(nums):
                ans.append(t[:])
                return
            t.append(nums[i])
            dfs(i + 1)
            x = t.pop()
            while i + 1 < len(nums) and nums[i + 1] == x:
                i += 1
            dfs(i + 1)

        nums.sort()
        ans = []
        t = []
        dfs(0)
        return ans
```

Solution 2: Sorting + Binary Enumeration

> **How to think about it**
>
> Solution 1 already deduplicates, but recursion pays a stack and the skip logic is easy to get wrong. n ≤ 10, so we can enumerate all 2^n masks. What it lacks is “take or skip” as bits. Bit i of mask means taking nums[i]; taking i without i - 1 when the values are equal skips an earlier copy — a duplicate, drop it. Same asymptotics, one loop.

Similar to Solution 1, we first sort the array nums to facilitate deduplication.

Next, we enumerate a binary number mask in the range $[0, 2^n)$, where the binary representation of mask is an n-bit bit string. If the i-th bit of mask is 1, it means selecting nums[i], and 0 means not selecting nums[i]. Note that if the (i - 1)-th bit of mask is 0 and nums[i] = nums[i - 1], it means that the i-th element is the same as the (i - 1)-th element in the current enumeration scheme. To avoid duplication, we skip this case. Otherwise, we add the subset corresponding to mask to the answer array.

After the enumeration, we return the answer array.

The time complexity is $O(n \times 2^n)$, and the space complexity is $O(n)$. Here, n is the length of the array nums.

Python 3

```python
class Solution:
    def subsetsWithDup(self, nums: List[int]) -> List[List[int]]:
        nums.sort()
        n = len(nums)
        ans = []
        for mask in range(1 << n):
            ok = True
            t = []
            for i in range(n):
                if mask >> i & 1:
                    if i and (mask >> (i - 1) & 1) == 0 and nums[i] == nums[i - 1]:
                        ok = False
                        break
                    t.append(nums[i])
            if ok:
                ans.append(t)
        return ans
```

★ **TOP 10 PROBLEM** in Backtracking / Subsets / Combinations / Permutations: master this one first

PROBLEM

Given an array `nums` of distinct integers, return all the possible permutations. You can return the answer in **any order**.

Example 1:

```
Input: nums = [1,2,3]
Output: [[1,2,3],[1,3,2],[2,1,3],[2,3,1],[3,1,2],[3,2,1]]
```

Example 2:

```
Input: nums = [0,1]
Output: [[0,1],[1,0]]
```

Example 3:

```
Input: nums = [1]
Output: [[1]]
```

Constraints:

- `1 <= nums.length <= 6`
- `-10 <= nums[i] <= 10`
- All the integers of `nums` are **unique**.

SOLUTION (PYTHON 3)

Solution 1: DFS (Backtracking)

How to think about it

The first idea is a language builtin or nested loops. n ≤ 6 so n! fits, but n is not fixed — we cannot hard-code loop depth. Generating every permutation means “pick an unused number for this position”. Reusing a number breaks the permutation, so we must mark. DFS fills index i: try each unused value, place it, recurse, then undo. n is tiny; O(n · n!) matches the output size.

We design a function dfs(i) to represent that the first i positions have been filled, and now we need to fill the i+1 position. We enumerate all possible numbers, if this number has not been filled, we fill in this number, and then continue to fill the next position, until all positions are filled.

The time complexity is O(n × n!), where n is the length of the array. There are n! permutations in total, and each permutation takes O(n) time to construct.

```

Constraints:

- `1 <= nums.length <= 8`
- `-10 <= nums[i] <= 10`

SOLUTION (PYTHON 3)

Solution 1: Sorting + Backtracking

How to think about it

The first idea is the same backtracking as unique permutations, then drop duplicates with a set. Correct, but n ≤ 8 and repeated numbers clone whole subtrees; filtering afterwards wastes time and space. The bottleneck is those duplicate branches. Swapping two equal values at the same depth yields the same permutation — each value may be chosen only once per layer. Sort so equals sit together, then skip a candidate when the previous equal is still unused. Each distinct value expands once at a position; every generated permutation is unique.

We can first sort the array so that duplicate numbers are placed together, making it easier to remove duplicates.

Then, we design a function dfs(i), which represents the current number to be placed at the i-th position. The specific implementation of the function is as follows:

- If i = n, it means we have filled all positions, add the current permutation to the answer array, and then return.
- Otherwise, we enumerate the number nums[j] for the i-th position, where the range of j is [0, n - 1]. We need to ensure that nums[j] has not been used and is different from the previously enumerated number to ensure that the current permutation is not duplicated. If the conditions are met, we can place nums[j] and continue to recursively fill the next position by calling dfs(i + 1). After the recursive call ends, we need to mark nums[j] as unused to facilitate subsequent enumeration.

In the main function, we first sort the array, then call dfs(0) to start filling from the 0th position, and finally return the answer array.

The time complexity is O(n × n!), and the space complexity is O(n). Here, n is the length of the array. We need to perform n! enumerations, and each enumeration requires O(n) time to check for duplicates. Additionally, we need a marker array to mark whether each position has been used, so the space complexity is O(n).

40. Combination Sum II

Medium · Array, Backtracking

leetcode.com/problems/combination-sum-ii

★ **TOP 10 PROBLEM** in Backtracking / Subsets / Combinations / Permutations: master this one first

PROBLEM

Given a collection of candidate numbers (`candidates`) and a target number (`target`), find all unique combinations in `candidates` where the candidate numbers sum to `target`.

Each number in `candidates` may only be used **once** in the combination.

Note: The solution set must not contain duplicate combinations.

Example 1:

```
Input: candidates = [10,1,2,7,6,1,5], target = 8
Output:
[
[1,1,6],
[1,2,5],
[1,7],
[2,6]
]
```

Example 2:

```
Input: candidates = [2,5,2,1,2], target = 5
Output:
[
[1,2,2],
[5]
]
```

Constraints:

- `1 <= candidates.length <= 100`
- `1 <= candidates[i] <= 50`
- `1 <= target <= 30`

SOLUTIONS (PYTHON 3)

Solution 1: Sorting + Pruning + Backtracking

How to think about it

Unlike the previous problem, each number may be used only once, and candidates may contain duplicates. Without deduping, the same multiset is found via different index combinations. n ≤ 100 and target ≤ 30 make pruning even more important. Sort so equal values sit together. At the same depth, if j > i and candidates[j] equals the previous value, that value has already been tried as “this level’s choice” and we skip it. The recursive call is dfs(j+1,…): this index cannot be reused. If the remainder s is already smaller than the current value, the whole branch stops.

We can first sort the array to facilitate pruning and skipping duplicate numbers.

Next, we design a function dfs(i, s), which means starting the search from index i with a remaining target value of s. Here, i and s are both non-negative integers, the current search path is t, and the answer is ans.

In the function dfs(i, s), we first check whether s is 0. If it is, we add the current search path t to the answer ans, and then return. If i ≥ n or s < candidates[i], the path is invalid, so we return directly. Otherwise, we start the search from index i, and the search index range is j ∈ [i, n), where n is the length of the array candidates. During the search, if j > i and candidates[j]

= candidates[j - 1], it means that the current number is the same as the previous number, we can skip the current number because the previous number has been searched. Otherwise, we add the current number to the search path t, recursively call the function dfs(j + 1, s - candidates[j]), and after the recursion ends, we remove the current number from the search path t.

We can also change the implementation logic of the function dfs(i, s) to another form. If we choose the current number, we add the current number to the search path t, then recursively call the function dfs(i + 1, s - candidates[i]), and after the recursion ends, we remove the current number from the search path t. If we do not choose the current number, we can skip all numbers that are the same as the current number, then recursively call the function dfs(j, s), where j is the index of the first number that is different from the current number.

In the main function, we just need to call the function dfs(0, target) to get the answer.

The time complexity is $O(2^n \times n)$, and the space complexity is $O(n)$. Here, n is the length of the array candidates. Due to pruning, the actual time complexity is much less than $O(2^n \times n)$.

Similar problems:

Python 3

```python
class Solution:
    def combinationSum2(self, candidates: List[int], target: int) -> List[List[int]]:
        def dfs(i: int, s: int):
            if s == 0:
                ans.append(t[:])
                return
            if i >= len(candidates) or s < candidates[i]:
                return
            for j in range(i, len(candidates)):
                if j > i and candidates[j] == candidates[j - 1]:
                    continue
                t.append(candidates[j])
                dfs(j + 1, s - candidates[j])
                t.pop()

        candidates.sort()
        ans = []
        t = []
        dfs(0, target)
        return ans
```

Solution 2: Sorting + Pruning + Backtracking(Another Form)

> **How to think about it**
>
> Method 1 skips same-depth duplicates inside the loop. We can instead choose or skip: taking x advances the index by one; skipping jumps over the whole run of x, so the same combination cannot reappear via different indices. Complexity is unchanged; deduping just moves onto the “skip” branch.

We can also change the implementation logic of the function dfs(i, s) to another form. If we choose the current number, we add the current number to the search path t, then recursively call the function dfs(i + 1, s - candidates[i]), and after the recursion ends, we remove the current number from the search path t. If we do not choose the current number, we can skip all numbers that are the same as the current number, then recursively call the function dfs(j, s), where j is the index of the first number that is different from the current number.

The time complexity is $O(2^n \times n)$, and the space complexity is $O(n)$. Here, n is the length of the array candidates. Due to pruning, the actual time complexity is much less than $O(2^n \times n)$.

                ans.append(t[:])
                return
            if i >= len(candidates) or s < candidates[i]:
                return
            x = candidates[i]
            t.append(x)
            dfs(i + 1, s - x)
            t.pop()
            while i < len(candidates) and candidates[i] == x:
                i += 1
            dfs(i, s)

        candidates.sort()
        ans = []
        t = []
        dfs(0, target)
        return ans
```

    return ways[target]
```

216. Combination Sum III

Medium · Array, Backtracking

leetcode.com/problems/combination-sum-iii

PROBLEM

Find all valid combinations of `k` numbers that sum up to `n` such that the following conditions are true:

- Only numbers `1` through `9` are used.
- Each number is used **at most once**.

Return *a list of all possible valid combinations*. The list must not contain the same combination twice, and the combinations may be returned in any order.

Example 1:

```
Input: k = 3, n = 7
Output: [[1,2,4]]
Explanation:
1 + 2 + 4 = 7
There are no other valid combinations.
```

Example 2:

```
Input: k = 3, n = 9
Output: [[1,2,6],[1,3,5],[2,3,4]]
Explanation:
1 + 2 + 6 = 9
1 + 3 + 5 = 9
2 + 3 + 4 = 9
There are no other valid combinations.
```

Example 3:

```
Input: k = 4, n = 1
Output: []
Explanation: There are no valid combinations.
Using 4 different numbers in the range [1,9], the smallest sum we can get is 1+2+3+4 = 10 and since 10
> 1, there are no valid combination.
```

Constraints:

- `2 <= k <= 9`
- `1 <= n <= 60`

SOLUTIONS (PYTHON 3)

Solution 1: Pruning + Backtracking (Two Approaches)

> **How to think about it**
>
> We choose k numbers from 1 through 9 that sum to n. The universe is tiny, so we can enumerate. Decide include-or-skip in increasing order, and prune when the remaining sum, the count, or the next integer is invalid. dfs(i,s) considers integer i with remaining sum s: take it via dfs(i+1,s-i), or skip via dfs(i+1,s).

We design a function dfs(i, s), which represents that we are currently enumerating the number i, and there are still numbers with a sum of s to be enumerated. The current search path is t, and the answer is ans.

The execution logic of the function dfs(i, s) is as follows:

Approach One:

- If s = 0 and the length of the current search path t is k, it means that a group of answers has been found. Add t to ans and then return.
- If i > 9 or i > s or the length of the current search path t is greater than k, it means that the current search path cannot be the answer, so return directly.
- Otherwise, we can choose to add the number i to the search path t, and then continue to search, i.e., execute dfs(i + 1, s - i). After the search is completed, remove i from the search path t; we can also choose not to add the number i to the search path t, and directly execute dfs(i + 1, s).

Python 3

```
class Solution:
    def combinationSum3(self, k: int, n: int) -> List[List[int]]:
        def dfs(i: int, s: int):
            if s == 0:
                if len(t) == k:
                    ans.append(t[:])
                return
            if i > 9 or i > s or len(t) >= k:
                return
            t.append(i)
            dfs(i + 1, s - i)
            t.pop()
            dfs(i + 1, s)

        ans = []
        t = []
        dfs(1, n)
        return ans
```

Another approach:

- If s = 0 and the length of the current search path t is k, it means that a group of answers has been found. Add t to ans and then return.
- If i > 9 or i > s or the length of the current search path t is greater than k, it means that the current search path cannot be the answer, so return directly.
- Otherwise, we enumerate the next number j, i.e., $j \in [i, 9]$, add the number j to the search path t, and then continue to search, i.e., execute dfs(j + 1, s - j). After the search is completed, remove j from the search path t.

In the main function, we call dfs(1, n), i.e., start enumerating from the number 1, and the remaining numbers with a sum of n need to be enumerated. After the search is completed, we can get all the answers.

The time complexity is $O(C_9^k \times k)$, and the space complexity is O(k).

Python 3

```
class Solution:
    def combinationSum3(self, k: int, n: int) -> List[List[int]]:
        def dfs(i: int, s: int):
            if s == 0:
                if len(t) == k:
                    ans.append(t[:])
                return
            if i > 9 or i > s or len(t) >= k:
                return
            for j in range(i, 10):
                t.append(j)
                dfs(j + 1, s - j)
                t.pop()

        ans = []
        t = []
        dfs(1, n)
        return ans
```

Solution 2: Binary Enumeration

> **How to think about it**
>
> Backtracking uses a call stack. There are only 2^9 subsets of {1,…,9}, so a 9-bit mask can list them all. If the mask has k bits set and those integers sum to n, we record the subset.

We can use a binary integer of length 9 to represent the selection of numbers 1 to 9, where the i-th bit of the binary integer represents whether the number i + 1 is selected. If the i-th bit is 1, it means that the number i + 1 is selected, otherwise, it means that the number i + 1 is not selected.

We enumerate binary integers in the range of $[0, 2^9)$. For the currently enumerated binary integer mask, if the number of 1s in the binary representation of mask is k, and the sum of the numbers corresponding to 1 in the binary representation of mask is n, it means that the number selection scheme corresponding to mask is a group of answers. We can add the number selection scheme corresponding to mask to the answer.

The time complexity is $O(2^9 \times 9)$, and the space complexity is O(k).

17. Letter Combinations of a Phone Number

Medium · Hash Table, String, Backtracking

leetcode.com/problems/letter-combinations-of-a-phone-number

★ **TOP 10 PROBLEM** in Backtracking / Subsets / Combinations / Permutations: master this one first

PROBLEM

Given a string containing digits from `2-9` inclusive, return all possible letter combinations that the number could represent. Return the answer in **any order**.

A mapping of digits to letters (just like on the telephone buttons) is given below. Note that 1 does not map to any letters.

Example 1:

```
Input: digits = "23"
Output: ["ad","ae","af","bd","be","bf","cd","ce","cf"]
```

Example 2:

```
Input: digits = "2"
Output: ["a","b","c"]
```

Constraints:

- `1 <= digits.length <= 4`
- `digits[i]` is a digit in the range `['2', '9']`.

SOLUTIONS (PYTHON 3)

Solution 1: Traversal

How to think about it

n≤ 4, so at most 4^n combinations; any enumeration would pass. The problem is a Cartesian product of letter groups. Nested loops cannot be written when n is not fixed. Start from the empty string: each new digit replaces the current prefixes with every concatenation against that digit's letters. That is the product expanded layer by layer. So we keep a mapping array and grow from a list that holds only the empty string. An empty input returns an empty list.

First, we use an array or hash table to store the letters corresponding to each digit. Then we traverse each digit, combine its corresponding letters with the previous results to get the new results.

The time complexity is $O(4^n)$, and the space complexity is $O(4^n)$. Here, n is the length of the input digits.

Python 3

```python
class Solution:
    def letterCombinations(self, digits: str) -> List[str]:
        if not digits:
            return []
        d = ["abc", "def", "ghi", "jkl", "mno", "pqrs", "tuv", "wxyz"]
        ans = [""]
        for i in digits:
            s = d[int(i) - 2]
            ans = [a + b for a in ans for b in s]
        return ans
```

Solution 2: DFS

> **How to think about it**
>
> Solution 1 already enumerates every answer, but each layer allocates a new prefix list, so intermediate strings stay $O(4^n)$. If we walk a single path and backtrack, extra space drops to O(n) (depth and path length). So we DFS by index: pick one letter for the current digit, go deeper, then undo. The combinations are the same; only the generation order changes from “expand by layer” to “one path to the end”.

We can use the method of depth-first search to enumerate all possible letter combinations. Suppose that a part of the letter combination has been generated, but some digits have not been exhausted. At this time, we take out the letters corresponding to the next digit, and then enumerate each letter corresponding to this digit one by one, add them to the letter combination that has been generated before, to form all possible combinations.

The time complexity is $O(4^n)$, and the space complexity is O(n). Here, n is the length of the input digits.

Python 3

```python
class Solution:
    def letterCombinations(self, digits: str) -> List[str]:
        def dfs(i: int):
            if i >= len(digits):
                ans.append("".join(t))
                return
            for c in d[int(digits[i]) - 2]:
                t.append(c)
                dfs(i + 1)
                t.pop()

        if not digits:
            return []
        d = ["abc", "def", "ghi", "jkl", "mno", "pqrs", "tuv", "wxyz"]
        ans = []
        t = []
        dfs(0)
        return ans
```

526. Beautiful Arrangement

Medium · Bit Manipulation, Array, Dynamic Programming, Backtracking, Bitmask

leetcode.com/problems/beautiful-arrangement

PROBLEM

Suppose you have `n` integers labeled `1` through `n`. A permutation of those `n` integers `perm` (**1-indexed**) is considered a **beautiful arrangement** if for every `i` (`1 <= i <= n`), **either** of the following is true:

- `perm[i]` is divisible by `i`.
- `i` is divisible by `perm[i]`.

Given an integer `n`, return *the **number** of the **beautiful arrangements** that you can construct*.

Example 1:

```
Input: n = 2
Output: 2
Explanation:
The first beautiful arrangement is [1,2]:
    - perm[1] = 1 is divisible by i = 1
    - perm[2] = 2 is divisible by i = 2
The second beautiful arrangement is [2,1]:
    - perm[1] = 2 is divisible by i = 1
    - i = 2 is divisible by perm[2] = 1
```

Example 2:

```
Input: n = 1
Output: 1
```

Constraints:

- `1 <= n <= 15`

SOLUTIONS (PYTHON 3)

Solution 1: Backtracking

> **How to think about it**
>
> Count permutations where value j at position i divides or is divided by i. Full 15! search is impossible, but few values fit each position. Precompute the legal values per position, then backtrack by position while marking used numbers. Reaching n+1 counts one arrangement. The divisibility lists keep the search inside the feasible set.

Assign unused numbers to each position when the divisibility condition holds.

Python 3

```python
class Solution:
    def countArrangement(self, n: int) -> int:
        def dfs(i):
            nonlocal ans, n
            if i == n + 1:
                ans += 1
                return
            for j in match[i]:
                if not vis[j]:
                    vis[j] = True
                    dfs(i + 1)
                    vis[j] = False

        ans = 0
        vis = [False] * (n + 1)
        match = defaultdict(list)
        for i in range(1, n + 1):
            for j in range(1, n + 1):
                if j % i == 0 or i % j == 0:
                    match[i].append(j)

        dfs(1)
        return ans
```

Complexity. Time: O(n!) in the worst case (pruned heavily in practice). Space: O(n^2) for the match table.

Solution 2: State Compression DP

> **How to think about it**
>
> Backtracking still expands a permutation tree and repeats the same unused-set at the same position. With n ≤ 15 the used set fits in 2^n bits. f[i] is the number of ways to reach used-set i. The pop-count is the next position; try each unused j that divides that position. f[0]=1 and the full mask is the answer. Each subset is filled once.

f[i] is the number of ways to form the chosen-number mask i.

Python 3 (written for this guide: the doocs page has no Python 3 version of this solution)

```python
class Solution:
    def countArrangement(self, n: int) -> int:
        size = 1 << n
        f = [0] * size                          # f[mask]: ways to fill the first popcount(mask) positions
with the numbers in mask
        f[0] = 1
        for mask in range(size):
            position = bin(mask).count("1") + 1
            for j in range(1, n + 1):
                if not (mask >> (j - 1)) & 1 and (position % j == 0 or j % position == 0):
                    f[mask | (1 << (j - 1))] += f[mask]
        return f[size - 1]
```

Complexity. Time: O(2^n * n). Space: O(2^n).

79. Word Search

Medium · Depth-First Search, Array, String, Backtracking, Matrix

leetcode.com/problems/word-search

★ **TOP 10 PROBLEM** in Backtracking / Subsets / Combinations / Permutations, Matrix / Grid Traversal: master this one first

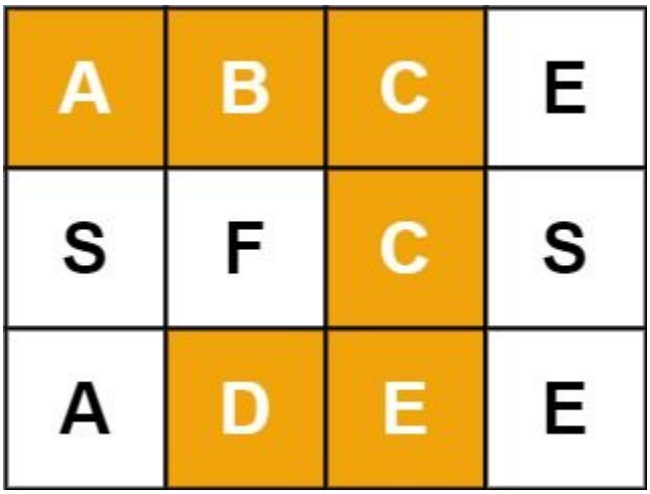
Also appears in pattern 18 Matrix / Grid Traversal

PROBLEM

Given an `m x n` grid of characters `board` and a string `word`, return `true` *if* `word` *exists in the grid*.

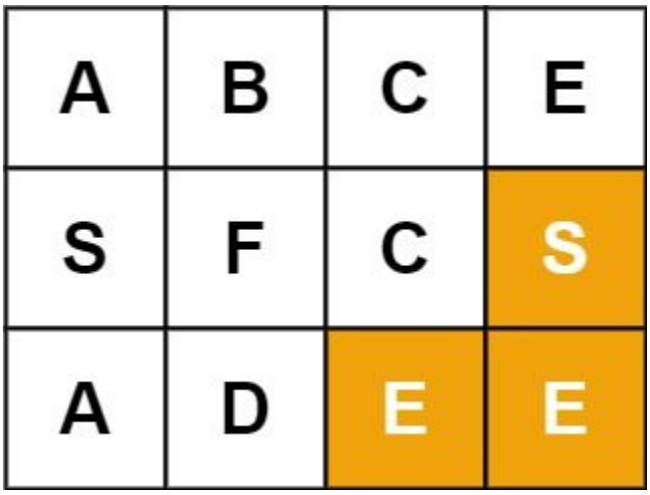
The word can be constructed from letters of sequentially adjacent cells, where adjacent cells are horizontally or vertically neighboring. The same letter cell may not be used more than once.

Example 1:



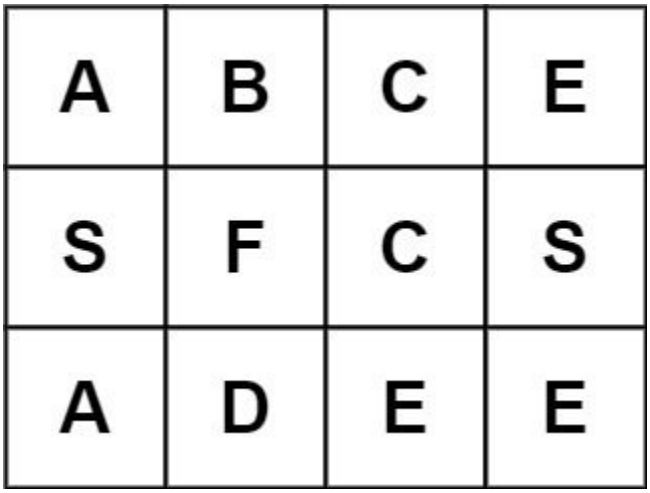
```
Input: board = [["A","B","C","E"],["S","F","C","S"],["A","D","E","E"]], word = "ABCCED"
Output: true
```

Example 2:



```
Input: board = [["A","B","C","E"],["S","F","C","S"],["A","D","E","E"]], word = "SEE"
Output: true
```

Example 3:



```
Input: board = [["A","B","C","E"],["S","F","C","S"],["A","D","E","E"]], word = "ABCB"
Output: false
```

Constraints:

- `m == board.length`
- `n = board[i].length`
- `1 <= m, n <= 6`
- `1 <= word.length <= 15`
- `board` and `word` consists of only lowercase and uppercase English letters.

Follow up: Could you use search pruning to make your solution faster with a larger `board`?

SOLUTION (PYTHON 3)

Solution 1: DFS (Backtracking)

How to think about it

From every cell, walk length-|word| paths and compare. At most 36 cells and |word| ≤ 15, unpruned search explodes. Match while walking, abort on mismatch, and never reuse a cell. Enumerate starts; dfs(i,j,k) means (i,j) should match word[k]. On match, write `'0'` to block re-entry, try four neighbors at k+1, then restore. Letters are never `'0'`, so no extra vis. Any successful start is enough.

We can enumerate each position (i, j) in the grid as the starting point of the search, and then start a depth-first search from the starting point. If we can search to the end of the word, it means the word exists, otherwise, it means the word does not exist.

Therefore, we design a function dfs(i, j, k), which represents whether we can successfully search from the (i, j) position of the grid, starting from the kth character of the word. The execution steps of the function dfs(i, j, k) are as follows:

- If k = |word|-1, it means that we have searched to the last character of the word. At this time, we only need to judge whether the character at the (i, j) position of the grid is equal to word[k]. If they are equal, it means the word exists, otherwise, it means the word does not exist. Whether the word exists or not, there is no need to continue to search, so return the result directly.
- Otherwise, if the word[k] character is not equal to the character at the (i, j) position of the grid, it means that the search failed this time, so return `false` directly.
- Otherwise, we temporarily store the character at the (i, j) position of the grid in c, and then modify the character at this position to a special character `'0'`, indicating that the character at this position has been used to prevent it from being reused in subsequent searches. Then we start from the up, down, left, and right directions of the (i, j) position to search for the k+1th character in the grid. If any direction is successful, it means the search is successful, otherwise, it means the search failed. At this time, we need to restore the character at the (i, j) position of the grid, that is, put c back to the

(i, j) position (backtracking).

In the main function, we enumerate each position (i, j) in the grid as the starting point. If calling dfs(i, j, 0) returns `true`, it means the word exists, otherwise, it means the word does not exist, so return `false`.

The time complexity is $O(m \times n \times 3^k)$, and the space complexity is $O(\min(m \times n, k))$. Here, m and n are the number of rows and columns of the grid, respectively; and k is the length of the string word.

Python 3

```
class Solution:
    def exist(self, board: List[List[str]], word: str) -> bool:
        def dfs(i: int, j: int, k: int) -> bool:
            if k == len(word) - 1:
                return board[i][j] == word[k]
            if board[i][j] != word[k]:
                return False
            c = board[i][j]
            board[i][j] = "0"
            for a, b in pairwise((-1, 0, 1, 0, -1)):
                x, y = i + a, j + b
                ok = 0 <= x < m and 0 <= y < n and board[x][y] != "0"
                if ok and dfs(x, y, k + 1):
                    return True
            board[i][j] = c
            return False

        m, n = len(board), len(board[0])
        return any(dfs(i, j, 0) for i in range(m) for j in range(n))
```

131. Palindrome Partitioning

Medium · String, Dynamic Programming, Backtracking

leetcode.com/problems/palindrome-partitioning

★ **TOP 10 PROBLEM** in Backtracking / Subsets / Combinations / Permutations: master this one first

PROBLEM

Given a string `s`, partition `s` such that every substring of the partition is a **palindrome**. Return *all possible palindrome partitioning of* `s`.

Example 1:

```
Input: s = "aab"
Output: [["a","a","b"],["aa","b"]]
```

Example 2:

```
Input: s = "a"
Output: [["a"]]
```

Constraints:

- `1 <= s.length <= 16`
- `s` contains only lowercase English letters.

SOLUTION (PYTHON 3)

Solution 1: Preprocessing + DFS (Backtracking)

How to think about it

List every way to cut s into palindromic pieces. n≤ 16, so at most 2^{n-1} partitions; backtracking is fine. Checking palindromes at each cut rescans the same spans. Precompute f[i][j] whether s[i..j] is a palindrome, then try the next cut only when f[i][j] is true.

We can use dynamic programming to preprocess whether any substring in the string is a palindrome, i.e., f[i][j] indicates whether the substring s[i..j] is a palindrome.

Next, we design a function dfs(i), which represents starting from the i-th character of the string and partitioning it into several palindromic substrings, with the current partition scheme being t.

If i = |s|, it means the partitioning is complete, and we add t to the answer array and then return.

Otherwise, we can start from i and enumerate the end position j from small to large. If s[i..j] is a palindrome, we add s[i..j] to t, then continue to recursively call dfs(j+1). When backtracking, we need to pop s[i..j].

The time complexity is $O(n \times 2^n)$, and the space complexity is $O(n^2)$. Here, n is the length of the string.

Python 3

```python
class Solution:
    def partition(self, s: str) -> List[List[str]]:
        def dfs(i: int):
            if i == n:
                ans.append(t[:])
                return
            for j in range(i, n):
                if f[i][j]:
                    t.append(s[i : j + 1])
                    dfs(j + 1)
                    t.pop()

        n = len(s)
        f = [[True] * n for _ in range(n)]
        for i in range(n - 1, -1, -1):
            for j in range(i + 1, n):
                f[i][j] = s[i] == s[j] and f[i + 1][j - 1]
        ans = []
        t = []
        dfs(0)
        return ans
```

                ways[end] += ways[start]
    return ways[n]
```

93. Restore IP Addresses

Medium · String, Backtracking

leetcode.com/problems/restore-ip-addresses

PROBLEM

A **valid IP address** consists of exactly four integers separated by single dots. Each integer is between `0` and `255` (**inclusive**) and cannot have leading zeros.

- For example, `"0.1.2.201"` and `"192.168.1.1"` are **valid** IP addresses, but `"0.011.255.245"`, `"192.168.1.312"` and `"192.168@1.1"` are **invalid** IP addresses.

Given a string `s` containing only digits, return *all possible valid IP addresses that can be formed by inserting dots into* `s`. You are **not** allowed to reorder or remove any digits in `s`. You may return the valid IP addresses in **any** order.

Example 1:

```
Input: s = "25525511135"
Output: ["255.255.11.135","255.255.111.35"]
```

Example 2:

```
Input: s = "0000"
Output: ["0.0.0.0"]
```

Example 3:

```
Input: s = "101023"
Output: ["1.0.10.23","1.0.102.3","10.1.0.23","10.10.2.3","101.0.2.3"]
```

Constraints:

- `1 <= s.length <= 20`
- `s` consists of digits only.

SOLUTION (PYTHON 3)

Solution 1: DFS

> **How to think about it**
>
> An IP is exactly four segments, each 0– 255 with no leading zeros. n ≤ 20, so enumerating three cuts works, but leading zeros, overflow, and segment count scatter across nested loops. Backtracking is the natural shape: from index i, try 1–3 digits as the next segment, and recurse if valid. Collect only when we have four segments and the string is consumed; stop if we already have four or run past the end. Prune illegal prefixes early.

We define a function dfs(i), which represents the list of IP addresses that can be formed starting from the ith position of string s.

The execution steps of function dfs(i) are as follows:

If i is greater than or equal to the length of string s, it means that we have completed the splicing of four segments of the IP address. At this point, we need to check whether it meets the requirements of the four segments of the IP address. If it does, add the current IP to the answer.

If i is less than the length of string s, it means that we still need to splice a segment of the IP address. At this point, we need to determine the value of this segment of the IP address. If the value is greater than 255, or the current position i is 0 and the value of several positions after i is greater than 0, it means that it does not meet the requirements, so we return directly. Otherwise, add it to the IP address list, and continue to search for the next segment of the IP address.

The time complexity is $O(n \times 3^4)$, and the space complexity is $O(n)$. Here, n is the length of string s.

Python 3

```python
class Solution:
    def restoreIpAddresses(self, s: str) -> List[str]:
        def check(i: int, j: int) -> int:
            if s[i] == "0" and i != j:
                return False
            return 0 <= int(s[i : j + 1]) <= 255

        def dfs(i: int):
            if i >= n and len(t) == 4:
                ans.append(".".join(t))
                return
            if i >= n or len(t) >= 4:
                return
            for j in range(i, min(i + 3, n)):
                if check(i, j):
                    t.append(s[i : j + 1])
                    dfs(j + 1)
                    t.pop()

        n = len(s)
        ans = []
        t = []
        dfs(0)
        return ans
```

PATTERN 15 · BACKTRACKING / SUBSETS / COMBINATIONS / PERMUTATIONS · PROBLEM 16 OF 20

89. Gray Code

Medium · Bit Manipulation, Math, Backtracking

leetcode.com/problems/gray-code

Also appears in pattern 27 Bit Manipulation

PROBLEM

An **n-bit gray code sequence** is a sequence of 2^n integers where:

- Every integer is in the **inclusive** range `[0, 2^n - 1]`,
- The first integer is `0`,
- An integer appears **no more than once** in the sequence,
- The binary representation of every pair of **adjacent** integers differs by **exactly one bit**, and
- The binary representation of the **first** and **last** integers differs by **exactly one bit**.

Given an integer `n`, return *any valid **n-bit gray code sequence***.

Example 1:

```
Input: n = 2
Output: [0,1,3,2]
Explanation:
The binary representation of [0,1,3,2] is [00,01,11,10].
- 00 and 01 differ by one bit
- 01 and 11 differ by one bit
- 11 and 10 differ by one bit
- 10 and 00 differ by one bit
[0,2,3,1] is also a valid gray code sequence, whose binary representation is [00,10,11,01].
- 00 and 10 differ by one bit
- 10 and 11 differ by one bit
- 11 and 01 differ by one bit
- 01 and 00 differ by one bit
```

Example 2:

```
Input: n = 1
Output: [0,1]
```

Constraints:

- `1 <= n <= 16`

SOLUTION (PYTHON 3)

Solution 1: Binary to Gray Code Conversion

> **How to think about it**
>
> The first idea is backtrack: start at 0, flip an unused bit each time, until 2^n numbers. Correct, and n ≤ 16 would pass, but we must dedup and also make first and last differ by one bit. The bottleneck is maintaining "adjacent codes differ by one bit" by hand. Binary-reflected Gray code has a closed form: i maps to i xor (i ≫ 1). That formula already guarantees adjacent integers differ by one bit, and 0 versus 2^n - 1 differs only in the top bit. So just map [0, 2^n) — no search.

Gray code is a type of encoding method that we often encounter in engineering. Its basic feature is that only one bit of binary number is different between any two adjacent codes.

The rule for converting binary code to binary Gray code is to keep the highest bit of the binary code as the highest bit of the Gray code, and the second highest bit of the Gray code is the XOR of the highest bit and the second highest bit of the binary code. The calculation of the remaining bits of the Gray code is similar to the second highest bit.

Assume that a binary number is represented as $B_{n-1}B_{n-2}...B_2B_1B_0$, and its Gray code is represented as $G_{n-1}G_{n-2}...G_2G_1G_0$. The highest bit is retained, so $G_{n-1} = B_{n-1}$; and the other bits $G_i = B_{i+1}$ xor B_i, where i=0,1,2..,n-2.

Therefore, for an integer x, we can use the function gray(x) to get its Gray code:

```
int gray(x) {
    return x ^ (x >> 1);
}
```

We directly map the integers $[0,..2^n - 1]$ to the corresponding Gray codes to get the answer array.

The time complexity is $O(2^n)$, where n is the integer given in the problem. Ignoring the space consumption of the answer, the space complexity is O(1).

Python 3

```
class Solution:
    def grayCode(self, n: int) -> List[int]:
        return [i ^ (i >> 1) for i in range(1 << n)]
```

    return sequence
```

254. Factor Combinations

Medium · Backtracking, Prime Factorization

leetcode.com/problems/factor-combinations

PROBLEM

Numbers can be regarded as the product of their factors.

- For example, `8 = 2 x 2 x 2 = 2 x 4`.

Given an integer `n`, return *all possible combinations of its factors*. You may return the answer in **any order**.

Note that the factors should be in the range `[2, n - 1]`.

Example 1:

```
Input: n = 1
Output: []
```

Example 2:

```
Input: n = 12
Output: [[2,6],[3,4],[2,2,3]]
```

Example 3:

```
Input: n = 37
Output: []
```

Constraints:

- $1 <= n <= 10^7$

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Factorizations of n with at least two factors should be generated in nondecreasing order to avoid permutations. Enumerate factors from the current minimum i up to √n. dfs(n,i) records the chosen factors plus leftover n, then tries each j≥ i that divides n and recurses on n/j.

Python 3

```python
class Solution:
    def getFactors(self, n: int) -> List[List[int]]:
        def dfs(n, i):
            if t:
                ans.append(t + [n])
            j = i
            while j * j <= n:
                if n % j == 0:
                    t.append(j)
                    dfs(n // j, j)
                    t.pop()
                j += 1

        t = []
        ans = []
        dfs(n, 2)
        return ans
```

Complexity. Time: about O(F * sqrt(n)), F = number of factorisations. Space: O(log n) recursion depth (plus the answers).

698. Partition to K Equal Sum Subsets

Medium · Bit Manipulation, Memoization, Array, Dynamic Programming, Backtracking, Bitmask

leetcode.com/problems/partition-to-k-equal-sum-subsets

★ **TOP 10 PROBLEM** in Dynamic Programming - Knapsack Style: master this one first

Also appears in pattern 28 Dynamic Programming - Knapsack Style

PROBLEM

Given an integer array `nums` and an integer `k`, return `true` if it is possible to divide this array into `k` non-empty subsets whose sums are all equal.

Example 1:

```
Input: nums = [4,3,2,3,5,2,1], k = 4
Output: true
Explanation: It is possible to divide it into 4 subsets (5), (1, 4), (2,3), (2,3) with equal sums.
```

Example 2:

```
Input: nums = [1,2,3,4], k = 3
Output: false
```

Constraints:

- `1 <= k <= nums.length <= 16`
- `1 <= nums[i] <= 10^4`
- The frequency of each element is in the range `[1, 4]`.

SOLUTIONS (PYTHON 3)

Solution 1: DFS + Pruning

How to think about it

Partition into k equal-sum subsets. If the total is not divisible by k, fail. n≤ 16 allows DFS if we cut symmetric fillings. Target s, array cur holds bucket sums. Place numbers largest-first: skip a bucket that would exceed s or that matches the previous bucket. Success when every number is placed.

According to the problem description, we need to partition the array nums into k subsets such that the sum of each subset is equal. Therefore, we first sum all the elements in nums. If the total sum cannot be divided by k, it means we cannot partition the array into k subsets, and we return false early.

If the total sum can be divided by k, let's denote the expected sum of each subset as s. Then, we create an array cur of length k to represent the current sum of each subset.

We sort the array nums in descending order (to reduce the number of searches), and then start from the first element, trying to add it to each subset in cur one by one. If adding nums[i] to a subset cur[j] makes the subset's sum exceed s, it means it cannot be placed in that subset, and we can skip it. Additionally, if cur[j] is equal to cur[j - 1], it means we have already completed the search for cur[j - 1], and we can skip the current search.

If we can add all elements to cur, it means we can partition the array into k subsets, and we return true.

Python 3

```python
class Solution:
    def canPartitionKSubsets(self, nums: List[int], k: int) -> bool:
        def dfs(i: int) -> bool:
            if i == len(nums):
                return True
            for j in range(k):
                if j and cur[j] == cur[j - 1]:
                    continue
                cur[j] += nums[i]
                if cur[j] <= s and dfs(i + 1):
                    return True
                cur[j] -= nums[i]
            return False

        s, mod = divmod(sum(nums), k)
        if mod:
            return False
        cur = [0] * k
        nums.sort(reverse=True)
        return dfs(0)
```

Complexity. Time: O(k^n) in the worst case (pruned in practice). Space: O(n + k).

Solution 2: State Compression + Memoization

> **How to think about it**
>
> Bucket DFS can still revisit the same used set. A mask state plus the current bucket remainder t memoizes the search. Sorting ascending lets us break once t+v>s.

Similar to Solution 1, we first check whether the array nums can be partitioned into k subsets. If it cannot be divided by k, we directly return false.

Let s be the expected sum of each subset, and let state represent the current partitioning state of the elements. For the i-th number, if the i-th bit of state is 0, it means the i-th element has not been partitioned.

Our goal is to form k subsets with a sum of s from all elements. Let t be the current sum of the subset. When the i-th element is not partitioned:

- If t + nums[i] > s, it means the i-th element cannot be added to the current subset. Since we sort the array nums in ascending order, all elements from position i onwards cannot be added to the current subset, and we directly return false.
- Otherwise, add the i-th element to the current subset, change the state to state | 2^i, and continue searching for unpartitioned elements. Note that if t + nums[i] = s, it means we can form a subset with a sum of s. The next step is to reset t to zero (which can be achieved by (t + nums[i]) mod s) and continue partitioning the next subset.

To avoid repeated searches, we use an array f of length 2^n to record the search results for each state. The array f has three possible values:

- `0` indicates that the current state has not been searched yet;
- `-1`: indicates that the current state cannot be partitioned into k subsets;
- `1`: indicates that the current state can be partitioned into k subsets.

The time complexity is $O(n \times 2^n)$, and the space complexity is $O(2^n)$. Here, n represents the length of the array nums. For each state, we need to traverse the array nums, which has a time complexity of O(n). The total number of states is 2^n, so the overall time complexity is $O(n \times 2^n)$.

Python 3

```python
class Solution:
    def canPartitionKSubsets(self, nums: List[int], k: int) -> bool:
        @cache
        def dfs(state, t):
            if state == mask:
                return True
            for i, v in enumerate(nums):
                if (state >> i) & 1:
                    continue
                if t + v > s:
                    break
                if dfs(state | 1 << i, (t + v) % s):
                    return True
            return False

        s, mod = divmod(sum(nums), k)
        if mod:
            return False
        nums.sort()
        mask = (1 << len(nums)) - 1
        return dfs(0, 0)
```

Solution 3: Dynamic Programming

> **How to think about it**
>
> Memoization is top-down. Bottom-up, f[i] says whether mask i is reachable and cur[i] is the current bucket fill. Try unused j to set f[i|2^j] without recursion.

We can use dynamic programming to solve this problem.

We define f[i] to represent whether there exists k subsets that meet the requirements when the current selected numbers' state is i. Initially, f[0] = true, and the answer is f[2^n - 1], where n is the length of the array nums. Additionally, we define cur[i] to represent the sum of the last subset when the current selected numbers' state is i.

We enumerate the states i in the range [0, 2^n]. For each state i, if f[i] is false, we skip it. Otherwise, we enumerate any number nums[j] in the array nums. If cur[i] + nums[j] > s, we break the enumeration loop because the subsequent numbers are larger and cannot be placed in the current subset. Otherwise, if the j-th bit of the binary representation of i is 0, it means the current nums[j] has not been selected. We can place it in the current subset, change the state to i | 2^j, update cur[i | 2^j] = (cur[i] + nums[j]) mod s, and set f[i | 2^j] = true.

Finally, we return f[2^n - 1].

The time complexity is $O(n \times 2^n)$, and the space complexity is $O(2^n)$. Here, n represents the length of the array nums.

Python 3

```python
class Solution:
    def canPartitionKSubsets(self, nums: List[int], k: int) -> bool:
        s = sum(nums)
        if s % k:
            return False
        s //= k
        nums.sort()
        n = len(nums)
        f = [False] * (1 << n)
        cur = [0] * (1 << n)
        f[0] = True
        for i in range(1 << n):
            if not f[i]:
                continue
            for j in range(n):
                if cur[i] + nums[j] > s:
                    break
                if (i >> j & 1) == 0:
                    if not f[i | 1 << j]:
                        cur[i | 1 << j] = (cur[i] + nums[j]) % s
                        f[i | 1 << j] = True
        return f[-1]
```

51. N-Queens

Hard · Array, Backtracking, Algorithm X

leetcode.com/problems/n-queens

★ **TOP 10 PROBLEM** in Backtracking / Subsets / Combinations / Permutations: master this one first

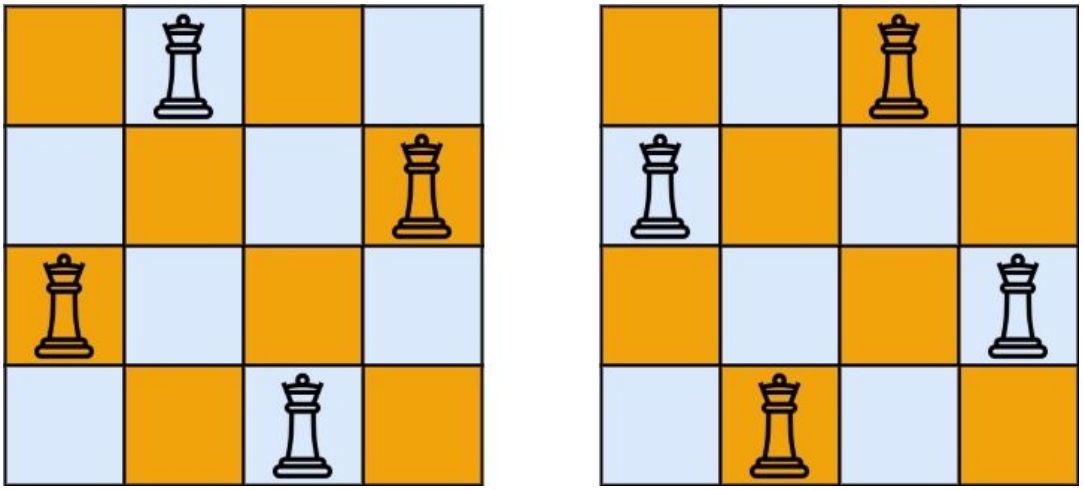
PROBLEM

The **n-queens** puzzle is the problem of placing `n` queens on an `n x n` chessboard such that no two queens attack each other.

Given an integer `n`, return *all distinct solutions to the **n-queens puzzle***. You may return the answer in **any order**.

Each solution contains a distinct board configuration of the n-queens' placement, where `'Q'` and `'.'` both indicate a queen and an empty space, respectively.

Example 1:



```
Input: n = 4
Output: [[".Q..","...Q","Q...","..Q."],["..Q.","Q...","...Q",".Q.."]]
Explanation: There exist two distinct solutions to the 4-queens puzzle as shown above
```

Example 2:

```
Input: n = 1
Output: [["Q"]]
```

Constraints:

- `1 <= n <= 9`

SOLUTION (PYTHON 3)

Solution 1: DFS (Backtracking)

How to think about it

The first idea is to try every column permutation: put the queen in row i at column p_i, then check diagonals. n ≤ 9, so 9! is searchable, but we only discover a conflict after the board is full, and we still have to build the string grid. The waste is placing everything, then validating. One queen per row is mandatory; conflicts are only the same column or the same diagonal. Column, i+j, and n-i+j can all be marked in O(1). So we DFS row by row: place and mark only when legal, then backtrack. The board g flips `'Q'`/`'.'` in lockstep; at row n we copy one answer.

We define three arrays col, dg, and udg to represent whether there is a queen in the column, the main diagonal, and the anti-diagonal, respectively. If there is a queen at position (i, j), then col[j], dg[i + j], and udg[n - i + j] are all 1. In addition, we use an array g to record the current state of the chessboard, where all elements in g are initially `'.'`.

Next, we define a function dfs(i), which represents placing queens starting from the ith row.

In dfs(i), if i = n, it means that we have completed the placement of all queens. We put the current g into the answer array and end the recursion.

Otherwise, we enumerate each column j of the current row. If there is no queen at position (i, j), that is, col[j], dg[i + j], and udg[n - i + j] are all 0, then we can place a queen, that is, change g[i][j] to `'Q'`, and set col[j], dg[i + j], and udg[n - i + j] to 1. Then we continue to search the next row, that is, call dfs(i + 1). After the recursion ends, we need to change g[i][j] back to `'.'` and set col[j], dg[i + j], and udg[n - i + j] to 0.

In the main function, we call dfs(0) to start recursion, and finally return the answer array.

The time complexity is $O(n^2 \times n!)$, and the space complexity is O(n). Here, n is the integer given in the problem.

Python 3

```python
class Solution:
    def solveNQueens(self, n: int) -> List[List[str]]:
        def dfs(i: int):
            if i == n:
                ans.append(["".join(row) for row in g])
                return
            for j in range(n):
                if col[j] + dg[i + j] + udg[n - i + j] == 0:
                    g[i][j] = "Q"
                    col[j] = dg[i + j] = udg[n - i + j] = 1
                    dfs(i + 1)
                    col[j] = dg[i + j] = udg[n - i + j] = 0
                    g[i][j] = "."

        ans = []
        g = [["."] * n for _ in range(n)]
        col = [0] * n
        dg = [0] * (n << 1)
        udg = [0] * (n << 1)
        dfs(0)
        return ans
```

37. Sudoku Solver

Hard · Array, Hash Table, Backtracking, Matrix, Algorithm X, Dancing Links

leetcode.com/problems/sudoku-solver

PROBLEM

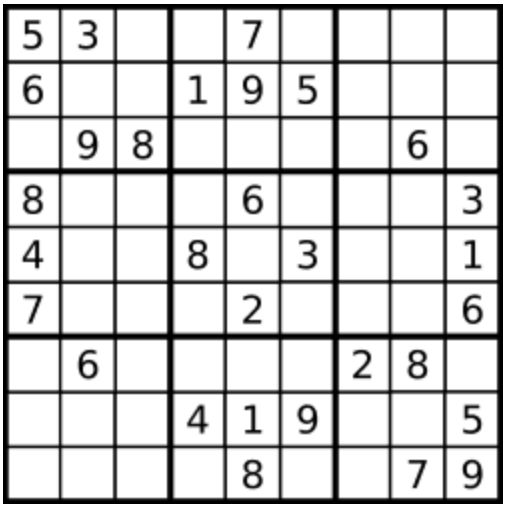
Write a program to solve a Sudoku puzzle by filling the empty cells.

A sudoku solution must satisfy **all of the following rules**:

1. Each of the digits `1-9` must occur exactly once in each row.
2. Each of the digits `1-9` must occur exactly once in each column.
3. Each of the digits `1-9` must occur exactly once in each of the 9 `3x3` sub-boxes of the grid.

The `'.'` character indicates empty cells.

Example 1:



```
Input: board = [["5","3",".",".","7",".",".",".","."],["6",".",".","1","9","5",".",".","."],[".","9","8",".",".",".",".",".","6","."],["8",".",".",".","6",".",".",".","3"],["4",".",".","8",".","3",".",".","1"],["7",".",".",".","2",".",".",".","6"],[".","6",".",".",".",".","2","8","."],[".",".",".","4","1","9",".",".","5"],[".",".",".",".","8",".",".","7","9"]]
Output: [["5","3","4","6","7","8","9","1","2"],["6","7","2","1","9","5","3","4","8"],["1","9","8","3","4","2","5","6","7"],["8","5","9","7","6","1","4","2","3"],["4","2","6","8","5","3","7","9","1"],["7","1","3","9","2","4","8","5","6"],["9","6","1","5","3","7","2","8","4"],["2","8","7","4","1","9","6","3","5"],["3","4","5","2","8","6","1","7","9"]]
Explanation: The input board is shown above and the only valid solution is shown below:
```

Constraints:

- `board.length == 9`
- `board[i].length == 9`
- `board[i][j]` is a digit or `'.'`.
- It is **guaranteed** that the input board has only one solution.

SOLUTION (PYTHON 3)

Solution 1: Backtracking

> **How to think about it**
>
> There can be dozens of empty cells and 9 choices each, so brute force is impossible. We must stop as soon as a row, column, or box is violated. As in Valid Sudoku, the bottleneck is repeatedly asking whether a digit is already used. Record the given digits in row, col, and block, then search only the empty-cell list t. dfs(k) fills the k-th empty cell: try each unused v, write it, and recurse. When a solution is found, ok cuts off further tries. Backtracking restores the occupancy flags; digits on the successful path stay on the board.

We use arrays row, col, and box to record whether each number has appeared in each row, each column, and each 3x3 sub-box, respectively. If the number i has appeared in row r, column c, or the b-th 3x3 sub-box, then row[r][i], col[c][i], and box[b][i] are all set to true.

We iterate over every empty cell in the board and enumerate the possible numbers v that can be filled in. If v has not appeared in the current row, column, or 3x3 sub-box, we can try filling in v and continue searching for the next empty cell. If we reach the end and all cells are filled, it means we have found a valid solution.

Python 3

```python
class Solution:
    def solveSudoku(self, board: List[List[str]]) -> None:
        def dfs(k):
            nonlocal ok
            if k == len(t):
                ok = True
                return
            i, j = t[k]
            for v in range(9):
                if row[i][v] == col[j][v] == block[i // 3][j // 3][v] == False:
                    row[i][v] = col[j][v] = block[i // 3][j // 3][v] = True
                    board[i][j] = str(v + 1)
                    dfs(k + 1)
                    row[i][v] = col[j][v] = block[i // 3][j // 3][v] = False
                if ok:
                    return

        row = [[False] * 9 for _ in range(9)]
        col = [[False] * 9 for _ in range(9)]
        block = [[[False] * 9 for _ in range(3)] for _ in range(3)]
        t = []
        ok = False
        for i in range(9):
            for j in range(9):
                if board[i][j] == '.':
                    t.append((i, j))
                else:
                    v = int(board[i][j]) - 1
                    row[i][v] = col[j][v] = block[i // 3][j // 3][v] = True
        dfs(0)
```

Complexity. Time: O(9^m), m = number of empty cells (pruned heavily in practice). Space: O(m).

PATTERN 16 · GRAPH DFS · PROBLEM 1 OF 20

733. Flood Fill

Easy · Depth-First Search, Breadth-First Search, Array, Matrix

leetcode.com/problems/flood-fill

★ **TOP 10 PROBLEM** in Graph DFS, Matrix / Grid Traversal: master this one first

Also appears in pattern 18 Matrix / Grid Traversal

PROBLEM

You are given an image represented by an `m x n` grid of integers `image`, where `image[i][j]` represents the pixel value of the image. You are also given three integers `sr`, `sc`, and `color`. Your task is to perform a **flood fill** on the image starting from the pixel `image[sr][sc]`.

To perform a **flood fill**:

1. Begin with the starting pixel and change its color to `color`.
2. Perform the same process for each pixel that is **directly adjacent** (pixels that share a side with the original pixel, either horizontally or vertically) and shares the **same color** as the starting pixel.
3. Keep **repeating** this process by checking neighboring pixels of the *updated* pixels and modifying their color if it matches the original color of the starting pixel.
4. The process **stops** when there are **no more** adjacent pixels of the original color to update.

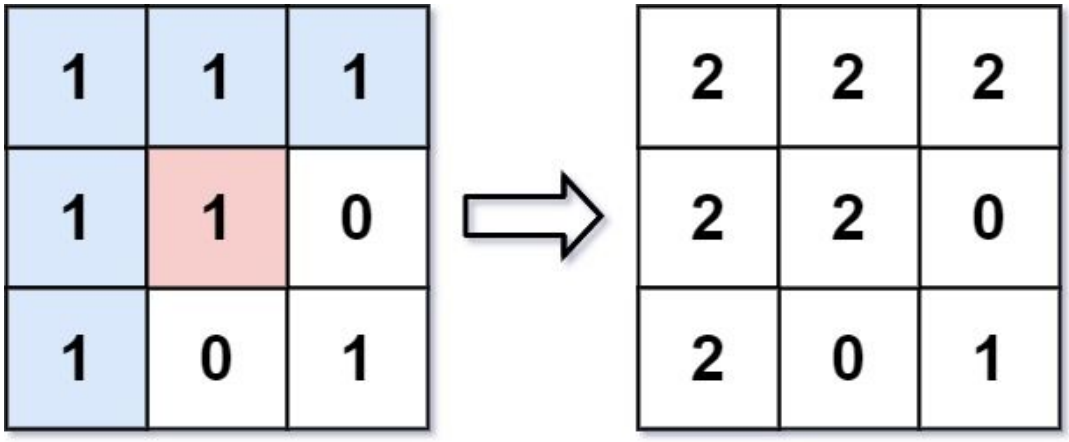
Return the **modified** image after performing the flood fill.

Example 1:

Input: image = [[1,1,1],[1,1,0],[1,0,1]], sr = 1, sc = 1, color = 2

Output: [[2,2,2],[2,2,0],[2,0,1]]

Explanation:



From the center of the image with position `(sr, sc) = (1, 1)` (i.e., the red pixel), all pixels connected by a path of the same color as the starting pixel (i.e., the blue pixels) are colored with the new color.

Note the bottom corner is **not** colored 2, because it is not horizontally or vertically connected to the starting pixel.

Example 2:

Input: image = [[0,0,0],[0,0,0]], sr = 0, sc = 0, color = 0

Output: [[0,0,0],[0,0,0]]

Explanation:

The starting pixel is already colored with 0, which is the same as the target color. Therefore, no changes are made to the image.

Constraints:

- `m == image.length`
- `n == image[i].length`
- `1 <= m, n <= 50`
- `0 <= image[i][j], color < 2^16`
- `0 <= sr < m`
- `0 <= sc < n`

SOLUTIONS (PYTHON 3)

Solution 1: DFS

How to think about it

Recolor the 4-connected component of the start pixel. The grid is small. If the start already has the target color we must not recurse, or we loop. The component is a grid graph. DFS recolors every neighbor that still equals the original color oc; the new color is the visited mark. Record oc and recurse from (sr,sc) only when it differs from color.

We denote the initial pixel's color as oc. If oc is not equal to the target color color, we start a depth-first search from (sr, sc) to change the color of all eligible pixels to the target color.

The time complexity is O(m × n), and the space complexity is O(m × n). Here, m and n are the number of rows and columns of the 2D array image, respectively.

Python 3

```
class Solution:
    def floodFill(
        self, image: List[List[int]], sr: int, sc: int, color: int
    ) -> List[List[int]]:
        def dfs(i: int, j: int):
            image[i][j] = color
            for a, b in pairwise(dirs):
                x, y = i + a, j + b
                if 0 <= x < len(image) and 0 <= y < len(image[0]) and image[x][y] == oc:
                    dfs(x, y)

        oc = image[sr][sc]
        if oc != color:
            dirs = (-1, 0, 1, 0, -1)
            dfs(sr, sc)
        return image
```

Solution 2: BFS

How to think about it

Solution 1 is recursive; a large component uses O(mn) stack. The same flood can proceed level by level. BFS from the start: pop a pixel, recolor neighbors that still equal oc, and enqueue them. Same asymptotics, no call stack.

We first check if the initial pixel's color is equal to the target color. If it is, we return the original image directly. Otherwise, we can use the breadth-first search method, starting from (sr, sc), to change the color of all eligible pixels to the target color.

Specifically, we define a queue q and add the initial pixel (sr, sc) to the queue. Then, we continuously take pixels (i, j) from the queue, change their color to the target color, and add the pixels in the four directions (up, down, left, right) that have the same original color as the initial pixel to the queue. When the queue is empty, we have completed the flood fill.

The time complexity is O(m × n), and the space complexity is O(m × n). Here, m and n are the number of rows and columns of the 2D array image, respectively.

Python 3

```python
class Solution:
    def floodFill(
        self, image: List[List[int]], sr: int, sc: int, color: int
    ) -> List[List[int]]:
        if image[sr][sc] == color:
            return image
        q = deque([(sr, sc)])
        oc = image[sr][sc]
        image[sr][sc] = color
        dirs = (-1, 0, 1, 0, -1)
        while q:
            i, j = q.popleft()
            for a, b in pairwise(dirs):
                x, y = i + a, j + b
                if 0 <= x < len(image) and 0 <= y < len(image[0]) and image[x][y] == oc:
                    q.append((x, y))
                    image[x][y] = color
        return image
```

PATTERN 16 · GRAPH DFS · PROBLEM 2 OF 20

200. Number of Islands

Medium · Depth-First Search, Breadth-First Search, Union Find, Array, Matrix

leetcode.com/problems/number-of-islands

★ **TOP 10 PROBLEM** in Graph DFS, Matrix / Grid Traversal: master this one first

Also appears in pattern 18 Matrix / Grid Traversal

PROBLEM

Given an `m x n` 2D binary grid `grid` which represents a map of `'1'`s (land) and `'0'`s (water), return *the number of islands*.

An **island** is surrounded by water and is formed by connecting adjacent lands horizontally or vertically. You may assume all four edges of the grid are all surrounded by water.

Example 1:

```
Input: grid = [
  ["1","1","1","1","0"],
  ["1","1","0","1","0"],
  ["1","1","0","0","0"],
  ["0","0","0","0","0"]
]
Output: 1
```

Example 2:

```
Input: grid = [
  ["1","1","0","0","0"],
  ["1","1","0","0","0"],
  ["0","0","1","0","0"],
  ["0","0","0","1","1"]
]
Output: 3
```

Constraints:

- `m == grid.length`
- `n == grid[i].length`
- `1 <= m, n <= 300`
- `grid[i][j]` is `'0'` or `'1'`.

SOLUTIONS (PYTHON 3)

Solution 1: DFS

How to think about it

Counting every cell with value 1 as its own island would double-count 4-connected land. With m,n ≤ 300, a full scan is acceptable, but each connected component must be cleared in one search. Adjacent land cells form one component, so a DFS from any unseen land cell covers the whole island. We scan the grid, start DFS at each 1, rewrite visited land to 0, and increment the answer once per search.

We can use depth-first search (DFS) to traverse each island. We iterate through each cell (i, j) in the grid. If the cell's value is '1', it means we have found a new island. We can start a DFS from this cell, marking all connected land cells as '0' to avoid duplicate counting. Each time we find a new island, we increment the island count by 1.

The time complexity is O(m × n), and the space complexity is O(m × n). Where m and n are the number of rows and columns in the grid, respectively.

Python 3

```
class Solution:
    def numIslands(self, grid: List[List[str]]) -> int:
        def dfs(i, j):
            grid[i][j] = '0'
            for a, b in pairwise(dirs):
                x, y = i + a, j + b
                if 0 <= x < m and 0 <= y < n and grid[x][y] == '1':
                    dfs(x, y)

        ans = 0
        dirs = (-1, 0, 1, 0, -1)
        m, n = len(grid), len(grid[0])
        for i in range(m):
            for j in range(n):
                if grid[i][j] == '1':
                    dfs(i, j)
                    ans += 1
        return ans
```

Solution 2: BFS

> **How to think about it**
>
> Solution 1 already clears each component with an explicit stack. The same 4-connectivity can be expanded with a queue. The scan order matches Solution 1. The extra space is still the size of the frontier.

We can also use breadth-first search (BFS) to traverse each island. We iterate through each cell (i, j) in the grid. If the cell's value is '1', it means we have found a new island. We can start a BFS from this cell, marking all connected land cells as '0' to avoid duplicate counting. Each time we find a new island, we increment the island count by 1.

The specific BFS process is as follows:

1. Enqueue the starting cell (i, j) and mark its value as '0'.
2. While the queue is not empty, perform the following operations:
   - Dequeue a cell p.
   - Iterate through the four adjacent cells (x, y) of p. If (x, y) is within the grid bounds and its value is '1', enqueue it and mark its value as '0'.

The time complexity is O(m × n), and the space complexity is O(m × n). Where m and n are the number of rows and columns in the grid, respectively.

Python 3

```
class Solution:
    def numIslands(self, grid: List[List[str]]) -> int:
        def bfs(i, j):
            grid[i][j] = '0'
            q = deque([(i, j)])
            while q:
                i, j = q.popleft()
                for a, b in pairwise(dirs):
                    x, y = i + a, j + b
                    if 0 <= x < m and 0 <= y < n and grid[x][y] == '1':
                        q.append((x, y))
                        grid[x][y] = 0

        ans = 0
        dirs = (-1, 0, 1, 0, -1)
        m, n = len(grid), len(grid[0])
        for i in range(m):
            for j in range(n):
                if grid[i][j] == '1':
                    bfs(i, j)
                    ans += 1
        return ans
```

Solution 3: Union-Find

> **How to think about it**
>
> If we want adjacency as an explicit partition, treat each land cell as a union-find node and union it with neighboring land. The number of islands is the number of components after the scan. Unions and finds are nearly linear; space remains proportional to the grid.

We can use the Union-Find data structure to solve this problem. We traverse each cell (i, j) in the grid, and if the cell's value is '1', we merge it with adjacent land cells. Finally, we count the number of distinct root nodes in the Union-Find structure, which represents the number of islands.

The time complexity is O(m × n × log (m × n)), and the space complexity is O(m × n). Where m and n are the number of rows and columns in the grid, respectively.

Python 3

```python
class Solution:
    def numIslands(self, grid: List[List[str]]) -> int:
        def find(x):
            if p[x] != x:
                p[x] = find(p[x])
            return p[x]

        dirs = (0, 1, 0)
        m, n = len(grid), len(grid[0])
        p = list(range(m * n))
        for i in range(m):
            for j in range(n):
                if grid[i][j] == '1':
                    for a, b in pairwise(dirs):
                        x, y = i + a, j + b
                        if x < m and y < n and grid[x][y] == '1':
                            p[find(i * n + j)] = find(x * n + y)
        return sum(
            grid[i][j] == '1' and i * n + j == find(i * n + j)
            for i in range(m)
            for j in range(n)
        )
```

Solution 4: Explicit Stack

> **How to think about it**
>
> Counting every cell with value 1 as its own island would double-count 4-connected land. With m,n ≤ 300, a full scan is acceptable, but each component must be cleared in one search. Recursing along a snake of 1000 land cells overflows the call stack, and a 300× 300 grid can hold that snake. Clearing an island does not need a return value. It only rewrites 4-connected 1s to 0. When a 1 is found, push it onto an explicit stack. Pop a cell and push each neighboring 1 after marking it. Each time a search starts, add one to the answer.

Scan every cell. When the value is `'1'`, flood the island with an explicit stack, rewrite connected land to `'0'`, and add one to the answer.

The time complexity is O(m × n), and the space complexity is O(m × n). Where m and n are the number of rows and columns in the grid, respectively.

Python 3

```
class Solution:
    def numIslands(self, grid: List[List[str]]) -> int:
        def flood(i: int, j: int):
            stk = [(i, j)]
            grid[i][j] = '0'
            while stk:
                i, j = stk.pop()
                for a, b in pairwise(dirs):
                    x, y = i + a, j + b
                    if 0 <= x < m and 0 <= y < n and grid[x][y] == '1':
                        grid[x][y] = '0'
                        stk.append((x, y))

        ans = 0
        dirs = (-1, 0, 1, 0, -1)
        m, n = len(grid), len(grid[0])
        for i in range(m):
            for j in range(n):
                if grid[i][j] == '1':
                    flood(i, j)
                    ans += 1
        return ans
```

PATTERN 16 · GRAPH DFS · PROBLEM 3 OF 20

695. Max Area of Island

Medium · Depth-First Search, Breadth-First Search, Union Find, Array, Matrix

leetcode.com/problems/max-area-of-island

★ **TOP 10 PROBLEM** in Graph DFS: master this one first

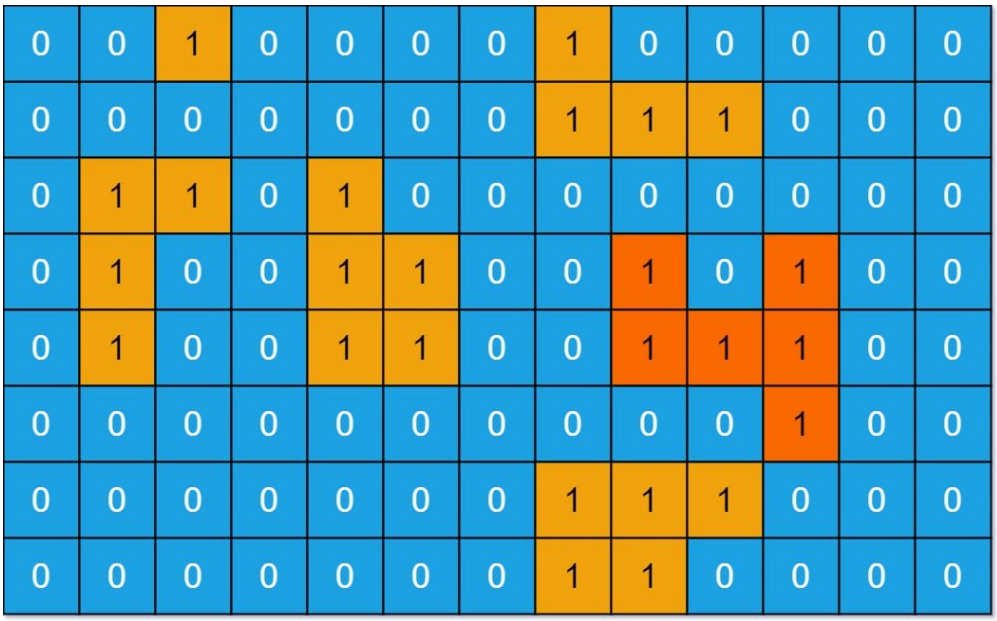
PROBLEM

You are given an `m x n` binary matrix `grid`. An island is a group of `1`'s (representing land) connected **4-directionally** (horizontal or vertical.) You may assume all four edges of the grid are surrounded by water.

The **area** of an island is the number of cells with a value `1` in the island.

Return *the maximum **area** of an island in* `grid`. If there is no island, return `0`.

Example 1:



```
Input: grid = [[0,0,1,0,0,0,0,1,0,0,0,0,0],[0,0,0,0,0,0,0,1,1,1,0,0,0],[0,1,1,0,1,0,0,0,0,0,0,0,0],[0,1,0,0,1,1,0,0,1,0,1,0,0],[0,1,0,0,1,1,0,0,1,1,1,0,0],[0,0,0,0,0,0,0,0,0,0,1,0,0],[0,0,0,0,0,0,0,1,1,1,0,0,0],[0,0,0,0,0,0,0,1,1,0,0,0,0]]
Output: 6
Explanation: The answer is not 11, because the island must be connected 4-directionally.
```

Example 2:

```
Input: grid = [[0,0,0,0,0,0,0,0]]
Output: 0
```

Constraints:

- `m == grid.length`
- `n == grid[i].length`
- `1 <= m, n <= 50`
- `grid[i][j]` is either `0` or `1`.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Area is the count of 4-connected land cells. Each cell is visited at most once. DFS a land cell, set it to 0, and add the four recursive calls. The answer is the maximum over all starts.

Python 3

```
class Solution:
    def maxAreaOfIsland(self, grid: List[List[int]]) -> int:
        def dfs(i: int, j: int) -> int:
            if grid[i][j] == 0:
                return 0
            ans = 1
            grid[i][j] = 0
            dirs = (-1, 0, 1, 0, -1)
            for a, b in pairwise(dirs):
                x, y = i + a, j + b
                if 0 <= x < m and 0 <= y < n:
                    ans += dfs(x, y)
            return ans

        m, n = len(grid), len(grid[0])
        return max(dfs(i, j) for i in range(m) for j in range(n))
```

Complexity. Time: O(m * n). Space: O(m * n) recursion in the worst case.

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

PATTERN 16 · GRAPH DFS · PROBLEM 4 OF 20

133. Clone Graph

Medium · Depth-First Search, Breadth-First Search, Graph, Hash Table

leetcode.com/problems/clone-graph

★ **TOP 10 PROBLEM** in Graph DFS: master this one first

PROBLEM

Given a reference of a node in a **connected** undirected graph.

Return a **deep copy** (clone) of the graph.

Each node in the graph contains a value (`int`) and a list (`List[Node]`) of its neighbors.

```
class Node {
    public int val;
    public List<Node> neighbors;
}
```

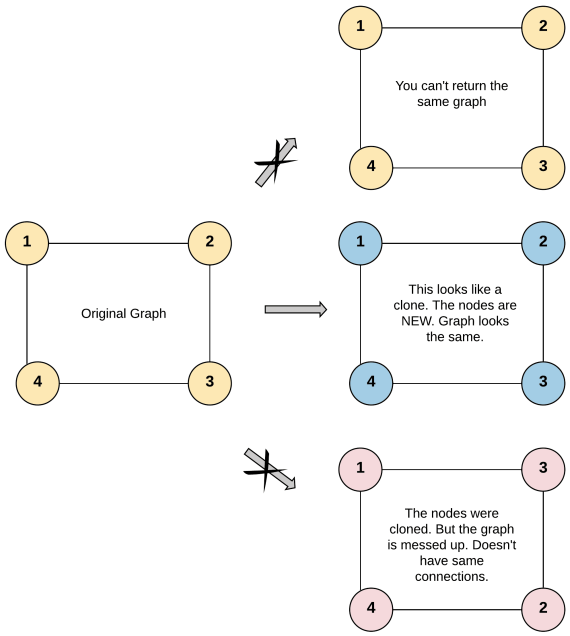
Test case format:

For simplicity, each node's value is the same as the node's index (1-indexed). For example, the first node with `val == 1`, the second node with `val == 2`, and so on. The graph is represented in the test case using an adjacency list.

An adjacency list is a collection of unordered **lists** used to represent a finite graph. Each list describes the set of neighbors of a node in the graph.

The given node will always be the first node with `val = 1`. You must return the **copy of the given node** as a reference to the cloned graph.

Example 1:



```
Input: adjList = [[2,4],[1,3],[2,4],[1,3]]
Output: [[2,4],[1,3],[2,4],[1,3]]
Explanation: There are 4 nodes in the graph.
1st node (val = 1)'s neighbors are 2nd node (val = 2) and 4th node (val = 4).
2nd node (val = 2)'s neighbors are 1st node (val = 1) and 3rd node (val = 3).
3rd node (val = 3)'s neighbors are 2nd node (val = 2) and 4th node (val = 4).
4th node (val = 4)'s neighbors are 1st node (val = 1) and 3rd node (val = 3).
```

Example 2:

```
Input: adjList = [[]]
Output: [[]]
Explanation: Note that the input contains one empty list. The graph consists of only one node with val = 1 and it does not have any neighbors.
```

Example 3:

```
Input: adjList = []
Output: []
Explanation: This an empty graph, it does not have any nodes.
```

Constraints:

- The number of nodes in the graph is in the range `[0, 100]`.
- `1 <= Node.val <= 100`
- `Node.val` is unique for each node.
- There are no repeated edges and no self-loops in the graph.
- The Graph is connected and all nodes can be visited starting from the given node.

SOLUTION (PYTHON 3)

Solution 1: Hash Table + DFS

How to think about it

Deep-copy a connected undirected graph; values are unique and n≤ 100. Copying values is not enough: neighbor pointers must refer to the new nodes, and cycles would loop if we recurse blindly. A map from original node to clone does it. On the first visit we create the clone and recurse on neighbors; a later visit returns the existing clone, which cuts cycles.

We use a hash table g to record the correspondence between each node in the original graph and its copy, and then perform depth-first search.

We define the function dfs(node), which returns the copy of the node. The process of dfs(node) is as follows:

- If node is null, then the return value of dfs(node) is null.
- If node is in g, then the return value of dfs(node) is g[node].
- Otherwise, we create a new node cloned and set the value of g[node] to cloned. Then, we traverse all the neighbor nodes nxt of node and add dfs(nxt) to the neighbor list of cloned.
- Finally, return cloned.

In the main function, we return dfs(node).

The time complexity is O(n), and the space complexity is O(n). Here, n is the number of nodes.

Python 3

```
"""
# Definition for a Node.
class Node:
    def __init__(self, val = 0, neighbors = None):
        self.val = val
        self.neighbors = neighbors if neighbors is not None else []
"""

from typing import Optional

class Solution:
    def cloneGraph(self, node: Optional["Node"]) -> Optional["Node"]:
        def dfs(node):
            if node is None:
                return None
            if node in g:
                return g[node]
            cloned = Node(node.val)
            g[node] = cloned
            for nxt in node.neighbors:
                cloned.neighbors.append(dfs(nxt))
            return cloned

        g = defaultdict()
        return dfs(node)
```

PATTERN 16 · GRAPH DFS · PROBLEM 5 OF 20

417. Pacific Atlantic Water Flow

Medium · Depth-First Search, Breadth-First Search, Array, Matrix

leetcode.com/problems/pacific-atlantic-water-flow

★ **TOP 10 PROBLEM** in Graph DFS: master this one first

Also appears in pattern 18 Matrix / Grid Traversal

PROBLEM

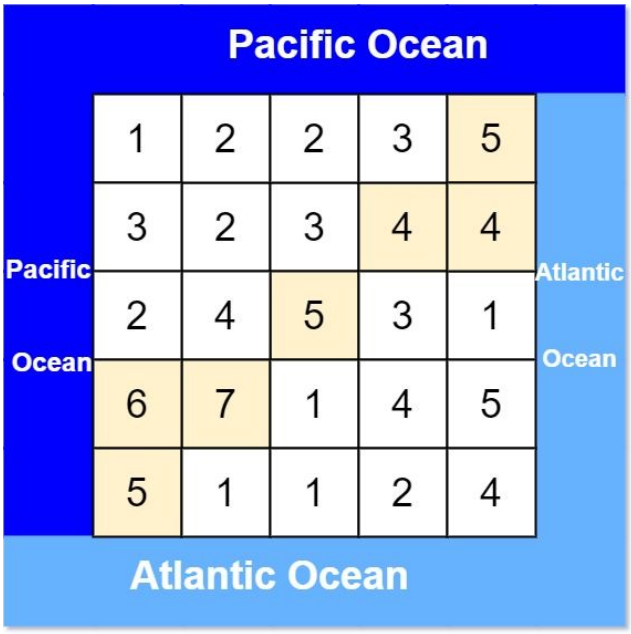
There is an `m x n` rectangular island that borders both the **Pacific Ocean** and **Atlantic Ocean**. The **Pacific Ocean** touches the island's left and top edges, and the **Atlantic Ocean** touches the island's right and bottom edges.

The island is partitioned into a grid of square cells. You are given an `m x n` integer matrix `heights` where `heights[r][c]` represents the **height above sea level** of the cell at coordinate `(r, c)`.

The island receives a lot of rain, and the rain water can flow to neighboring cells directly north, south, east, and west if the neighboring cell's height is **less than or equal to** the current cell's height. Water can flow from any cell adjacent to an ocean into the ocean.

Return *a **2D list** of grid coordinates* `result` *where* `result[i] = [r_i, c_i]` *denotes that rain water can flow from cell* `(r_i, c_i)` *to **both** the Pacific and Atlantic oceans*.

Example 1:



```
Input: heights = [[1,2,2,3,5],[3,2,3,4,4],[2,4,5,3,1],[6,7,1,4,5],[5,1,1,2,4]]
Output: [[0,4],[1,3],[1,4],[2,2],[3,0],[3,1],[4,0]]
Explanation: The following cells can flow to the Pacific and Atlantic oceans, as shown below:
[0,4]: [0,4] -> Pacific Ocean
       [0,4] -> Atlantic Ocean
[1,3]: [1,3] -> [0,3] -> Pacific Ocean
       [1,3] -> [1,4] -> Atlantic Ocean
[1,4]: [1,4] -> [1,3] -> [0,3] -> Pacific Ocean
       [1,4] -> Atlantic Ocean
[2,2]: [2,2] -> [1,2] -> [0,2] -> Pacific Ocean
       [2,2] -> [2,3] -> [2,4] -> Atlantic Ocean
[3,0]: [3,0] -> Pacific Ocean
       [3,0] -> [4,0] -> Atlantic Ocean
[3,1]: [3,1] -> [3,0] -> Pacific Ocean
       [3,1] -> [4,1] -> Atlantic Ocean
[4,0]: [4,0] -> Pacific Ocean
       [4,0] -> Atlantic Ocean
Note that there are other possible paths for these cells to flow to the Pacific and Atlantic oceans.
```

Example 2:

```
Input: heights = [[1]]
Output: [[0,0]]
Explanation: The water can flow from the only cell to the Pacific and Atlantic oceans.
```

Constraints:

- `m == heights.length`
- `n == heights[r].length`
- `1 <= m, n <= 200`
- `0 <= heights[r][c] <= 10^5`

SOLUTION (PYTHON 3)

Solution 1: BFS

How to think about it

Walking downhill from every cell toward an ocean revisits the same cells. With m,n≤ 200 that duplication is costly. The reverse of flowing down is climbing to a neighbor that is at least as high. BFS from the Pacific border and from the Atlantic border; the intersection can reach both oceans. A neighbor is admissible only when heights[nx][ny]≥ heights[x][y]. Starting at a border guarantees a path back to that ocean.

We can start from the boundaries of the Pacific and Atlantic oceans and perform breadth-first search (BFS) respectively to find all cells that can flow to the Pacific and Atlantic oceans. Finally, we take the intersection of the two results, which represents cells that can flow to both the Pacific and Atlantic oceans.

Specifically, we define a queue q_1 to store all cells adjacent to the Pacific ocean, and define a boolean matrix vis_1 to record which cells can flow to the Pacific ocean. Similarly, we define queue q_2 and boolean matrix vis_2 to handle the Atlantic ocean. Initially, we add all cells adjacent to the Pacific ocean to queue q_1 and mark them as visited in vis_1. Similarly, we add all cells adjacent to the Atlantic ocean to queue q_2 and mark them as visited in vis_2.

Then, we perform BFS on q_1 and q_2 respectively. In each BFS, we dequeue a cell (x, y) from the queue and check its four adjacent cells (nx, ny). If an adjacent cell is within the matrix bounds, has not been visited, and its height is not less than the current cell's height (i.e., water can flow to that cell), we add it to the queue and mark it as visited.

Finally, we traverse the entire matrix to find cells that are marked as visited in both vis_1 and vis_2. These cells are our answer.

The time complexity is $O(m \times n)$ and the space complexity is $O(m \times n)$, where m and n are the number of rows and columns in the matrix, respectively.

Python 3

```python
class Solution:
    def pacificAtlantic(self, heights: List[List[int]]) -> List[List[int]]:
        def bfs(q: Deque[Tuple[int, int]], vis: List[List[bool]]) -> None:
            while q:
                x, y = q.popleft()
                for dx, dy in pairwise(dirs):
                    nx, ny = x + dx, y + dy
                    if (
                        0 <= nx < m
                        and 0 <= ny < n
                        and not vis[nx][ny]
                        and heights[nx][ny] >= heights[x][y]
                    ):
                        vis[nx][ny] = True
                        q.append((nx, ny))

        m, n = len(heights), len(heights[0])
        vis1 = [[False] * n for _ in range(m)]
        vis2 = [[False] * n for _ in range(m)]
        q1: Deque[Tuple[int, int]] = deque()
        q2: Deque[Tuple[int, int]] = deque()
        dirs = (-1, 0, 1, 0, -1)

        for i in range(m):
            q1.append((i, 0))
            vis1[i][0] = True
            q2.append((i, n - 1))
            vis2[i][n - 1] = True

        for j in range(n):
            q1.append((0, j))
            vis1[0][j] = True
            q2.append((m - 1, j))
            vis2[m - 1][j] = True

        bfs(q1, vis1)
        bfs(q2, vis2)

        return [[i, j] for i in range(m) for j in range(n) if vis1[i][j] and vis2[i][j]]

PATTERN 16 · GRAPH DFS · PROBLEM 6 OF 20

130. Surrounded Regions

Medium · Depth-First Search, Breadth-First Search, Union Find, Array, Matrix

leetcode.com/problems/surrounded-regions

★ **TOP 10 PROBLEM** in Graph DFS: master this one first

Also appears in pattern 18 Matrix / Grid Traversal

PROBLEM

You are given an `m x n` matrix `board` containing **letters** `'X'` and `'O'`, **capture regions** that are **surrounded**:

- **Connect**: A cell is connected to adjacent cells horizontally or vertically.
- **Region**: To form a region **connect every** `'O'` cell.
- **Surround**: A region is surrounded if none of the `'O'` cells in that region are on the edge of the board. Such regions are **completely enclosed** by `'X'` cells.

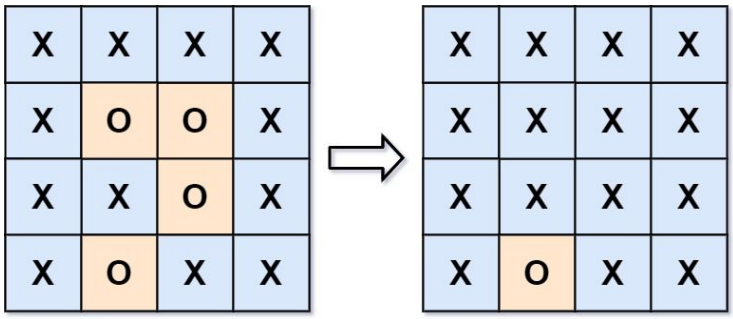
To capture a **surrounded region**, replace all `'O'`s with `'X'`s **in-place** within the original board. You do not need to return anything.

Example 1:

Input: board = [["X","X","X","X"],["X","O","O","X"],["X","X","O","X"],["X","O","X","X"]]

Output: [["X","X","X","X"],["X","X","X","X"],["X","X","X","X"],["X","O","X","X"]]

Explanation:



In the above diagram, the bottom region is not captured because it is on the edge of the board and cannot be surrounded.

Example 2:

Input: board = [["X"]]

Output: [["X"]]

Constraints:

- `m == board.length`
- `n == board[i].length`
- `1 <= m, n <= 200`
- `board[i][j]` is `'X'` or `'O'`.

SOLUTIONS (PYTHON 3)

Solution 1: Depth-First Search (DFS)

> **How to think about it**
>
> Surrounded `'O'`s become `'X'`; those connected to the border stay. m,n≤ 200. Starting from interior cells to ask “am I surrounded?” must flood a whole component and is easy to get wrong on the border. Mark the unsurrounded cells instead. DFS from every border `'O'`, paint those cells with a placeholder, flip remaining `'O'`s to `'X'`, then restore the placeholders.

We can start from the boundary of the matrix, taking each 'O' on the matrix boundary as a starting point, and perform depth-first search. All 'O's found in the search are replaced with '.'.

Then we traverse the matrix again, for each position:

- If it is '.', replace it with 'O';
- Otherwise, if it is 'O', replace it with 'X'.

The time complexity is O(m × n), and the space complexity is O(m × n). Here, m and n are the number of rows and columns in the matrix, respectively.

Python 3

```
class Solution:
    def solve(self, board: List[List[str]]) -> None:
        def dfs(i: int, j: int):
            if not (0 <= i < m and 0 <= j < n and board[i][j] == "O"):
                return
            board[i][j] = "."
            for a, b in pairwise((-1, 0, 1, 0, -1)):
                dfs(i + a, j + b)

        m, n = len(board), len(board[0])
        for i in range(m):
            dfs(i, 0)
            dfs(i, n - 1)
        for j in range(n):
            dfs(0, j)
            dfs(m - 1, j)
        for i in range(m):
            for j in range(n):
                if board[i][j] == ".":
                    board[i][j] = "O"
                elif board[i][j] == "O":
                    board[i][j] = "X"
```

Solution 2: Union-Find Set

> **How to think about it**
>
> Solution 1 uses DFS paint to mark border-connected cells. Union-find links adjacent `'O'`s and hooks every border `'O'` to a dummy node. Any `'O'` not in that component is surrounded. No recursion stack, and the connectivity is explicit.

We can also use a union-find set, connecting each 'O' on the matrix boundary with a super node m × n, and connecting each 'O' in the matrix with the 'O's above, below, left, and right of it.

Then we traverse this matrix, for each position, if it is 'O' and it is not connected to the super node, then we replace it with 'X'.

The time complexity is O(m × n × α(m × n)), and the space complexity is O(m × n). Here, m and n are the number of rows and columns in the matrix, respectively, and α is the inverse Ackermann function.

Python 3

```python
class Solution:
    def solve(self, board: List[List[str]]) -> None:
        def find(x: int) -> int:
            if p[x] != x:
                p[x] = find(p[x])
            return p[x]

        m, n = len(board), len(board[0])
        p = list(range(m * n + 1))
        for i in range(m):
            for j in range(n):
                if board[i][j] == "O":
                    if i in (0, m - 1) or j in (0, n - 1):
                        p[find(i * n + j)] = find(m * n)
                    else:
                        for a, b in pairwise((-1, 0, 1, 0, -1)):
                            x, y = i + a, j + b
                            if board[x][y] == "O":
                                p[find(x * n + y)] = find(i * n + j)
        for i in range(m):
            for j in range(n):
                if board[i][j] == "O" and find(i * n + j) != find(m * n):
                    board[i][j] = "X"
```

PATTERN 16 · GRAPH DFS · PROBLEM 7 OF 20

207. Course Schedule

Medium · Depth-First Search, Breadth-First Search, Graph, Topological Sort, Directed Acyclic Graph

leetcode.com/problems/course-schedule

★ **TOP 10 PROBLEM** in Graph DFS, Topological Sort: master this one first

Also appears in pattern 30 Topological Sort

PROBLEM

There are a total of `numCourses` courses you have to take, labeled from `0` to `numCourses - 1`. You are given an array `prerequisites` where `prerequisites[i] = [a_i, b_i]` indicates that you **must** take course b_i first if you want to take course a_i.

- For example, the pair `[0, 1]`, indicates that to take course `0` you have to first take course `1`.

Return `true` if you can finish all courses. Otherwise, return `false`.

Example 1:

```
Input: numCourses = 2, prerequisites = [[1,0]]
Output: true
Explanation: There are a total of 2 courses to take.
To take course 1 you should have finished course 0. So it is possible.
```

Example 2:

```
Input: numCourses = 2, prerequisites = [[1,0],[0,1]]
Output: false
Explanation: There are a total of 2 courses to take.
To take course 1 you should have finished course 0, and to take course 0 you should also have finished
course 1. So it is impossible.
```

Constraints:

- `1 <= numCourses <= 2000`
- `0 <= prerequisites.length <= 5000`
- `prerequisites[i].length == 2`
- $0 <= a_i, b_i < numCourses$
- All the pairs prerequisites[i] are **unique**.

SOLUTION (PYTHON 3)

Solution 1: Topological Sorting

How to think about it

Prerequisites form a directed graph; finishing every course is possible iff the graph is acyclic. Enumerating orders is not viable at the given size. Kahn's algorithm repeatedly takes a vertex of indegree 0 and decrements its successors. If every course enters the queue, there is no cycle.

For this problem, we can consider the courses as nodes in a graph, and prerequisites as edges in the graph. Thus, we can transform this problem into determining whether there is a cycle in the directed graph.

Specifically, we can use the idea of topological sorting. For each node with an in-degree of 0, we reduce the in-degree of its out-degree nodes by 1, until all nodes have been traversed.

If all nodes have been traversed, it means there is no cycle in the graph, and we can complete all courses; otherwise, we cannot complete all courses.

The time complexity is O(n + m), and the space complexity is O(n + m). Here, n and m are the number of courses and prerequisites respectively.

Python 3

```python
class Solution:
    def canFinish(self, numCourses: int, prerequisites: List[List[int]]) -> bool:
        g = [[] for _ in range(numCourses)]
        indeg = [0] * numCourses
        for a, b in prerequisites:
            g[b].append(a)
            indeg[a] += 1
        q = [i for i, x in enumerate(indeg) if x == 0]
        for i in q:
            numCourses -= 1
            for j in g[i]:
                indeg[j] -= 1
                if indeg[j] == 0:
                    q.append(j)
        return numCourses == 0
```

PATTERN 16 · GRAPH DFS · PROBLEM 8 OF 20

547. Number of Provinces

Medium · Depth-First Search, Breadth-First Search, Union Find, Graph

leetcode.com/problems/number-of-provinces

★ **TOP 10 PROBLEM** in Graph DFS, Union-Find (Disjoint Set): master this one first

Also appears in pattern 31 Union-Find (Disjoint Set)

PROBLEM

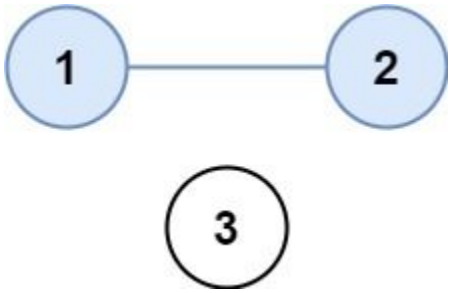
There are `n` cities. Some of them are connected, while some are not. If city `a` is connected directly with city `b`, and city `b` is connected directly with city `c`, then city `a` is connected indirectly with city `c`.

A **province** is a group of directly or indirectly connected cities and no other cities outside of the group.

You are given an `n x n` matrix `isConnected` where `isConnected[i][j] = 1` if the i^{th} city and the j^{th} city are directly connected, and `isConnected[i][j] = 0` otherwise.

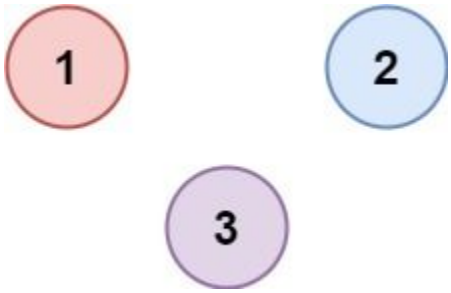
Return *the total number of **provinces***.

Example 1:



```
Input: isConnected = [[1,1,0],[1,1,0],[0,0,1]]
Output: 2
```

Example 2:



```
Input: isConnected = [[1,0,0],[0,1,0],[0,0,1]]
Output: 3
```

Constraints:

- `1 <= n <= 200`
- `n == isConnected.length`
- `n == isConnected[i].length`
- `isConnected[i][j]` is `1` or `0`.
- `isConnected[i][i] == 1`
- `isConnected[i][j] == isConnected[j][i]`

SOLUTIONS (PYTHON 3)

Solution 1: DFS

> **How to think about it**
>
> A province is a connected component. The matrix tells which cities share an edge, so DFS or BFS from each unseen city paints one component. Scan cities, start a DFS at every unvisited index, and increment the answer. The visited array visits each city once.

We create an array vis to record whether each city has been visited.

Next, we traverse each city i. If the city has not been visited, we start a depth-first search from that city. Using the matrix isConnected, we find the cities directly connected to this city. These cities and the current city belong to the same province. We continue the depth-first search for these cities until all cities in the same province have been visited. This counts as one province, so we increment the answer ans by 1. Then, we move to the next unvisited city and repeat the process until all cities have been traversed.

Finally, return the answer.

The time complexity is $O(n^2)$, and the space complexity is $O(n)$. Here, n is the number of cities.

Python 3

```python
class Solution:
    def findCircleNum(self, isConnected: List[List[int]]) -> int:
        def dfs(i: int):
            vis[i] = True
            for j, x in enumerate(isConnected[i]):
                if not vis[j] and x:
                    dfs(j)

        n = len(isConnected)
        vis = [False] * n
        ans = 0
        for i in range(n):
            if not vis[i]:
                dfs(i)
                ans += 1
        return ans
```

Solution 2: Union-Find

> **How to think about it**
>
> DFS needs a recursion stack and a visited array. Union-find merges along edges: start with n components and decrement when an edge joins two roots. Iterate the upper triangle to avoid duplicate edges. Path compression keeps finds cheap. The remaining roots are the provinces.

We can also use the union-find data structure to maintain each connected component. Initially, each city belongs to a different connected component, so the number of provinces is n.

Next, we traverse the matrix isConnected. If there is a connection between two cities (i, j) and they belong to two different connected components, they will be merged into one connected component, and the number of provinces is decremented by 1.

Finally, return the number of provinces.

The time complexity is $O(n^2 \times \log n)$, and the space complexity is $O(n)$. Here, n is the number of cities, and $\log n$ is the time complexity of path compression in the union-find data structure.

Python 3

```
class Solution:
    def findCircleNum(self, isConnected: List[List[int]]) -> int:
        def find(x: int) -> int:
            if p[x] != x:
                p[x] = find(p[x])
            return p[x]

        n = len(isConnected)
        p = list(range(n))
        ans = n
        for i in range(n):
            for j in range(i + 1, n):
                if isConnected[i][j]:
                    pa, pb = find(i), find(j)
                    if pa != pb:
                        p[pa] = pb
                        ans -= 1
        return ans
```

PATTERN 16 · GRAPH DFS · PROBLEM 9 OF 20

1020. Number of Enclaves

Medium · Depth-First Search, Breadth-First Search, Union Find, Array, Matrix

leetcode.com/problems/number-of-enclaves

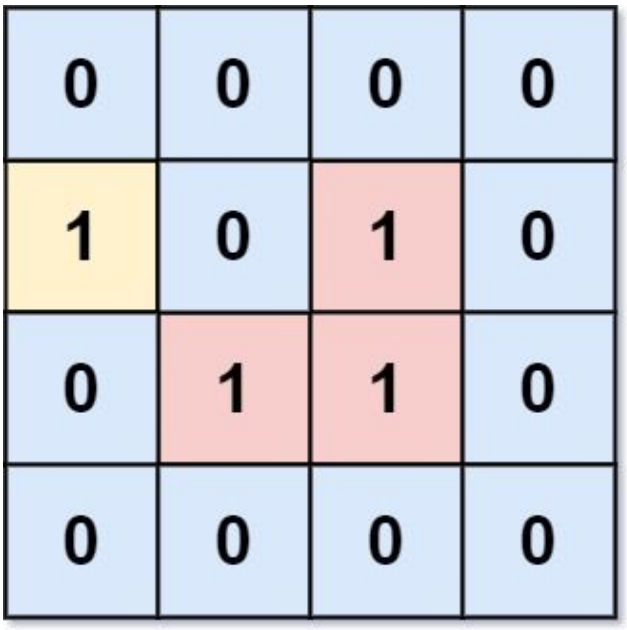
PROBLEM

You are given an `m x n` binary matrix `grid`, where `0` represents a sea cell and `1` represents a land cell.

A **move** consists of walking from one land cell to another adjacent (**4-directionally**) land cell or walking off the boundary of the `grid`.

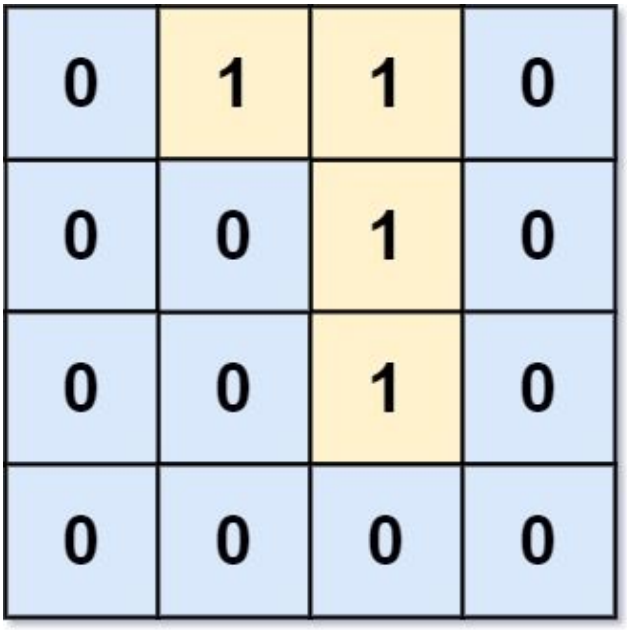
Return *the number of land cells in* `grid` *for which we cannot walk off the boundary of the grid in any number of* ***moves***.

Example 1:



```
Input: grid = [[0,0,0,0],[1,0,1,0],[0,1,1,0],[0,0,0,0]]
Output: 3
Explanation: There are three 1s that are enclosed by 0s, and one 1 that is not enclosed because its on the boundary.
```

Example 2:



```
Input: grid = [[0,1,1,0],[0,0,1,0],[0,0,1,0],[0,0,0,0]]
Output: 0
Explanation: All 1s are either on the boundary or can reach the boundary.
```

Constraints:

- `m == grid.length`
- `n == grid[i].length`
- `1 <= m, n <= 500`
- `grid[i][j]` is either `0` or `1`.

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

Testing whether each land cell can reach the border repeats searches over the same grid; m,n≤ 500 makes that wasteful. Enclaves are land that cannot reach the border, so they are the complement of border-connected land. Flooding from every 1 on the four borders removes all land that can leave. The remaining ones cannot. DFS performs the flood; the answer is the number of 1s left.

Python 3

```python
class Solution:
    def numEnclaves(self, grid: List[List[int]]) -> int:
        def dfs(i: int, j: int):
            grid[i][j] = 0
            for a, b in pairwise(dirs):
                x, y = i + a, j + b
                if 0 <= x < m and 0 <= y < n and grid[x][y]:
                    dfs(x, y)

        m, n = len(grid), len(grid[0])
        dirs = (-1, 0, 1, 0, -1)
        for j in range(n):
            if grid[0][j]:
                dfs(0, j)
            if grid[m - 1][j]:
                dfs(m - 1, j)
        for i in range(m):
            if grid[i][0]:
                dfs(i, 0)
            if grid[i][n - 1]:
                dfs(i, n - 1)
        return sum(sum(row) for row in grid)
```

Complexity. Time: O(m * n). Space: O(m * n).

Solution 2

How to think about it

Solution 1 already floods from the border with an explicit stack. Connectivity does not depend on search order, so a queue can clear the same cells by layers. Pop a cell and mark each neighboring 1. After the borders are processed, the remaining 1s are still the enclaves.

Python 3

```python
class Solution:
    def numEnclaves(self, grid: List[List[int]]) -> int:
        m, n = len(grid), len(grid[0])
        q = deque()
        for i in range(m):
            for j in range(n):
                if grid[i][j] and (i == 0 or i == m - 1 or j == 0 or j == n - 1):
                    q.append((i, j))
                    grid[i][j] = 0
        dirs = (-1, 0, 1, 0, -1)
        while q:
            i, j = q.popleft()
            for a, b in pairwise(dirs):
                x, y = i + a, j + b
                if x >= 0 and x < m and y >= 0 and y < n and grid[x][y]:
                    q.append((x, y))
                    grid[x][y] = 0
        return sum(v for row in grid for v in row)
```

Complexity. Time: O(m * n). Space: O(m * n).

Solution 3

How to think about it

Search still uses a stack or queue proportional to the component size. The same connectivity can be recorded with union-find: adjacent land is united, and every border land is united with a dummy exterior node. Cells that stay land and are not in the exterior component are enclaves, so we count those sizes.

Python 3

```
class UnionFind:
    def __init__(self, n):
        self.p = list(range(n))
        self.size = [1] * n

    def find(self, x):
        if self.p[x] != x:
            self.p[x] = self.find(self.p[x])
        return self.p[x]

    def union(self, a, b):
        pa, pb = self.find(a), self.find(b)
        if pa != pb:
            if self.size[pa] > self.size[pb]:
                self.p[pb] = pa
                self.size[pa] += self.size[pb]
            else:
                self.p[pa] = pb
                self.size[pb] += self.size[pa]

class Solution:
    def numEnclaves(self, grid: List[List[int]]) -> int:
        m, n = len(grid), len(grid[0])
        uf = UnionFind(m * n + 1)
        dirs = (-1, 0, 1, 0, -1)
        for i, row in enumerate(grid):
            for j, v in enumerate(row):
                if v:
                    if i == 0 or i == m - 1 or j == 0 or j == n - 1:
                        uf.union(i * n + j, m * n)
                    else:
                        for a, b in pairwise(dirs):
                            x, y = i + a, j + b
                            if x >= 0 and x < m and y >= 0 and y < n and grid[x][y]:
                                uf.union(i * n + j, x * n + y)
        return sum(
            grid[i][j] == 1 and uf.find(i * n + j) != uf.find(m * n)
            for i in range(m)
            for j in range(n)
        )
```

Complexity. Time: O(m * n * alpha(m * n)), almost O(m * n). Space: O(m * n).

Solution 4: Explicit Stack

> **How to think about it**
>
> An enclave is land that cannot reach the border. Testing every land cell separately repeats the same search. With m,n≤ 500, the complement is the land connected to the border. Recursing along a border-connected snake of about a thousand cells exhausts the call stack before the flood finishes. The flood only needs to mark reachable cells as 0. It does not wait on a return value. An explicit stack holds the cells still to clear. Pop a cell and push each neighboring 1 after marking it. After all four borders are processed, the remaining 1s are enclaves.

Flood from every land cell on the four borders with an explicit stack, marking reachable cells as 0. The number of 1s left is the answer.

Python 3

```python
class Solution:
    def numEnclaves(self, grid: List[List[int]]) -> int:
        def flood(i: int, j: int):
            stk = [(i, j)]
            grid[i][j] = 0
            while stk:
                i, j = stk.pop()
                for a, b in pairwise(dirs):
                    x, y = i + a, j + b
                    if 0 <= x < m and 0 <= y < n and grid[x][y]:
                        grid[x][y] = 0
                        stk.append((x, y))

        m, n = len(grid), len(grid[0])
        dirs = (-1, 0, 1, 0, -1)
        for j in range(n):
            for i in (0, m - 1):
                if grid[i][j]:
                    flood(i, j)
        for i in range(m):
            for j in (0, n - 1):
                if grid[i][j]:
                    flood(i, j)
        return sum(sum(row) for row in grid)
```

Complexity. Time: O(m * n). Space: O(m * n).

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

Built on the solutions above: helper functions, then the function for each follow-up. No tests and no restating of the question.

```python
# FOLLOW-UPS (answered below, in this order):
# 1. The size of every enclave

# ============================================================
# FOLLOW-UP 1: The size of every enclave
# ============================================================

# ---- follow-up 1: function ----
# Answer: Remove the land connected to the border, then
# measure each remaining group of land.
# Time: O(m * n).  Space: O(m * n).
def enclave_sizes(grid):
    rows, cols = len(grid), len(grid[0])
    seen = set()

    def spread(r, c):
        size = 0
        stack = [(r, c)]
        seen.add((r, c))
        while stack:

```

841. Keys and Rooms

Medium · Depth-First Search, Breadth-First Search, Graph

leetcode.com/problems/keys-and-rooms

PROBLEM

There are `n` rooms labeled from `0` to `n - 1` and all the rooms are locked except for room `0`. Your goal is to visit all the rooms. However, you cannot enter a locked room without having its key.

When you visit a room, you may find a set of **distinct keys** in it. Each key has a number on it, denoting which room it unlocks, and you can take all of them with you to unlock the other rooms.

Given an array `rooms` where `rooms[i]` is the set of keys that you can obtain if you visited room `i`, return `true` *if you can visit **all** the rooms, or* `false` *otherwise*.

Example 1:

```
Input: rooms = [[1],[2],[3],[]]
Output: true
Explanation:
We visit room 0 and pick up key 1.
We then visit room 1 and pick up key 2.
We then visit room 2 and pick up key 3.
We then visit room 3.
Since we were able to visit every room, we return true.
```

Example 2:

```
Input: rooms = [[1,3],[3,0,1],[2],[0]]
Output: false
Explanation: We can not enter room number 2 since the only key that unlocks it is in that room.
```

Constraints:

- `n == rooms.length`
- `2 <= n <= 1000`
- `0 <= rooms[i].length <= 1000`
- `1 <= sum(rooms[i].length) <= 3000`
- `0 <= rooms[i][j] < n`
- All the values of `rooms[i]` are **unique**.

SOLUTIONS (PYTHON 3)

Solution 1: Depth-First Search (DFS)

How to think about it

Rooms form a directed graph whose edges are keys. We ask whether 0 reaches every room. n≤ 1000, so one traversal is enough. DFS from 0 follows keys; success is |vis|=n.

We can use the Depth-First Search (DFS) method to traverse the entire graph, count the number of reachable nodes, and use an array `vis` to mark whether the current node has been visited to prevent repeated visits.

Finally, we count the number of visited nodes. If it is the same as the total number of nodes, it means that all nodes can be visited; otherwise, there are nodes that cannot be reached.

The time complexity is O(n + m), and the space complexity is O(n), where n is the number of nodes, and m is the number of edges.

Python 3

```python
class Solution:
    def canVisitAllRooms(self, rooms: List[List[int]]) -> bool:
        def dfs(i: int):
            if i in vis:
                return
            vis.add(i)
            for j in rooms[i]:
                dfs(j)

        vis = set()
        dfs(0)
        return len(vis) == len(rooms)
```

Solution 2: BFS

> **How to think about it**
>
> Solution 1 follows keys with an explicit stack. The same reachability is a queue: start at 0 and enqueue a room when a key to it is found and that room is still unvisited. The visited marks still drop duplicate keys, and the answer still compares the visited count with n.

We can also use the Breadth-First Search (BFS) method to traverse the entire graph. We use a hash table or an array `vis` to mark whether the current node has been visited to prevent repeated visits.

Specifically, we define a queue q, initially put node 0 into the queue, and then continuously traverse the queue. Each time we take out the front node i of the queue, if i has been visited, we skip it directly; otherwise, we mark it as visited, and then add the nodes that i can reach to the queue.

Finally, we count the number of visited nodes. If it is the same as the total number of nodes, it means that all nodes can be visited; otherwise, it means that there are unreachable nodes.

The time complexity is O(n + m), and the space complexity is O(n). Where n is the number of nodes, and m is the number of edges.

Python 3

```python
class Solution:
    def canVisitAllRooms(self, rooms: List[List[int]]) -> bool:
        vis = set()
        q = deque([0])
        while q:
            i = q.popleft()
            if i in vis:
                continue
            vis.add(i)
            q.extend(j for j in rooms[i])
        return len(vis) == len(rooms)
```

Solution 3: Explicit Stack

> **How to think about it**
>
> Rooms form a directed graph whose edges are keys. The question is whether room 0 reaches every room. With n ≤ 1000, one traversal is enough. Following a chain of keys by recursion uses a call depth equal to the room count and overflows Python once the chain reaches length 1000. A stack therefore holds the rooms still to open: a popped room is skipped when it was already visited, and otherwise it is marked and its keys are pushed. Duplicate keys may push the same room again, and the mark expands it only once. Every room is reachable when the visited count equals n.

Start at room 0 and walk the reachable rooms with an explicit stack. The stack begins with 0. When room i is popped, skip it if it has already been visited; otherwise mark it and push the room behind each key found in i. A repeated key only pushes that room again, and the later pop is skipped.

Finally, check whether every room was visited. If so, return true; otherwise some room cannot be reached.

The time complexity is O(n + m), and the space complexity is O(n), where n is the number of nodes, and m is the number of edges.

Python 3

```python
class Solution:
    def canVisitAllRooms(self, rooms: List[List[int]]) -> bool:
        n = len(rooms)
        vis = [False] * n
        stk = [0]
        while stk:
            i = stk.pop()
            if vis[i]:
                continue
            vis[i] = True
            for j in rooms[i]:
                stk.append(j)
        return all(vis)
```

1466. Reorder Routes to Make All Paths Lead to the City Zero

Medium · Depth-First Search, Breadth-First Search, Graph

leetcode.com/problems/reorder-routes-to-make-all-paths-lead-to-the-city-zero

PROBLEM

There are `n` cities numbered from `0` to `n - 1` and `n - 1` roads such that there is only one way to travel between two different cities (this network form a tree). Last year, The ministry of transport decided to orient the roads in one direction because they are too narrow.

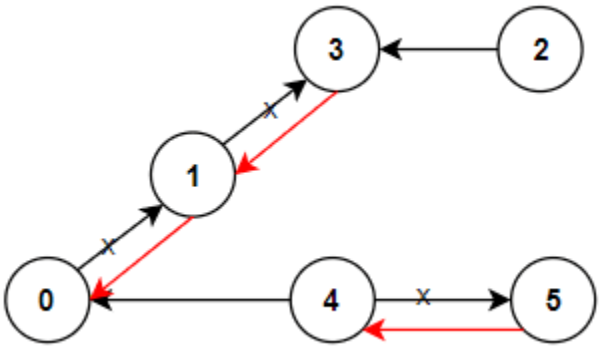
Roads are represented by `connections` where `connections[i] = [a_i, b_i]` represents a road from city `a_i` to city `b_i`.

This year, there will be a big event in the capital (city `0`), and many people want to travel to this city.

Your task consists of reorienting some roads such that each city can visit the city `0`. Return the **minimum** number of edges changed.

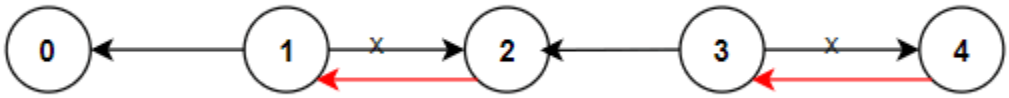
It's **guaranteed** that each city can reach city `0` after reorder.

Example 1:



```
Input: n = 6, connections = [[0,1],[1,3],[2,3],[4,0],[4,5]]
Output: 3
Explanation: Change the direction of edges show in red such that each node can reach the node 0
(capital).
```

Example 2:



```
Input: n = 5, connections = [[1,0],[1,2],[3,2],[3,4]]
Output: 2
Explanation: Change the direction of edges show in red such that each node can reach the node 0
(capital).
```

Example 3:

```
Input: n = 3, connections = [[1,0],[2,0]]
Output: 0
```

Constraints:

- `2 <= n <= 5 * 10^4`
- `connections.length == n - 1`

- `connections[i].length == 2`
- $0 <= a_i, b_i <= n - 1$
- $a_i != b_i$

SOLUTIONS (PYTHON 3)

Solution 1: DFS

> **How to think about it**
>
> Ignoring direction, the graph is a tree; every city must reach 0. Walking outward from 0, an original forward edge must be reversed. Store cost 1 with the given direction and 0 with the reverse, then DFS the costs.

The route map given in the problem has n nodes and n-1 edges. If we ignore the direction of the edges, then these n nodes form a tree. The problem requires us to change the direction of some edges so that each node can reach node 0.

We might as well consider starting from node 0 and reaching all other nodes. The direction is opposite to the problem description, which means that when we build the graph, for the directed edge [a, b], we should regard it as the directed edge [b, a]. That is to say, if it is from a to b, we need to change the direction once; if it is from b to a, no direction change is needed.

Next, we only need to start from node 0, search all other nodes, and during the process, if we encounter an edge that needs to change direction, we accumulate the number of direction changes once.

The time complexity is O(n), and the space complexity is O(n). Here, n is the number of nodes in the problem.

Python 3

```python
class Solution:
    def minReorder(self, n: int, connections: List[List[int]]) -> int:
        def dfs(a: int, fa: int) -> int:
            return sum(c + dfs(b, a) for b, c in g[a] if b != fa)

        g = [[] for _ in range(n)]
        for a, b in connections:
            g[a].append((b, 1))
            g[b].append((a, 0))
        return dfs(0, -1)
```

Solution 2: BFS

> **How to think about it**
>
> Method 1 already walks the same adjacency list with an explicit stack. BFS leaves 0 level by level and adds the edge cost the first time a neighbor is seen, so the visit order differs from the stack.

We can use the Breadth-First Search (BFS) method, starting from node 0, to search all other nodes. During the process, if we encounter an edge that requires a change of direction, we increment the count of direction changes.

The time complexity is O(n), and the space complexity is O(n). Where n is the number of nodes in the problem.

Python 3

```python
class Solution:
    def minReorder(self, n: int, connections: List[List[int]]) -> int:
        g = [[] for _ in range(n)]
        for a, b in connections:
            g[a].append((b, 1))
            g[b].append((a, 0))
        q = deque([0])
        vis = {0}
        ans = 0
        while q:
            a = q.popleft()
            for b, c in g[a]:
                if b not in vis:
                    vis.add(b)
                    q.append(b)
                    ans += c
        return ans
```

Solution 3: Explicit Stack

> **How to think about it**
>
> Ignoring direction, the graph is a tree. Walking outward from 0, an original forward edge must be reversed. n can reach 5×10^4. On a chain the first recursive call always follows the only child, so the depth is n and exceeds the default recursion limit. The cost of a tree edge is known as soon as the walk leaves its parent, so the total does not have to wait for the subtree to return. An explicit stack starts at 0. After a node is popped, each neighbor that is not the parent adds its edge cost and is pushed. A forward edge costs 1 and a reverse edge costs 0.

The route map given in the problem has n nodes and n-1 edges. If we ignore the direction of the edges, then these n nodes form a tree. The problem requires us to change the direction of some edges so that each node can reach node 0.

We might as well consider starting from node 0 and reaching all other nodes. The direction is opposite to the problem description, which means that when we build the graph, for the directed edge [a, b], we should regard it as the directed edge [b, a]. That is to say, if it is from a to b, we need to change the direction once; if it is from b to a, no direction change is needed.

An explicit stack walks the tree from node 0. After a node is popped, each neighbor that is not the parent adds its edge weight to the answer and is pushed. A forward edge has weight 1, and a reverse edge has weight 0.

The time complexity is O(n), and the space complexity is O(n). Here, n is the number of nodes in the problem.

Python 3

```python
class Solution:
    def minReorder(self, n: int, connections: List[List[int]]) -> int:
        g = [[] for _ in range(n)]
        for a, b in connections:
            g[a].append((b, 1))
            g[b].append((a, 0))
        ans = 0
        stk = [(0, -1)]
        while stk:
            a, fa = stk.pop()
            for b, c in g[a]:
                if b != fa:
                    ans += c
                    stk.append((b, a))
        return ans
```

```

797. All Paths From Source to Target

Medium · Depth-First Search, Breadth-First Search, Graph, Backtracking, Directed Acyclic Graph

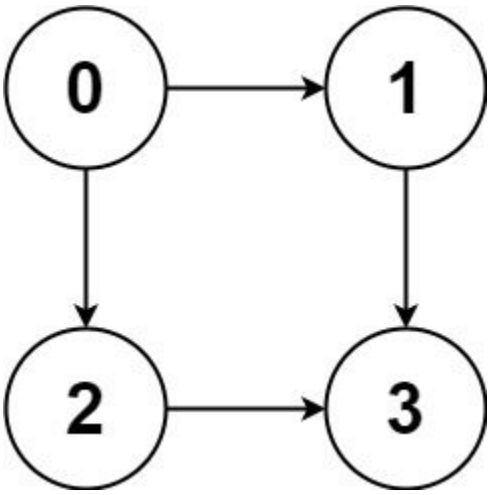
leetcode.com/problems/all-paths-from-source-to-target

PROBLEM

Given a directed acyclic graph (**DAG**) of `n` nodes labeled from `0` to `n - 1`, find all possible paths from node `0` to node `n - 1` and return them in **any order**.

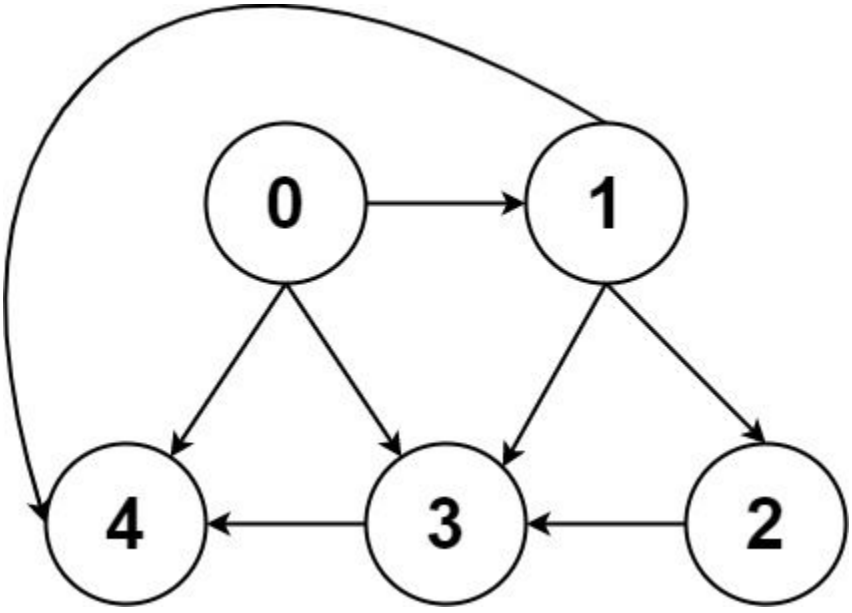
The graph is given as follows: `graph[i]` is a list of all nodes you can visit from node `i` (i.e., there is a directed edge from node `i` to node `graph[i][j]`).

Example 1:



```
Input: graph = [[1,2],[3],[3],[]]
Output: [[0,1,3],[0,2,3]]
Explanation: There are two paths: 0 -> 1 -> 3 and 0 -> 2 -> 3.
```

Example 2:



```
Input: graph = [[4,3,1],[3,2,4],[3],[4],[]]
Output: [[0,4],[0,3,4],[0,1,3,4],[0,1,2,3,4],[0,1,4]]
```

Constraints:

- `n == graph.length`
- `2 <= n <= 15`
- `0 <= graph[i][j] < n`
- `graph[i][j] != i` (i.e., there will be no self-loops).
- All the elements of `graph[i]` are **unique**.
- The input graph is **guaranteed** to be a **DAG**.

SOLUTIONS (PYTHON 3)

Solution 1: BFS

> **How to think about it**
>
> List every path from 0 to n-1 in a DAG. n≤ 15; all paths must be reported. BFS stores full paths; a finished path is recorded, otherwise each neighbor is appended and enqueued.

Start from node 0, keep paths in a queue, and record a path when it reaches n-1.

Python 3

```python
class Solution:
    def allPathsSourceTarget(self, graph: List[List[int]]) -> List[List[int]]:
        n = len(graph)
        q = deque([[0]])
        ans = []
        while q:
            path = q.popleft()
            u = path[-1]
            if u == n - 1:
                ans.append(path)
                continue
            for v in graph[u]:
                q.append(path + [v])
        return ans
```

Complexity. Time: O(2^n * n). Space: O(2^n * n).

Solution 2: DFS

> **How to think about it**
>
> BFS copies every prefix. DFS appends on one array, snapshots at the sink, and pops—fewer intermediate lists.

DFS from node 0 and backtrack after each path that reaches the target.

Python 3

```python
class Solution:
    def allPathsSourceTarget(self, graph: List[List[int]]) -> List[List[int]]:
        def dfs(t):
            if t[-1] == len(graph) - 1:
                ans.append(t[:])
                return
            for v in graph[t[-1]]:
                t.append(v)
                dfs(t)
                t.pop()

        ans = []
        dfs([0])
        return ans
```

Complexity. Time: O(2^n * n). Space: O(n) recursion (plus the answers).

802. Find Eventual Safe States

Medium · Depth-First Search, Breadth-First Search, Graph, Topological Sort, Kosaraju, Tarjan

leetcode.com/problems/find-eventual-safe-states

★ **TOP 10 PROBLEM** in Graph DFS, Topological Sort: master this one first

Also appears in pattern 30 Topological Sort

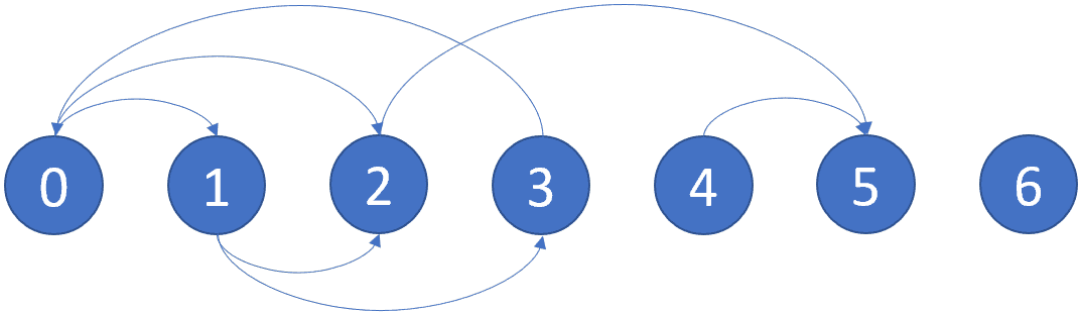
PROBLEM

There is a directed graph of `n` nodes with each node labeled from `0` to `n - 1`. The graph is represented by a **0-indexed** 2D integer array `graph` where `graph[i]` is an integer array of nodes adjacent to node `i`, meaning there is an edge from node `i` to each node in `graph[i]`.

A node is a **terminal node** if there are no outgoing edges. A node is a **safe node** if every possible path starting from that node leads to a **terminal node** (or another safe node).

Return *an array containing all the **safe nodes** of the graph*. The answer should be sorted in **ascending** order.

Example 1:



```
Input: graph = [[1,2],[2,3],[5],[0],[5],[],[]]
Output: [2,4,5,6]
Explanation: The given graph is shown above.
Nodes 5 and 6 are terminal nodes as there are no outgoing edges from either of them.
Every path starting at nodes 2, 4, 5, and 6 all lead to either node 5 or 6.
```

Example 2:

```
Input: graph = [[1,2,3,4],[1,2],[3,4],[0,4],[]]
Output: [4]
Explanation:
Only node 4 is a terminal node, and every path starting at node 4 leads to node 4.
```

Constraints:

- `n == graph.length`
- `1 <= n <= 10^4`
- `0 <= graph[i].length <= n`
- `0 <= graph[i][j] <= n - 1`
- `graph[i]` is sorted in a strictly increasing order.
- The graph may contain self-loops.
- The number of edges in the graph will be in the range `[1, 4 * 10^4]`.

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

A node is eventually safe if every walk from it ends at a terminal and never enters a cycle. Searching from every node independently retraces the same chains. Reverse the edges so original out-degree becomes in-degree. Kahn deletion from in-degree 0 removes exactly the nodes that cannot reach a cycle, i.e. the safe nodes. One linear pass is enough for $n \leq 10^4$.

Python 3

```python
class Solution:
    def eventualSafeNodes(self, graph: List[List[int]]) -> List[int]:
        rg = defaultdict(list)
        indeg = [0] * len(graph)
        for i, vs in enumerate(graph):
            for j in vs:
                rg[j].append(i)
            indeg[i] = len(vs)
        q = deque([i for i, v in enumerate(indeg) if v == 0])
        while q:
            i = q.popleft()
            for j in rg[i]:
                indeg[j] -= 1
                if indeg[j] == 0:
                    q.append(j)
        return [i for i, v in enumerate(indeg) if v == 0]
```

Complexity. Time: O(n + e), e = number of edges. Space: O(n + e).

Solution 2

How to think about it

The topological approach builds a reverse graph and in-degrees. A three-color DFS on the original graph is enough: gray means the current path has a cycle; black after the recursion means every walk from that node is safe. No reverse graph is stored. The answer is the nodes whose DFS returns true, still in linear time.

Python 3

```python
class Solution:
    def eventualSafeNodes(self, graph: List[List[int]]) -> List[int]:
        def dfs(i):
            if color[i]:
                return color[i] == 2
            color[i] = 1
            for j in graph[i]:
                if not dfs(j):
                    return False
            color[i] = 2
            return True

        n = len(graph)
        color = [0] * n
        return [i for i in range(n) if dfs(i)]
```

Complexity. Time: O(n + e). Space: O(n).

PATTERN 16 · GRAPH DFS · PROBLEM 14 OF 20

1254. Number of Closed Islands

Medium · Depth-First Search, Breadth-First Search, Union Find, Array, Matrix

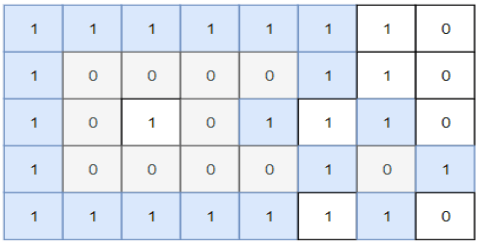
leetcode.com/problems/number-of-closed-islands

PROBLEM

Given a 2D `grid` consists of `0s` (land) and `1s` (water). An *island* is a maximal 4-directionally connected group of `0s` and a *closed island* is an island **totally** (all left, top, right, bottom) surrounded by `1s`.

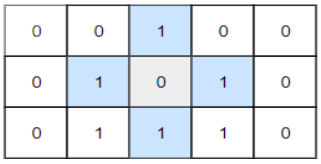
Return the number of *closed islands*.

Example 1:



```
Input: grid =
[[1,1,1,1,1,1,1,0],[1,0,0,0,0,1,1,0],[1,0,1,0,1,1,1,0],[1,0,0,0,0,1,0,1],[1,1,1,1,1,1,1,0]]
Output: 2
Explanation:
Islands in gray are closed because they are completely surrounded by water (group of 1s).
```

Example 2:



```
Input: grid = [[0,0,1,0,0],[0,1,0,1,0],[0,1,1,1,0]]
Output: 1
```

Example 3:

```
Input: grid = [[1,1,1,1,1,1,1],
               [1,0,0,0,0,0,1],
               [1,0,1,1,1,0,1],
               [1,0,1,0,1,0,1],
               [1,0,1,1,1,0,1],
               [1,0,0,0,0,0,1],
               [1,1,1,1,1,1,1]]
Output: 2
```

Constraints:

- `1 <= grid.length, grid[0].length <= 100`
- `0 <= grid[i][j] <=1`

SOLUTIONS (PYTHON 3)

Solution 1: DFS

> **How to think about it**
>
> A closed island is a land component that never touches the border. m,n ≤ 100 allows flood fill. From each unseen land cell we DFS, painting water to avoid revisits, and count the component if every cell is interior. The return value ANDs "this cell is not on the border" with all neighbors. In-place writes serve as the visited mark.

We traverse the matrix, and for each piece of land, we perform a depth-first search to find all the land connected to it. Then we check if there is any land on the boundary. If there is, it is not a closed island; otherwise, it is a closed island, and we increment the answer by one.

Finally, we return the answer.

The time complexity is O(m × n), and the space complexity is O(m × n). Where m and n are the number of rows and columns in the matrix, respectively.

Python 3

```python
class Solution:
    def closedIsland(self, grid: List[List[int]]) -> int:
        def dfs(i: int, j: int) -> int:
            res = int(0 < i < m - 1 and 0 < j < n - 1)
            grid[i][j] = 1
            for a, b in pairwise(dirs):
                x, y = i + a, j + b
                if 0 <= x < m and 0 <= y < n and grid[x][y] == 0:
                    res &= dfs(x, y)
            return res

        m, n = len(grid), len(grid[0])
        dirs = (-1, 0, 1, 0, -1)
        return sum(grid[i][j] == 0 and dfs(i, j) for i in range(m) for j in range(n))
```

Solution 2: Union-Find

> **How to think about it**
>
> DFS uses a call stack and mutates the grid. Union-find links adjacent land and also links border cells to a dummy node; we count land whose root is itself and is not the dummy. Iterative unions avoid recursion; the meaning is still "land components off the border".

We can use a union-find set to maintain each piece of connected land.

We traverse the matrix, if the current position is on the boundary, we connect it with the virtual node m × n. If the current position is land, we connect it with the land below and to the right.

Then, we traverse the matrix again, for each piece of land, if its root node is itself, we increment the answer by one.

Finally, we return the answer.

The time complexity is O(m × n × α(m × n)), and the space complexity is O(m × n). Where m and n are the number of rows and columns in the matrix, respectively.

Python 3

```python
class UnionFind:
    def __init__(self, n: int):
        self.p = list(range(n))
        self.size = [1] * n

    def find(self, x: int) -> int:
        if self.p[x] != x:
            self.p[x] = self.find(self.p[x])
        return self.p[x]

    def union(self, a: int, b: int):
        pa, pb = self.find(a), self.find(b)
        if pa != pb:
            if self.size[pa] > self.size[pb]:
                self.p[pb] = pa
                self.size[pa] += self.size[pb]
            else:
                self.p[pa] = pb
                self.size[pb] += self.size[pa]

class Solution:
    def closedIsland(self, grid: List[List[int]]) -> int:
        m, n = len(grid), len(grid[0])
        uf = UnionFind(m * n + 1)
        for i in range(m):
            for j in range(n):
                if i == 0 or i == m - 1 or j == 0 or j == n - 1:
                    uf.union(i * n + j, m * n)
                if grid[i][j] == 0:
                    if i < m - 1 and grid[i + 1][j] == 0:
                        uf.union(i * n + j, (i + 1) * n + j)
                    if j < n - 1 and grid[i][j + 1] == 0:
                        uf.union(i * n + j, i * n + j + 1)
        ans = 0
        for i in range(m):
            for j in range(n):
                ans += grid[i][j] == 0 and uf.find(i * n + j) == i * n + j
        return ans
```

1376. Time Needed to Inform All Employees

Medium · Tree, Depth-First Search, Breadth-First Search

leetcode.com/problems/time-needed-to-inform-all-employees

PROBLEM

A company has `n` employees with a unique ID for each employee from `0` to `n - 1`. The head of the company is the one with `headID`.

Each employee has one direct manager given in the `manager` array where `manager[i]` is the direct manager of the `i-th` employee, `manager[headID] = -1`. Also, it is guaranteed that the subordination relationships have a tree structure.

The head of the company wants to inform all the company employees of an urgent piece of news. He will inform his direct subordinates, and they will inform their subordinates, and so on until all employees know about the urgent news.

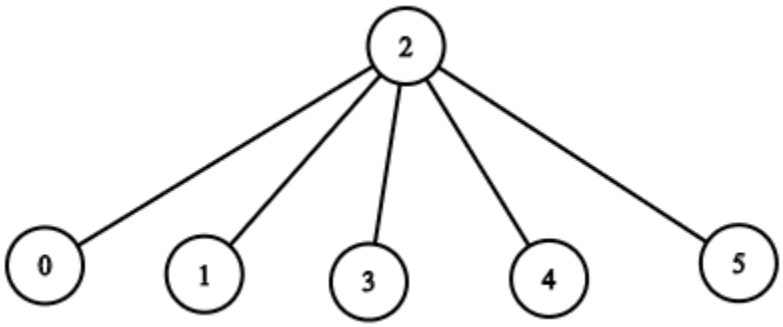
The `i-th` employee needs `informTime[i]` minutes to inform all of his direct subordinates (i.e., After informTime[i] minutes, all his direct subordinates can start spreading the news).

Return *the number of minutes* needed to inform all the employees about the urgent news.

Example 1:

```
Input: n = 1, headID = 0, manager = [-1], informTime = [0]
Output: 0
Explanation: The head of the company is the only employee in the company.
```

Example 2:



```
Input: n = 6, headID = 2, manager = [2,2,-1,2,2,2], informTime = [0,0,1,0,0,0]
Output: 1
Explanation: The head of the company with id = 2 is the direct manager of all the employees in the
company and needs 1 minute to inform them all.
The tree structure of the employees in the company is shown.
```

Constraints:

- `1 <= n <= 10^5`
- `0 <= headID < n`
- `manager.length == n`
- `0 <= manager[i] < n`
- `manager[headID] == -1`
- `informTime.length == n`
- `0 <= informTime[i] <= 1000`
- `informTime[i] == 0` if employee `i` has no subordinates.
- It is **guaranteed** that all the employees can be informed.

SOLUTIONS (PYTHON 3)

Solution 1: DFS

> **How to think about it**
>
> In a tree of managers, a message starts at the head; an edge costs that employee's inform time. $n \le 10^5$ forbids summing a path per leaf. After building the child list, dfs(i) is the time for i to inform its whole subtree: informTime[i] plus the slowest dfs(j) among direct reports. The answer is dfs(headID).

We first build an adjacent list g according to the manager array, where g[i] represents all direct subordinates of employee i.

Next, we design a function dfs(i), which means the time required for employee i to notify all his subordinates (including direct subordinates and indirect subordinates), and then the answer is dfs(headID).

In function dfs(i), we need to traverse all direct subordinates j of i. For each subordinate, employee i needs to notify him, which takes informTime[i] time, and his subordinates need to notify their subordinates, which takes dfs(j) time. We take the maximum value of informTime[i] + dfs(j) as the return value of function dfs(i).

The time complexity is O(n), and the space complexity is O(n). Where n is the number of employees.

Python 3

```python
class Solution:
    def numOfMinutes(
        self, n: int, headID: int, manager: List[int], informTime: List[int]
    ) -> int:
        def dfs(i: int) -> int:
            ans = 0
            for j in g[i]:
                ans = max(ans, dfs(j) + informTime[i])
            return ans

        g = defaultdict(list)
        for i, x in enumerate(manager):
            g[x].append(i)
        return dfs(headID)
```

Solution 2: Explicit Stack

> **How to think about it**
>
> The reporting lines form a tree rooted at the head, and an edge costs that employee's inform time. With $n \le 10^5$, recursing from the head to score every subtree is too deep: a chain makes the call depth n. The time for employee i to inform a whole subtree is i's own inform time plus the slowest direct report. A leaf has no reports, so that time is 0. The value depends only on results that are already known for the children. An explicit stack starts at headID and walks (employee, state) in postorder. On entry we push the exit marker and then the reports, and on exit we store the maximum of informTime[i] + time[j]. The head's time is the answer.

We first build an adjacent list g according to the manager array, where g[i] represents all direct subordinates of employee i.

The time for employee i to inform the whole subtree is informTime[i] plus the maximum time among the direct reports, or 0 when there are no reports. An explicit stack walks from headID in postorder and writes that time when the node is left. The answer is the head's time.

The time complexity is O(n), and the space complexity is O(n). Where n is the number of employees.

Python 3

```python
class Solution:
    def numOfMinutes(
        self, n: int, headID: int, manager: List[int], informTime: List[int]
    ) -> int:
        g = [[] for _ in range(n)]
        for i, x in enumerate(manager):
            if x != -1:
                g[x].append(i)
        time = [0] * n
        stk = [(headID, 0)]
        while stk:
            i, state = stk.pop()
            if state == 0:
                stk.append((i, 1))
                for j in g[i]:
                    stk.append((j, 0))
            else:
                ans = 0
                for j in g[i]:
                    ans = max(ans, time[j] + informTime[i])
                time[i] = ans
        return time[headID]
```

```

```
    times = inform_times(n, head_id, manager, inform_time)
    last = head_id
    for employee in range(n):
        if times[employee] > times[last]:
            last = employee
    return last
```

947. Most Stones Removed with Same Row or Column

Medium · Depth-First Search, Union Find, Graph, Hash Table, Bipartite Graph

leetcode.com/problems/most-stones-removed-with-same-row-or-column

★ **TOP 10 PROBLEM** in Union-Find (Disjoint Set): master this one first

Also appears in pattern 31 Union-Find (Disjoint Set)

PROBLEM

On a 2D plane, we place `n` stones at some integer coordinate points. Each coordinate point may have at most one stone.

A stone can be removed if it shares either **the same row or the same column** as another stone that has not been removed.

Given an array `stones` of length `n` where `stones[i] = [x_i, y_i]` represents the location of the `i^th` stone, return *the largest possible number of stones that can be removed*.

Example 1:

```
Input: stones = [[0,0],[0,1],[1,0],[1,2],[2,1],[2,2]]
Output: 5
Explanation: One way to remove 5 stones is as follows:
1. Remove stone [2,2] because it shares the same row as [2,1].
2. Remove stone [2,1] because it shares the same column as [0,1].
3. Remove stone [1,2] because it shares the same row as [1,0].
4. Remove stone [1,0] because it shares the same column as [0,0].
5. Remove stone [0,1] because it shares the same row as [0,0].
Stone [0,0] cannot be removed since it does not share a row/column with another stone still on the
plane.
```

Example 2:

```
Input: stones = [[0,0],[0,2],[1,1],[2,0],[2,2]]
Output: 3
Explanation: One way to make 3 moves is as follows:
1. Remove stone [2,2] because it shares the same row as [2,0].
2. Remove stone [2,0] because it shares the same column as [0,0].
3. Remove stone [0,2] because it shares the same row as [0,0].
Stones [0,0] and [1,1] cannot be removed since they do not share a row/column with another stone still
on the plane.
```

Example 3:

```
Input: stones = [[0,0]]
Output: 0
Explanation: [0,0] is the only stone on the plane, so you cannot remove it.
```

Constraints:

- `1 <= stones.length <= 1000`
- `0 <= x_i, y_i <= 10^4`
- No two stones are at the same coordinate point.

SOLUTIONS (PYTHON 3)

Solution 1: Union-Find

> **How to think about it**
>
> Stones that share a row or column can reach each other. One stone remains per component, so the answer is n minus the number of components. Union every pair that shares a row or column; each successful union is one removable stone.

We can use a union-find data structure to maintain the relationships between stones. If two stones are in the same row or column, we consider them to be connected and use the union-find to link them together. In the end, we count how many connected components there are in the union-find, which corresponds to the number of stones that can remain. Therefore, the total number of stones that can be removed is the total number of stones minus the number of stones that can remain. We can also record the number of successful unions during the merge process, which equals the number of stones that can be removed.

The time complexity is $O(n^2 \times \alpha(n))$, and the space complexity is $O(n)$. Here, n is the number of stones.

Python 3

```python
class UnionFind:
    def __init__(self, n):
        self.p = list(range(n))
        self.size = [1] * n

    def find(self, x):
        if self.p[x] != x:
            self.p[x] = self.find(self.p[x])
        return self.p[x]

    def union(self, a, b):
        pa, pb = self.find(a), self.find(b)
        if pa == pb:
            return False
        if self.size[pa] > self.size[pb]:
            self.p[pb] = pa
            self.size[pa] += self.size[pb]
        else:
            self.p[pa] = pb
            self.size[pb] += self.size[pa]
        return True

class Solution:
    def removeStones(self, stones: List[List[int]]) -> int:
        uf = UnionFind(len(stones))
        ans = 0
        for i, (x1, y1) in enumerate(stones):
            for j, (x2, y2) in enumerate(stones[:i]):
                if x1 == x2 or y1 == y2:
                    ans += uf.union(i, j)
        return ans
```

Solution 2: Union-Find (Optimized)

> **How to think about it**
>
> Method 1 links stone pairs and is quadratic. Treat rows and columns as elements: shift columns by an offset and union each stone's row with its column, so a shared row or column connects automatically. Remaining components equal the number of distinct row roots.

We can add an offset to the y-coordinates of the stones, allowing us to unify the x-coordinates and y-coordinates. Then, we use a union-find data structure to maintain the relationship between x-coordinates and y-coordinates.

We iterate through each stone, merging its x-coordinate with its y-coordinate.

Finally, we iterate through all the stones again, putting the root node of each stone's x-coordinate into a set. The number of elements in this set represents the number of stones that can remain. Therefore, the total number of stones that can be removed is the total number of stones minus the number of stones that can remain.

The time complexity is $O(n \times \alpha(m))$, and the space complexity is $O(m)$. Here, n and m represent the number of stones and the maximum value of the coordinates, respectively.

Python 3

```
class UnionFind:
    def __init__(self, n):
        self.p = list(range(n))
        self.size = [1] * n

    def find(self, x):
        if self.p[x] != x:
            self.p[x] = self.find(self.p[x])
        return self.p[x]

    def union(self, a, b):
        pa, pb = self.find(a), self.find(b)
        if pa == pb:
            return False
        if self.size[pa] > self.size[pb]:
            self.p[pb] = pa
            self.size[pa] += self.size[pb]
        else:
            self.p[pa] = pb
            self.size[pb] += self.size[pa]
        return True

class Solution:
    def removeStones(self, stones: List[List[int]]) -> int:
        m = 10001
        uf = UnionFind(m << 1)
        for x, y in stones:
            uf.union(x, y + m)
        return len(stones) - len({uf.find(x) for x, _ in stones})
```

Solution 3: Breadth-First Search

> **How to think about it**
>
> Without union-find, build a graph on shared rows or columns and BFS to count components. The implementation is direct; the worst-case number of edges is still quadratic.

Connect stones that share a row or a column. Each connected component can keep only one stone, so the answer is the number of stones minus the number of components.

Start a BFS from every unvisited stone to mark its component.

The time complexity is $O(n^2)$ and the space complexity is $O(n^2)$, where n is the number of stones.

Python 3 (written for this guide: the doocs page has no Python 3 version of this solution)

```python
class Solution:
    def removeStones(self, stones: List[List[int]]) -> int:
        n = len(stones)
        graph = [[] for _ in range(n)]
        for i in range(n):
            for j in range(i + 1, n):
                if stones[i][0] == stones[j][0] or stones[i][1] == stones[j][1]:
                    graph[i].append(j)
                    graph[j].append(i)
        seen = [False] * n
        components = 0
        for start in range(n):
            if seen[start]:
                continue
            components += 1
            seen[start] = True
            queue = deque([start])
            while queue:
                i = queue.popleft()
                for j in graph[i]:
                    if not seen[j]:
                        seen[j] = True
                        queue.append(j)
        return n - components
```

```

2101. Detonate the Maximum Bombs

Medium · Depth-First Search, Breadth-First Search, Graph, Geometry, Array, Math

leetcode.com/problems/detonate-the-maximum-bombs

PROBLEM

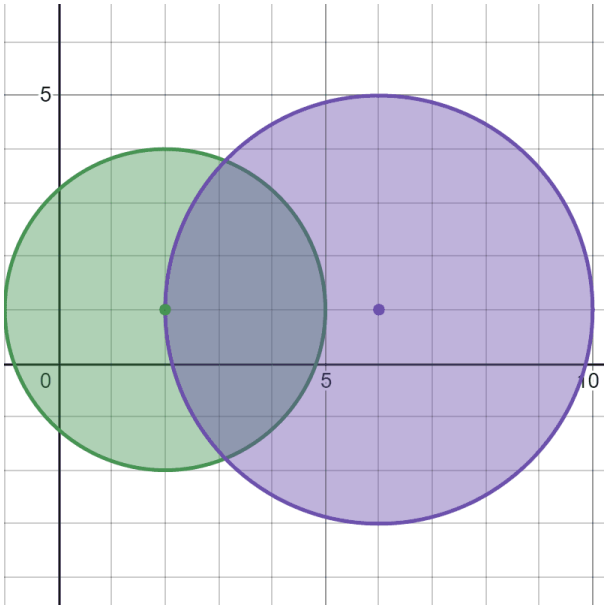
You are given a list of bombs. The **range** of a bomb is defined as the area where its effect can be felt. This area is in the shape of a **circle** with the center as the location of the bomb.

The bombs are represented by a **0-indexed** 2D integer array `bombs` where `bombs[i] = [x_i, y_i, r_i]`. x_i and y_i denote the X-coordinate and Y-coordinate of the location of the i^{th} bomb, whereas r_i denotes the **radius** of its range.

You may choose to detonate a **single** bomb. When a bomb is detonated, it will detonate **all bombs** that lie in its range. These bombs will further detonate the bombs that lie in their ranges.

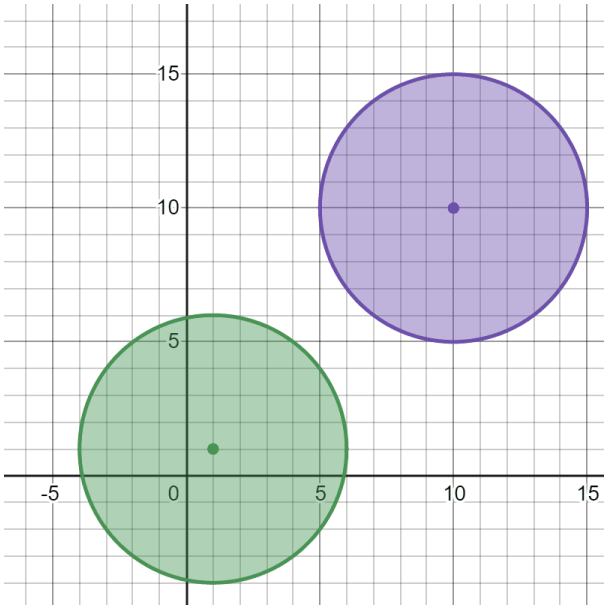
Given the list of `bombs`, return *the **maximum** number of bombs that can be detonated if you are allowed to detonate **only one** bomb.*

Example 1:



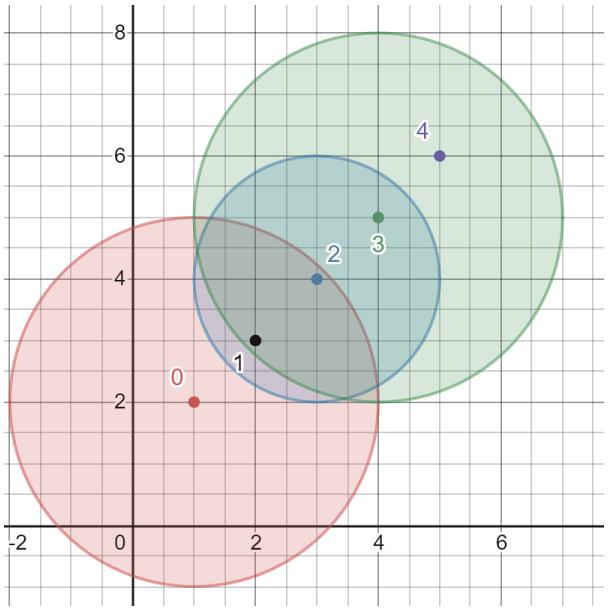
```
Input: bombs = [[2,1,3],[6,1,4]]
Output: 2
Explanation:
The above figure shows the positions and ranges of the 2 bombs.
If we detonate the left bomb, the right bomb will not be affected.
But if we detonate the right bomb, both bombs will be detonated.
So the maximum bombs that can be detonated is max(1, 2) = 2.
```

Example 2:



Input: bombs = [[1,1,5],[10,10,5]]
Output: 1
Explanation:
Detonating either bomb will not detonate the other bomb, so the maximum number of bombs that can be detonated is 1.

Example 3:



Input: bombs = [[1,2,3],[2,3,1],[3,4,2],[4,5,3],[5,6,4]]
Output: 5
Explanation:
The best bomb to detonate is bomb 0 because:
- Bomb 0 detonates bombs 1 and 2. The red circle denotes the range of bomb 0.
- Bomb 2 detonates bomb 3. The blue circle denotes the range of bomb 2.
- Bomb 3 detonates bomb 4. The green circle denotes the range of bomb 3.
Thus all 5 bombs are detonated.

Constraints:

- 1 <= bombs.length <= 100
- bombs[i].length == 3

- $1 <= x_i, y_i, r_i <= 10^5$

SOLUTION (PYTHON 3)

Solution 1: BFS

How to think about it

Detonation propagates along the “inside radius” relation, so we need the largest reachable set starting from one bomb. Treating the relation as undirected would miss one-way reachability when radii differ; rescanning all bombs on every detonation repeats the same distance work. With n≤ 100, building a directed graph g from every pair costs $O(n^2)$. A chain detonation is then a reachability search, which BFS solves in $O(n^2)$ per source. We therefore add edges by pairwise distance checks, then BFS from each bomb, returning n as soon as some search visits every vertex.

We define an array g of length n, where g[i] represents the indices of all bombs that can be triggered by bomb i within its explosion range.

Next, we iterate over all bombs. For two bombs (x_1, y_1, r_1) and (x_2, y_2, r_2), we calculate the distance between them $dist = \sqrt{(x_1 - x_2)^2 + (y_1 - y_2)^2}$. If $dist \le r_1$, then bomb i can trigger bomb j within its explosion range, so we add j to g[i]. If $dist \le r_2$, then bomb j can trigger bomb i within its explosion range, so we add i to g[j].

Next, we iterate over all bombs. For each bomb k, we use breadth-first search to calculate the indices of all bombs that can be triggered by bomb k within its explosion range and record them. If the number of these bombs equals n, then we can trigger all bombs and directly return n. Otherwise, we record the number of these bombs and return the maximum value.

The time complexity is $O(n^3)$ and the space complexity is $O(n^2)$, where n is the number of bombs.

Python 3

```python
class Solution:
    def maximumDetonation(self, bombs: List[List[int]]) -> int:
        n = len(bombs)
        g = [[] for _ in range(n)]
        for i in range(n - 1):
            x1, y1, r1 = bombs[i]
            for j in range(i + 1, n):
                x2, y2, r2 = bombs[j]
                dist = hypot(x1 - x2, y1 - y2)
                if dist <= r1:
                    g[i].append(j)
                if dist <= r2:
                    g[j].append(i)
        ans = 0
        for k in range(n):
            vis = {k}
            q = [k]
            for i in q:
                for j in g[i]:
                    if j not in vis:
                        vis.add(j)
                        q.append(j)
            if len(vis) == n:
                return n
            ans = max(ans, len(vis))
        return ans
```

```

1905. Count Sub Islands

Medium · Depth-First Search, Breadth-First Search, Union Find, Array, Matrix

leetcode.com/problems/count-sub-islands

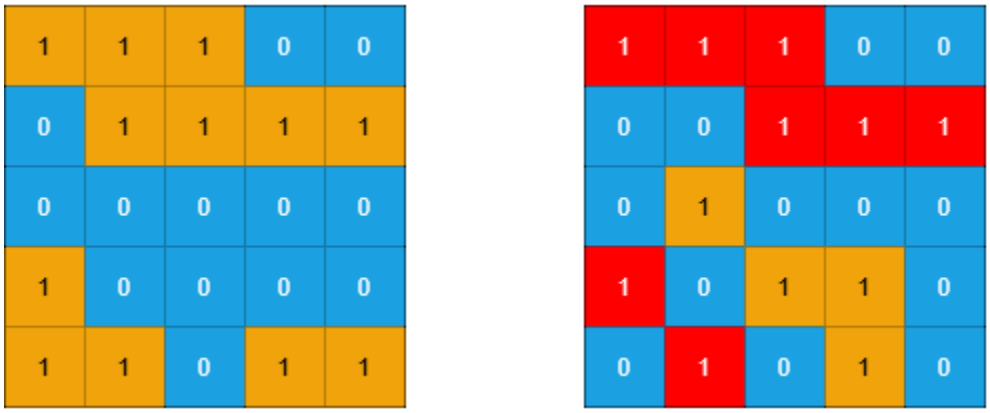
PROBLEM

You are given two `m x n` binary matrices `grid1` and `grid2` containing only `0`'s (representing water) and `1`'s (representing land). An **island** is a group of `1`'s connected **4-directionally** (horizontal or vertical). Any cells outside of the grid are considered water cells.

An island in `grid2` is considered a **sub-island** if there is an island in `grid1` that contains **all** the cells that make up **this** island in `grid2`.

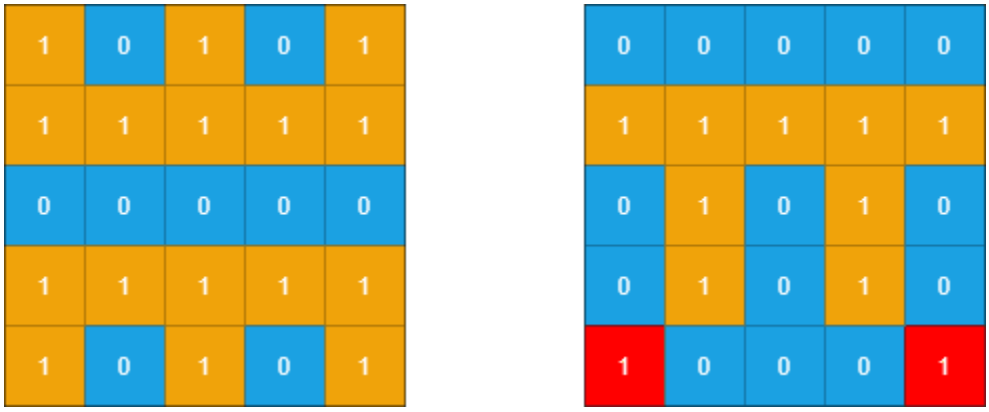
Return the ***number** of islands in `grid2` that are considered **sub-islands***.

Example 1:



```
Input: grid1 = [[1,1,1,0,0],[0,1,1,1,1],[0,0,0,0,0],[1,0,0,0,0],[1,1,0,1,1]], grid2 =
[[1,1,1,0,0],[0,0,1,1,1],[0,1,0,0,0],[1,0,1,1,0],[0,1,0,1,0]]
Output: 3
Explanation: In the picture above, the grid on the left is grid1 and the grid on the right is grid2.
The 1s colored red in grid2 are those considered to be part of a sub-island. There are three
sub-islands.
```

Example 2:



```
Input: grid1 = [[1,0,1,0,1],[1,1,1,1,1],[0,0,0,0,0],[1,1,1,1,1],[1,0,1,0,1]], grid2 =
[[0,0,0,0,0],[1,1,1,1,1],[0,1,0,1,0],[0,1,0,1,0],[1,0,0,0,1]]
Output: 2
Explanation: In the picture above, the grid on the left is grid1 and the grid on the right is grid2.
The 1s colored red in grid2 are those considered to be part of a sub-island. There are two sub-islands.
```

Constraints:

- `m == grid1.length == grid2.length`
- `n == grid1[i].length == grid2[i].length`
- `1 <= m, n <= 500`
- `grid1[i][j]` and `grid2[i][j]` are either `0` or `1`.

SOLUTIONS (PYTHON 3)

Solution 1: DFS

How to think about it

Each island of grid2 is a sub-island only if every land cell also lies on land in grid1. Checking cells in isolation cannot group them by island. One DFS (or BFS) walks a component, zeros grid2 to mark it visited, and ANDs the corresponding grid1 cells to decide whether the island is valid. A linear scan starts a search at every remaining 1 in grid2 and sums the return values.

We can traverse each cell (i, j) in the matrix `grid2`. If the value of the cell is 1, we start a depth-first search from this cell, set the value of all cells connected to this cell to 0, and record whether the corresponding cell in `grid1` is also 1 for all cells connected to this cell. If it is 1, it means that this cell is also an island in `grid1`, otherwise it is not. Finally, we count the number of sub-islands in `grid2`.

The time complexity is O(m × n), and the space complexity is O(m × n). Here, m and n are the number of rows and columns of the matrices `grid1` and `grid2`, respectively.

Python 3

```
class Solution:
    def countSubIslands(self, grid1: List[List[int]], grid2: List[List[int]]) -> int:
        def dfs(i: int, j: int) -> int:
            ok = grid1[i][j]
            grid2[i][j] = 0
            for a, b in pairwise(dirs):
                x, y = i + a, j + b
                if 0 <= x < m and 0 <= y < n and grid2[x][y] and not dfs(x, y):
                    ok = 0
            return ok

        m, n = len(grid1), len(grid1[0])
        dirs = (-1, 0, 1, 0, -1)
        return sum(dfs(i, j) for i in range(m) for j in range(n) if grid2[i][j])
```

Solution 2: Explicit Stack

How to think about it

An island of grid2 is a sub-island only when every land cell is also land in grid1. Cells that are not grouped by connectivity cannot be counted as one island. Recursing along a snake of 1000 land cells overflows the call stack, and m,n≤ 500 can hold that snake. The check only has to walk the whole island, zero grid2, and AND the matching grid1 cells. It does not need a recursive return. When a remaining 1 is found, push it onto an explicit stack. Pop a cell, AND it with grid1, and push each neighboring land cell after marking it. The sum of these results is the number of sub-islands.

Scan every cell of `grid2`. When it is still 1, walk that island with an explicit stack, set `grid2` to 0 along the way, and AND the matching `grid1` cells. A result of 1 means the island is a sub-island.

The time complexity is O(m × n), and the space complexity is O(m × n). Here, m and n are the number of rows and columns of the matrices `grid1` and `grid2`, respectively.

Python 3

```
class Solution:
    def countSubIslands(self, grid1: List[List[int]], grid2: List[List[int]]) -> int:
        def flood(i: int, j: int) -> int:
            ok = 1
            grid2[i][j] = 0
            stk = [(i, j)]
            while stk:
                i, j = stk.pop()
                ok &= grid1[i][j]
                for a, b in pairwise(dirs):

1514. Path with Maximum Probability

Medium · Graph, Array, Shortest Path, Dijkstra, Heap (Priority Queue)

leetcode.com/problems/path-with-maximum-probability

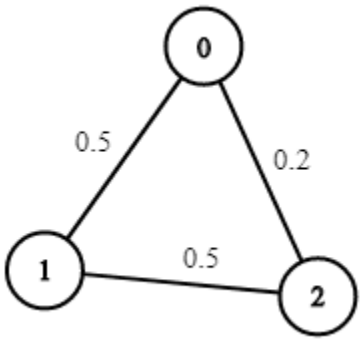
PROBLEM

You are given an undirected weighted graph of `n` nodes (0-indexed), represented by an edge list where `edges[i] = [a, b]` is an undirected edge connecting the nodes `a` and `b` with a probability of success of traversing that edge `succProb[i]`.

Given two nodes `start` and `end`, find the path with the maximum probability of success to go from `start` to `end` and return its success probability.

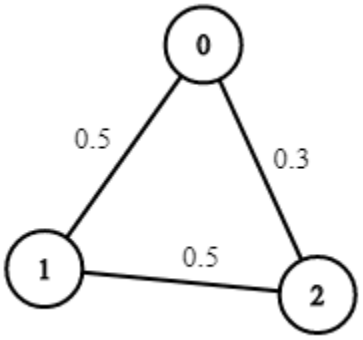
If there is no path from `start` to `end`, **return 0**. Your answer will be accepted if it differs from the correct answer by at most **1e-5**.

Example 1:



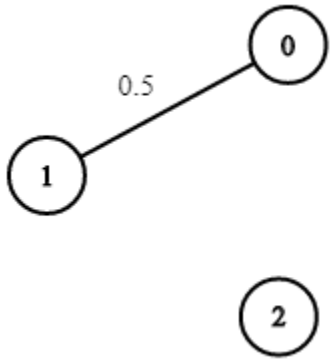
```
Input: n = 3, edges = [[0,1],[1,2],[0,2]], succProb = [0.5,0.5,0.2], start = 0, end = 2
Output: 0.25000
Explanation: There are two paths from start to end, one having a probability of success = 0.2 and the other has 0.5 * 0.5 = 0.25.
```

Example 2:



```
Input: n = 3, edges = [[0,1],[1,2],[0,2]], succProb = [0.5,0.5,0.3], start = 0, end = 2
Output: 0.30000
```

Example 3:



```
Input: n = 3, edges = [[0,1]], succProb = [0.5], start = 0, end = 2
Output: 0.00000
Explanation: There is no path between 0 and 2.
```

Constraints:

- `2 <= n <= 10^4`
- `0 <= start, end < n`
- `start != end`
- `0 <= a, b < n`
- `a != b`
- `0 <= succProb.length == edges.length <= 2*10^4`
- `0 <= succProb[i] <= 1`
- There is at most one edge between every two nodes.

SOLUTION (PYTHON 3)

Solution 1: Heap-Optimized Dijkstra Algorithm

How to think about it

We want the maximum success probability from start to end on an undirected graph whose edge weights multiply. n≤ 10^4 and m≤ 2× 10^4, so listing simple paths is impossible. Treating weights as the opposite of a cost, the problem is isomorphic to a shortest path: probabilities multiply and lie in (0,1], so the optimum has optimal substructure. A max-heap Dijkstra relaxes neighbors by the product of the current probability and the edge; storing negated values simulates the max-heap. The first time the destination is settled is the answer.

We can use Dijkstra's algorithm to find the shortest path, but here we modify it slightly to find the path with the maximum probability.

We use a priority queue (max-heap) pq to store the probability from the starting point to each node and the node's identifier. Initially, we set the probability of the starting point to 1 and the probabilities of the other nodes to 0, then add the starting point to pq.

In each iteration, we take out the node a with the highest probability from pq and its probability w. If the probability of node a is already greater than w, we can skip this node. Otherwise, we traverse all adjacent edges (a, b) of a. If the probability of b is less than the probability of a multiplied by the probability of (a, b), we update the probability of b and add b to pq.

Finally, we obtain the maximum probability from the starting point to the endpoint.

The time complexity is O(m × log m), and the space complexity is O(m). Here, m is the number of edges.

Python 3

```python
class Solution:
    def maxProbability(
        self,
        n: int,
        edges: List[List[int]],
        succProb: List[float],
        start_node: int,
        end_node: int,
    ) -> float:
        g: List[List[Tuple[int, float]]] = [[] for _ in range(n)]
        for (a, b), p in zip(edges, succProb):
            g[a].append((b, p))
            g[b].append((a, p))
        pq = [(-1, start_node)]
        dist = [0] * n
        dist[start_node] = 1
        while pq:
            w, a = heappop(pq)
            w = -w
            if dist[a] > w:
                continue
            for b, p in g[a]:
                if (t := w * p) > dist[b]:
                    dist[b] = t
                    heappush(pq, (-t, b))
        return dist[end_node]
```

PATTERN 16 · GRAPH DFS · PROBLEM 20 OF 20

827. Making A Large Island

Hard · Depth-First Search, Breadth-First Search, Union Find, Array, Matrix

leetcode.com/problems/making-a-large-island

★ **TOP 10 PROBLEM** in Graph DFS, Union-Find (Disjoint Set): master this one first

Also appears in pattern 31 Union-Find (Disjoint Set)

PROBLEM

You are given an `n x n` binary matrix `grid`. You are allowed to change **at most one** `0` to be `1`.

Return *the size of the largest **island** in* `grid` *after applying this operation*.

An **island** is a 4-directionally connected group of `1`s.

Example 1:

```
Input: grid = [[1,0],[0,1]]
Output: 3
Explanation: Change one 0 to 1 and connect two 1s, then we get an island with area = 3.
```

Example 2:

```
Input: grid = [[1,1],[1,0]]
Output: 4
Explanation: Change the 0 to 1 and make the island bigger, only one island with area = 4.
```

Example 3:

```
Input: grid = [[1,1],[1,1]]
Output: 4
Explanation: Can't change any 0 to 1, only one island with area = 4.
```

Constraints:

- `n == grid.length`
- `n == grid[i].length`
- `1 <= n <= 500`
- `grid[i][j]` is either `0` or `1`.

SOLUTION (PYTHON 3)

Solution 1: DFS

How to think about it

We may flip at most one 0 and want the largest island. n≤ 500, so flooding from every 0 would revisit the same islands. DFS first labels each island and records its area. Then each 0 sums the distinct neighboring islands plus one. If the grid is all ones, the answer is the largest existing island.

We can assign a unique identifier to each connected component, using an array p to record the connected component each position belongs to, i.e., p[i][j] represents the connected component number of (i, j). Use an array cnt to record the size of each connected component, i.e., cnt[root] represents the size of the connected component root.

First, we traverse the entire matrix. For each position grid[i][j] = 1 and p[i][j] = 0, we perform a depth-first search on it, mark its connected component as root, and count the size of the connected component.

Then, we traverse the entire matrix again. For each position grid[i][j] = 0, we find the connected components of the four positions above, below, left, and right of it, add up the sizes of these connected components, and add 1 for the current position, to get the maximum island area after changing the current position to 1.

The time complexity is $O(n^2)$, and the space complexity is $O(n^2)$. Where n is the length of the sides of the matrix.

Python 3

```python
class Solution:
    def largestIsland(self, grid: List[List[int]]) -> int:
        def dfs(i: int, j: int):
            p[i][j] = root
            cnt[root] += 1
            for a, b in pairwise(dirs):
                x, y = i + a, j + b
                if 0 <= x < n and 0 <= y < n and grid[x][y] and p[x][y] == 0:
                    dfs(x, y)

        n = len(grid)
        cnt = Counter()
        p = [[0] * n for _ in range(n)]
        dirs = (-1, 0, 1, 0, -1)
        root = 0
        for i, row in enumerate(grid):
            for j, x in enumerate(row):
                if x and p[i][j] == 0:
                    root += 1
                    dfs(i, j)
        ans = max(cnt.values() or [0])
        for i, row in enumerate(grid):
            for j, x in enumerate(row):
                if x == 0:
                    s = set()
                    for a, b in pairwise(dirs):
                        x, y = i + a, j + b
                        if 0 <= x < n and 0 <= y < n:
                            s.add(p[x][y])
                    ans = max(ans, sum(cnt[root] for root in s) + 1)
        return ans
```

PATTERN 17 · GRAPH BFS · PROBLEM 1 OF 20

994. Rotting Oranges

Medium · Breadth-First Search, Array, Matrix

leetcode.com/problems/rotting-oranges

★ **TOP 10 PROBLEM** in Graph BFS: master this one first

Also appears in pattern 18 Matrix / Grid Traversal

PROBLEM

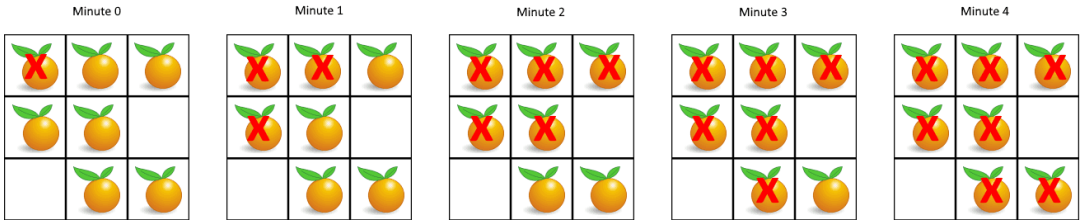
You are given an `m x n grid` where each cell can have one of three values:

- `0` representing an empty cell,
- `1` representing a fresh orange, or
- `2` representing a rotten orange.

Every minute, any fresh orange that is **4-directionally adjacent** to a rotten orange becomes rotten.

Return *the minimum number of minutes that must elapse until no cell has a fresh orange*. If *this is impossible, return* `-1`.

Example 1:



```
Input: grid = [[2,1,1],[1,1,0],[0,1,1]]
Output: 4
```

Example 2:

```
Input: grid = [[2,1,1],[0,1,1],[1,0,1]]
Output: -1
Explanation: The orange in the bottom left corner (row 2, column 0) is never rotten, because rotting
only happens 4-directionally.
```

Example 3:

```
Input: grid = [[0,2]]
Output: 0
Explanation: Since there are already no fresh oranges at minute 0, the answer is just 0.
```

Constraints:

- `m == grid.length`
- `n == grid[i].length`
- `1 <= m, n <= 10`
- `grid[i][j]` is `0`, `1`, or `2`.

SOLUTION (PYTHON 3)

Solution 1: BFS

How to think about it

Rot spreads to four-neighbors each minute; we want the time until every orange is rotten. Simultaneous multi-source spread is an unweighted shortest path. Enqueue every rotten orange and count the fresh ones, then BFS by layers. The layer that zeroes the fresh count is the answer; leftover fresh oranges yield -1.

First, we traverse the entire grid once, count the number of fresh oranges, denoted as cnt, and add the coordinates of all rotten oranges to the queue q.

Next, we perform a breadth-first search. In each round of the search, we let all the rotten oranges in the queue rot the fresh oranges in four directions, until the queue is empty or the number of fresh oranges is 0.

Finally, if the number of fresh oranges is 0, we return the current round number, otherwise, we return -1.

The time complexity is O(m × n), and the space complexity is O(m × n). Where m and n are the number of rows and columns of the grid, respectively.

Python 3

```python
class Solution:
    def orangesRotting(self, grid: List[List[int]]) -> int:
        m, n = len(grid), len(grid[0])
        cnt = 0
        q = deque()
        for i, row in enumerate(grid):
            for j, x in enumerate(row):
                if x == 2:
                    q.append((i, j))
                elif x == 1:
                    cnt += 1
        ans = 0
        dirs = (-1, 0, 1, 0, -1)
        while q and cnt:
            ans += 1
            for _ in range(len(q)):
                i, j = q.popleft()
                for a, b in pairwise(dirs):
                    x, y = i + a, j + b
                    if 0 <= x < m and 0 <= y < n and grid[x][y] == 1:
                        grid[x][y] = 2
                        q.append((x, y))
                        cnt -= 1
                        if cnt == 0:
                            return ans
        return -1 if cnt else 0
```

leetcode.com/problems/01-matrix

★ **TOP 10 PROBLEM** in Graph BFS, Matrix / Grid Traversal: master this one first

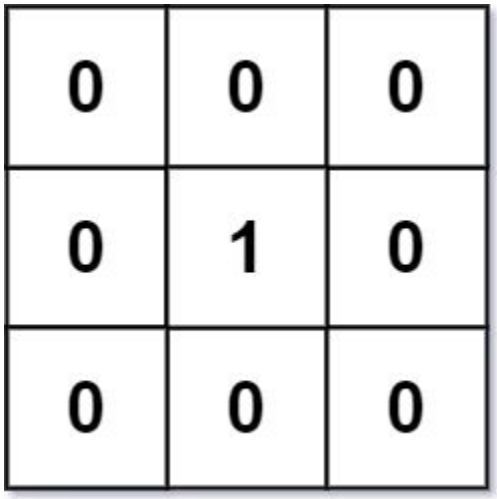
Also appears in pattern 18 Matrix / Grid Traversal

PROBLEM

Given an `m x n` binary matrix `mat`, return *the distance of the nearest* `0` *for each cell*.

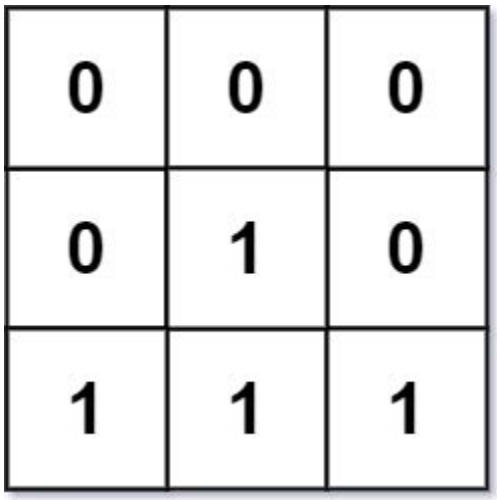
The distance between two cells sharing a common edge is `1`.

Example 1:



```
Input: mat = [[0,0,0],[0,1,0],[0,0,0]]
Output: [[0,0,0],[0,1,0],[0,0,0]]
```

Example 2:



```
Input: mat = [[0,0,0],[0,1,0],[1,1,1]]
Output: [[0,0,0],[0,1,0],[1,2,1]]
```

Constraints:

- `m == mat.length`
- `n == mat[i].length`
- `1 <= m, n <= 10^4`
- `1 <= m * n <= 10^4`
- `mat[i][j]` is either `0` or `1`.
- There is at least one `0` in `mat`.

Note: This question is the same as 1765: https://leetcode.com/problems/map-of-highest-peak/

SOLUTION (PYTHON 3)

Solution 1: BFS

> **How to think about it**
>
> Each 1 needs its distance to the nearest 0. A separate BFS from every 1 repeats O(mn) searches. Multi-source BFS: enqueue every 0 at distance 0 and expand to unseen neighbors. The first visit is the nearest 0. One queue pass covers the grid.

We create a matrix ans of the same size as mat and initialize all elements to -1.

Then, we traverse mat, adding the coordinates (i, j) of all 0 elements to the queue q, and setting ans[i][j] to 0.

Next, we use Breadth-First Search (BFS), removing an element (i, j) from the queue and traversing its four directions. If the element in that direction (x, y) satisfies $0 \le x < m$, $0 \le y < n$ and ans[x][y] = -1, then we set ans[x][y] to ans[i][j] + 1 and add (x, y) to the queue q.

Finally, we return ans.

The time complexity is $O(m \times n)$, and the space complexity is $O(m \times n)$. Here, m and n are the number of rows and columns in the matrix mat, respectively.

Python 3

```
class Solution:
    def updateMatrix(self, mat: List[List[int]]) -> List[List[int]]:
        m, n = len(mat), len(mat[0])
        ans = [[-1] * n for _ in range(m)]
        q = deque()
        for i, row in enumerate(mat):
            for j, x in enumerate(row):
                if x == 0:
                    ans[i][j] = 0
                    q.append((i, j))
        dirs = (-1, 0, 1, 0, -1)
        while q:
            i, j = q.popleft()
            for a, b in pairwise(dirs):
                x, y = i + a, j + b
                if 0 <= x < m and 0 <= y < n and ans[x][y] == -1:
                    ans[x][y] = ans[i][j] + 1
                    q.append((x, y))
        return ans
```

PATTERN 17 · GRAPH BFS · PROBLEM 3 OF 20

1091. Shortest Path in Binary Matrix

Medium · Breadth-First Search, Array, Matrix

leetcode.com/problems/shortest-path-in-binary-matrix

★ **TOP 10 PROBLEM** in Graph BFS: master this one first

Also appears in pattern 18 Matrix / Grid Traversal

PROBLEM

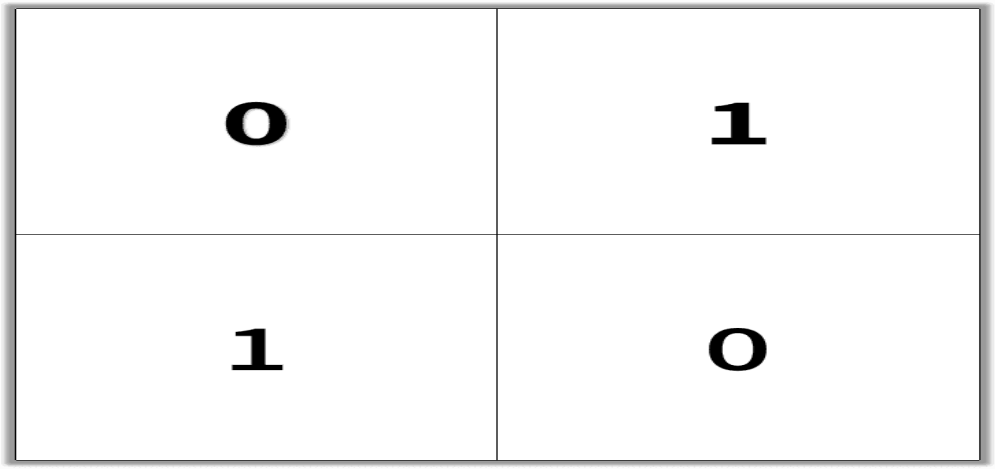
Given an `n x n` binary matrix `grid`, return *the length of the shortest **clear path** in the matrix*. If there is no clear path, return `-1`.

A **clear path** in a binary matrix is a path from the **top-left** cell (i.e., `(0, 0)`) to the **bottom-right** cell (i.e., `(n - 1, n - 1)`) such that:

- All the visited cells of the path are `0`.
- All the adjacent cells of the path are **8-directionally** connected (i.e., they are different and they share an edge or a corner).

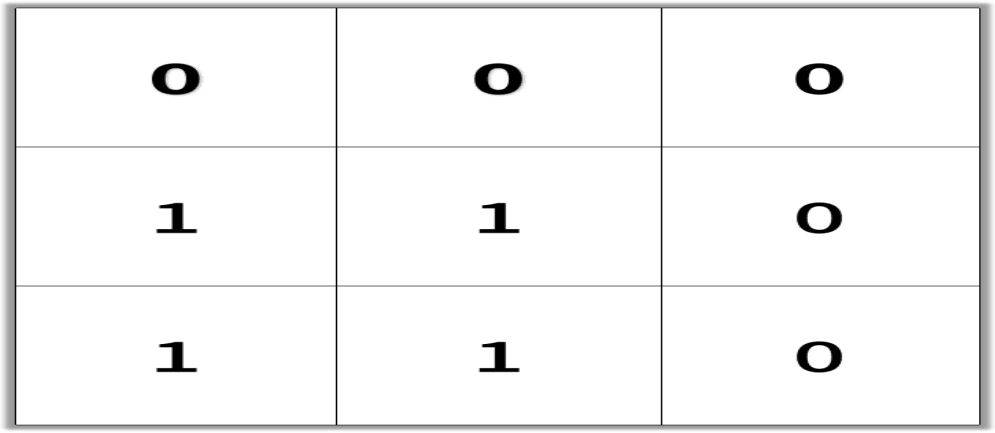
The **length of a clear path** is the number of visited cells of this path.

Example 1:



```
Input: grid = [[0,1],[1,0]]
Output: 2
```

Example 2:



```
Input: grid = [[0,0,0],[1,1,0],[1,1,0]]
Output: 4
```

Example 3:

```
Input: grid = [[1,0,0],[1,1,0],[1,1,0]]
Output: -1
```

Constraints:

- `n == grid.length`
- `n == grid[i].length`
- `1 <= n <= 100`
- `grid[i][j] is 0 or 1`

SOLUTION (PYTHON 3)

Solution 1

How to think about it

The eight-connected path has unit weights, so BFS by layer is the shortest length. n≤ 100 lets us mark visited cells in the grid. A blocked origin has no path. Enqueue (0,0) and mark it 1. Each layer expands the eight neighbors that are still 0. Reaching (n-1,n-1) yields the current layer index. If the queue empties first, the answer is -1.

Python 3

```python
class Solution:
    def shortestPathBinaryMatrix(self, grid: List[List[int]]) -> int:
        if grid[0][0]:
            return -1
        n = len(grid)
        grid[0][0] = 1
        q = deque([(0, 0)])
        ans = 1
        while q:
            for _ in range(len(q)):
                i, j = q.popleft()
                if i == j == n - 1:
                    return ans
                for x in range(i - 1, i + 2):
                    for y in range(j - 1, j + 2):
                        if 0 <= x < n and 0 <= y < n and grid[x][y] == 0:
                            grid[x][y] = 1
                            q.append((x, y))
            ans += 1
        return -1
```

Complexity. Time: O(n^2). Space: O(n^2).

```

PATTERN 17 · GRAPH BFS · PROBLEM 4 OF 20

752. Open the Lock

Medium · Breadth-First Search, Array, Hash Table, String, Bidirectional Search

leetcode.com/problems/open-the-lock

★ **TOP 10 PROBLEM** in Graph BFS: master this one first

PROBLEM

You have a lock in front of you with 4 circular wheels. Each wheel has 10 slots: `'0', '1', '2', '3', '4', '5', '6', '7', '8', '9'`. The wheels can rotate freely and wrap around: for example we can turn `'9'` to be `'0'`, or `'0'` to be `'9'`. Each move consists of turning one wheel one slot.

The lock initially starts at `'0000'`, a string representing the state of the 4 wheels.

You are given a list of `deadends` dead ends, meaning if the lock displays any of these codes, the wheels of the lock will stop turning and you will be unable to open it.

Given a `target` representing the value of the wheels that will unlock the lock, return the minimum total number of turns required to open the lock, or -1 if it is impossible.

Example 1:

```
Input: deadends = ["0201","0101","0102","1212","2002"], target = "0202"
Output: 6
Explanation:
A sequence of valid moves would be "0000" -> "1000" -> "1100" -> "1200" -> "1201" -> "1202" -> "0202".
Note that a sequence like "0000" -> "0001" -> "0002" -> "0102" -> "0202" would be invalid,
because the wheels of the lock become stuck after the display becomes the dead end "0102".
```

Example 2:

```
Input: deadends = ["8888"], target = "0009"
Output: 1
Explanation: We can turn the last wheel in reverse to move from "0000" -> "0009".
```

Example 3:

```
Input: deadends = ["8887","8889","8878","8898","8788","8988","7888","9888"], target = "8888"
Output: -1
Explanation: We cannot reach the target without getting stuck.
```

Constraints:

- `1 <= deadends.length <= 500`
- `deadends[i].length == 4`
- `target.length == 4`
- target **will not be** in the list `deadends`.
- `target` and `deadends[i]` consist of digits only.

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

A 4-digit lock, one wheel per move, avoiding dead ends. 10^4 states and 8 neighbors each: unweighted shortest path is BFS. Dead ends and visited codes share a set. If `0000` is dead the answer is -1; if it is the target, 0. Expand by layer; neighbors flip one digit by ± 1 on a wheel. The first time we see the target is the distance.

Python 3

```python
class Solution:
    def openLock(self, deadends: List[str], target: str) -> int:
        def next(s):
            res = []
            s = list(s)
            for i in range(4):
                c = s[i]
                s[i] = '9' if c == '0' else str(int(c) - 1)
                res.append(''.join(s))
                s[i] = '0' if c == '9' else str(int(c) + 1)
                res.append(''.join(s))
                s[i] = c
            return res

        if target == '0000':
            return 0
        s = set(deadends)
        if '0000' in s:
            return -1
        q = deque([('0000')])
        s.add('0000')
        ans = 0
        while q:
            ans += 1
            for _ in range(len(q)):
                p = q.popleft()
                for t in next(p):
                    if t == target:
                        return ans
                    if t not in s:
                        q.append(t)
                        s.add(t)
        return -1
```

Complexity. Time: O(D * 10^D) with D = 4 wheels, so a constant. Space: O(10^D).

Solution 2

How to think about it

One-sided BFS may expand most of the cube. The two ends are known, so bidirectional BFS meets in the middle with smaller fronts. Always extend the smaller queue. A neighbor already seen from the other side yields step+1+m_2[t]. Dead ends are skipped on both sides.

Python 3

```python
class Solution:
    def openLock(self, deadends: List[str], target: str) -> int:
        def next(s):
            res = []
            s = list(s)
            for i in range(4):
                c = s[i]
                s[i] = '9' if c == '0' else str(int(c) - 1)
                res.append(''.join(s))
                s[i] = '0' if c == '9' else str(int(c) + 1)
                res.append(''.join(s))
                s[i] = c
            return res

        def extend(m1, m2, q):
            for _ in range(len(q)):
                p = q.popleft()
                step = m1[p]
                for t in next(p):
                    if t in s or t in m1:
                        continue
                    if t in m2:
                        return step + 1 + m2[t]
                    m1[t] = step + 1
                    q.append(t)
            return -1

        def bfs():
            m1, m2 = {"0000": 0}, {target: 0}
            q1, q2 = deque([('0000')]), deque([(target)])
            while q1 and q2:
                t = extend(m1, m2, q1) if len(q1) <= len(q2) else extend(m2, m1, q2)
                if t != -1:
                    return t
            return -1

        if target == '0000':
            return 0
        s = set(deadends)
        if '0000' in s:
            return -1
        return bfs()
```

Complexity. Time: O(D * 10^D) in the worst case, but much faster in practice (two searches meet in the middle). Space: O(10^D).

Solution 3

> **How to think about it**
>
> Bidirectional BFS still expands uniformly. The sum of circular digit distances to the target is an admissible heuristic, so A* pops the target first with dist+f as the key. f never exceeds the true remaining moves (ignoring dead ends). Skip dead codes; decrease-key via a dist map.

Python 3

```python
class Solution:
    def openLock(self, deadends: List[str], target: str) -> int:
        def next(s):
            res = []
            s = list(s)
            for i in range(4):
                c = s[i]
                s[i] = '9' if c == '0' else str(int(c) - 1)
                res.append(''.join(s))
                s[i] = '0' if c == '9' else str(int(c) + 1)
                res.append(''.join(s))
                s[i] = c
            return res

        def f(s):
            ans = 0
            for i in range(4):
                a = ord(s[i]) - ord('0')
                b = ord(target[i]) - ord('0')
                if a > b:
                    a, b = b, a
                ans += min(b - a, a + 10 - b)
            return ans

        if target == '0000':
            return 0
        s = set(deadends)
        if '0000' in s:
            return -1
        start = '0000'
        q = [(f(start), start)]
        dist = {start: 0}
        while q:
            _, state = heappop(q)
            if state == target:
                return dist[state]
            for t in next(state):
                if t in s:
                    continue
                if t not in dist or dist[t] > dist[state] + 1:
                    dist[t] = dist[state] + 1
                    heappush(q, (dist[t] + f(t), t))
        return -1
```

Complexity. Time: O(D * 10^D * log(10^D)) in the worst case with D = 4 wheels (A* only reorders the search). Space: O(10^D).

PATTERN 17 · GRAPH BFS · PROBLEM 5 OF 20

909. Snakes and Ladders

Medium · Breadth-First Search, Array, Matrix

leetcode.com/problems/snakes-and-ladders

★ **TOP 10 PROBLEM** in Graph BFS: master this one first

Also appears in pattern 36 Simulation / Array Rearrangement

PROBLEM

You are given an `n x n` integer matrix `board` where the cells are labeled from `1` to n^2 in a **Boustrophedon style** starting from the bottom left of the board (i.e. `board[n - 1][0]`) and alternating direction each row.

You start on square `1` of the board. In each move, starting from square `curr`, do the following:

- Choose a destination square `next` with a label in the range `[curr + 1, min(curr + 6, n^2)]`.
  - This choice simulates the result of a standard **6-sided die roll**: i.e., there are always at most 6 destinations, regardless of the size of the board.
- If `next` has a snake or ladder, you **must** move to the destination of that snake or ladder. Otherwise, you move to `next`.
- The game ends when you reach the square n^2.

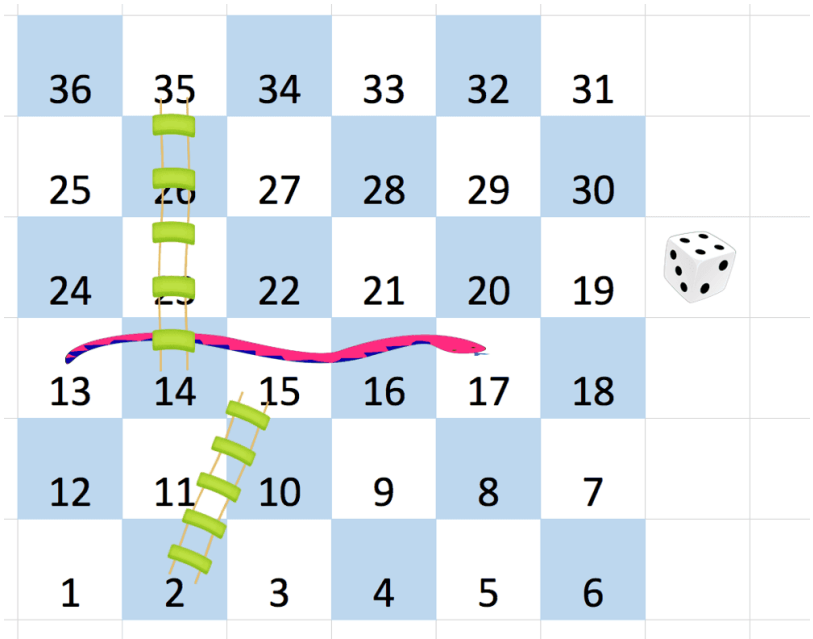
A board square on row `r` and column `c` has a snake or ladder if `board[r][c] != -1`. The destination of that snake or ladder is `board[r][c]`. Squares `1` and n^2 are not the starting points of any snake or ladder.

Note that you only take a snake or ladder at most once per dice roll. If the destination to a snake or ladder is the start of another snake or ladder, you do **not** follow the subsequent snake or ladder.

- For example, suppose the board is `[[-1,4],[-1,3]]`, and on the first move, your destination square is `2`. You follow the ladder to square `3`, but do **not** follow the subsequent ladder to `4`.

Return *the least number of dice rolls required to reach the square* n^2. *If it is not possible to reach the square, return* `-1`.

Example 1:



```
Input: board = [[-1,-1,-1,-1,-1,-1],[-1,-1,-1,-1,-1,-1],[-1,-1,-1,-1,-1,-1],[-1,35,-1,-1,13,-1],[-1,-1
,-1,-1,-1,-1],[-1,15,-1,-1,-1,-1]]
Output: 4
Explanation:
In the beginning, you start at square 1 (at row 5, column 0).
You decide to move to square 2 and must take the ladder to square 15.
You then decide to move to square 17 and must take the snake to square 13.
You then decide to move to square 14 and must take the ladder to square 35.
You then decide to move to square 36, ending the game.
This is the lowest possible number of moves to reach the last square, so return 4.
```

Example 2:

```
Input: board = [[-1,-1],[-1,3]]
Output: 1
```

Constraints:

- `n == board.length == board[i].length`
- `2 <= n <= 20`
- `board[i][j]` is either `-1` or in the range `[1, n^2]`.
- The squares labeled `1` and n^2 are not the starting points of any snake or ladder.

SOLUTION (PYTHON 3)

Solution 1: BFS

How to think about it

The board is at most 20× 20. The fewest die rolls is an unweighted shortest path. Labels snake through the grid; a snake or ladder teleports to its destination. BFS from 1 by layers, visiting each cell once. The layer that first reaches n^2 is the answer; if the queue empties, return -1.

We can use the Breadth-First Search (BFS) method, starting from the starting point, moving forward 1 to 6 steps each time, and then checking for snakes or ladders. If there are any, move to the destination of the snake or ladder; otherwise, move to the next square.

Specifically, we use a queue q to store the current reachable square numbers, initially putting number 1 into the queue. At the same time, we use a set vis to record the squares that have been reached to avoid revisiting them, initially adding number 1 to the set vis.

In each operation, we take out the square number x at the front of the queue. If x is the endpoint, we can return the current number of steps. Otherwise, we move x forward 1 to 6 steps, setting the new number as y. If y falls outside the board, we skip it directly. Otherwise, we need to find the row and column corresponding to y. Since the row numbers decrease from bottom to top, and the column numbers depend on the parity of the row, we need to perform some calculations to get the row and column corresponding to y.

If the square corresponding to y has a snake or ladder, we need to move to the destination of the snake or ladder, denoted as z. If z has not been visited, we add z to the queue and set, allowing us to continue the breadth-first search.

If we ultimately cannot reach the endpoint, we return -1.

The time complexity is $O(n^2)$, and the space complexity is $O(n^2)$. Here, n is the length of the side of the board.

Python 3

```python
class Solution:
    def snakesAndLadders(self, board: List[List[int]]) -> int:
        n = len(board)
        q = deque([1])
        vis = {1}
        ans = 0
        m = n * n
        while q:
            for _ in range(len(q)):
                x = q.popleft()
                if x == m:
                    return ans
                for y in range(x + 1, min(x + 6, m) + 1):
                    i, j = divmod(y - 1, n)
                    if i & 1:
                        j = n - j - 1
                    i = n - i - 1
                    z = y if board[i][j] == -1 else board[i][j]
                    if z not in vis:
                        vis.add(z)
                        q.append(z)
            ans += 1
        return -1
```

PATTERN 17 · GRAPH BFS · PROBLEM 6 OF 20

1926. Nearest Exit from Entrance in Maze

Medium · Breadth-First Search, Array, Matrix

leetcode.com/problems/nearest-exit-from-entrance-in-maze

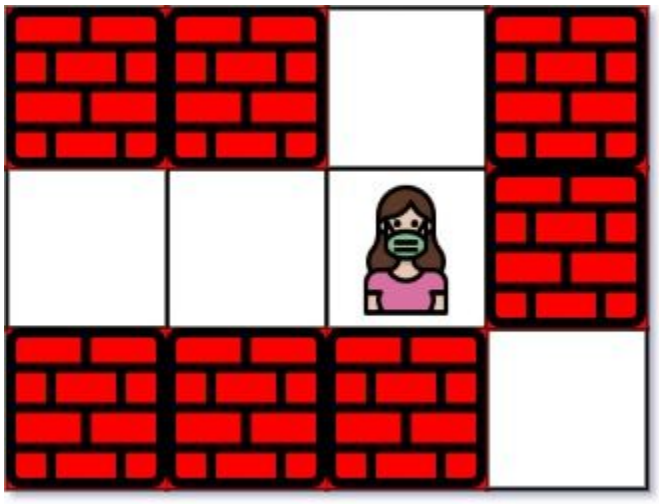
PROBLEM

You are given an `m x n` matrix `maze` (**0-indexed**) with empty cells (represented as `'.'`) and walls (represented as `'+'`). You are also given the `entrance` of the maze, where `entrance = [entrance_row, entrance_col]` denotes the row and column of the cell you are initially standing at.

In one step, you can move one cell **up**, **down**, **left**, or **right**. You cannot step into a cell with a wall, and you cannot step outside the maze. Your goal is to find the **nearest exit** from the `entrance`. An **exit** is defined as an **empty cell** that is at the **border** of the `maze`. The `entrance` **does not count** as an exit.

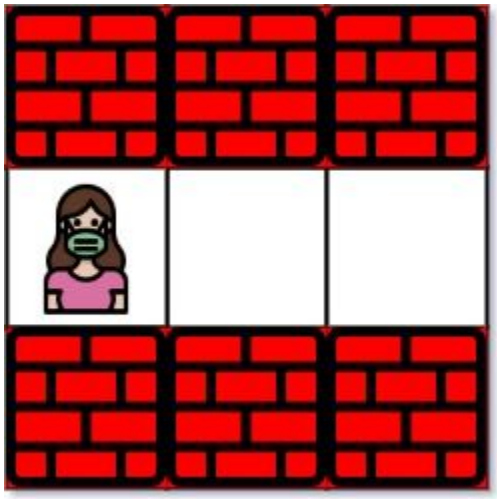
Return *the **number of steps** in the shortest path from the* `entrance` *to the nearest exit, or* `-1` *if no such path exists*.

Example 1:



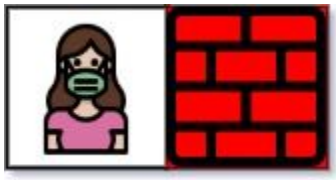
```
Input: maze = [["+","+",".","+"],[".",".",".","+"],["+","+","+","."]], entrance = [1,2]
Output: 1
Explanation: There are 3 exits in this maze at [1,0], [0,2], and [2,3].
Initially, you are at the entrance cell [1,2].
- You can reach [1,0] by moving 2 steps left.
- You can reach [0,2] by moving 1 step up.
It is impossible to reach [2,3] from the entrance.
Thus, the nearest exit is [0,2], which is 1 step away.
```

Example 2:



```
Input: maze = [["+","+","+"],[".",".","."],["+","+","+"]], entrance = [1,0]
Output: 2
Explanation: There is 1 exit in this maze at [1,2].
[1,0] does not count as an exit since it is the entrance cell.
Initially, you are at the entrance cell [1,0].
- You can reach [1,2] by moving 2 steps right.
Thus, the nearest exit is [1,2], which is 2 steps away.
```

Example 3:



```
Input: maze = [[".","+"]], entrance = [0,0]
Output: -1
Explanation: There are no exits in this maze.
```

Constraints:

- `maze.length == m`
- `maze[i].length == n`
- `1 <= m, n <= 100`
- `maze[i][j]` is either `'.'` or `'+'`.
- `entrance.length == 2`
- `0 <= entrance`$_{row}$ `< m`
- `0 <= entrance`$_{col}$ `< n`
- `entrance` will always be an empty cell.

SOLUTION (PYTHON 3)

Solution 1: BFS

How to think about it

The nearest exit is an unweighted shortest path. DFS does not guarantee minimality. The entrance is not an exit even if it lies on the border. BFS from the entrance, painting visited empty cells as walls. The first time a border empty cell is reached, the current distance is the answer; an empty queue means unreachable. Expanding four-neighbors level by level keeps the step count equal to distance.

We can start from the entrance and perform a breadth-first search (BFS). Each time we reach a new empty cell, we mark it as visited and add it to the queue until we find an empty cell on the boundary, then return the number of steps.

Specifically, we define a queue q, initially adding entrance to the queue. We define a variable ans to record the number of steps, initially set to 1. Then we start the BFS. In each round, we take out all elements from the queue and traverse them. For each element, we try to move in four directions. If the new position is an empty cell, we add it to the queue and mark it as visited. If the new position is an empty cell on the boundary, we return ans. If the queue is empty, we return -1. After this round of search, we increment ans by one and continue to the next round of search.

If we finish the traversal without finding an empty cell on the boundary, we return -1.

The time complexity is O(m × n), and the space complexity is O(m × n). Here, m and n are the number of rows and columns in the maze, respectively.

Python 3

```python
class Solution:
    def nearestExit(self, maze: List[List[str]], entrance: List[int]) -> int:
        m, n = len(maze), len(maze[0])
        i, j = entrance
        q = deque([(i, j)])
        maze[i][j] = "+"
        ans = 0
        while q:
            ans += 1
            for _ in range(len(q)):
                i, j = q.popleft()
                for a, b in [[0, -1], [0, 1], [-1, 0], [1, 0]]:
                    x, y = i + a, j + b
                    if 0 <= x < m and 0 <= y < n and maze[x][y] == ".":
                        if x == 0 or x == m - 1 or y == 0 or y == n - 1:
                            return ans
                        q.append((x, y))
                        maze[x][y] = "+"
        return -1
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

Built on the solutions above: helper functions, then the function for each follow-up. No tests and no restating of the question.

```python
# FOLLOW-UPS (answered below, in this order):
# 1. Return WHICH exit is the nearest
# 2. How many different exits can be reached?

# ============================================================
# FOLLOW-UP 1: Return WHICH exit is the nearest
# ============================================================

# ---- follow-up 1: function ----
# Answer: The BFS stops at the first border cell (other

1162. As Far from Land as Possible

Medium · Breadth-First Search, Array, Dynamic Programming, Matrix

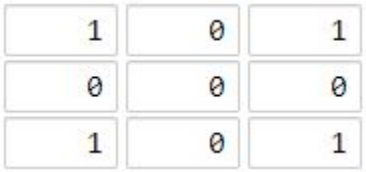
leetcode.com/problems/as-far-from-land-as-possible

PROBLEM

Given an `n x n grid` containing only values `0` and `1`, where `0` represents water and `1` represents land, find a water cell such that its distance to the nearest land cell is maximized, and return the distance. If no land or water exists in the grid, return `-1`.

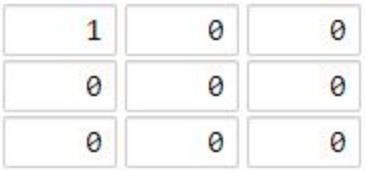
The distance used in this problem is the Manhattan distance: the distance between two cells `(x0, y0)` and `(x1, y1)` is `|x0 - x1| + |y0 - y1|`.

Example 1:



```
Input: grid = [[1,0,1],[0,0,0],[1,0,1]]
Output: 2
Explanation: The cell (1, 1) is as far as possible from all the land with distance 2.
```

Example 2:



```
Input: grid = [[1,0,0],[0,0,0],[0,0,0]]
Output: 4
Explanation: The cell (2, 2) is as far as possible from all the land with distance 4.
```

Constraints:

- `n == grid.length`
- `n == grid[i].length`
- `1 <= n <= 100`
- `grid[i][j]` is `0` or `1`

SOLUTION (PYTHON 3)

Solution 1: BFS

How to think about it

We want the maximum, over water cells, of the distance to the nearest land. A BFS from every water cell repeats visits. Multi-source BFS from all land cells grows one layer per step; the last water painted is that maximum. All-land or all-water grids have no answer, so return -1.

We can add all land cells to the queue q. If the queue is empty, or the number of elements in the queue equals the number of cells in the grid, it means that the grid contains only land or ocean, so return -1.

Otherwise, we start BFS from the land cells. Define the initial step count ans=-1.

In each round of search, we spread all cells in the queue in four directions. If a cell is an ocean cell, we mark it as a land cell and add it to the queue. After a round of spreading, we increase the step count by 1. Repeat this process until the queue is empty.

Finally, we return the step count ans.

The time complexity is $O(n^2)$, and the space complexity is $O(n^2)$. Here, n is the side length of the grid.

Python 3

```
class Solution:
    def maxDistance(self, grid: List[List[int]]) -> int:
        n = len(grid)
        q = deque((i, j) for i in range(n) for j in range(n) if grid[i][j])
        ans = -1
        if len(q) in (0, n * n):
            return ans
        dirs = (-1, 0, 1, 0, -1)
        while q:
            for _ in range(len(q)):
                i, j = q.popleft()
                for a, b in pairwise(dirs):
                    x, y = i + a, j + b
                    if 0 <= x < n and 0 <= y < n and grid[x][y] == 0:
                        grid[x][y] = 1
                        q.append((x, y))
            ans += 1
        return ans
```

1129. Shortest Path with Alternating Colors

Medium · Breadth-First Search, Graph

leetcode.com/problems/shortest-path-with-alternating-colors

PROBLEM

You are given an integer `n`, the number of nodes in a directed graph where the nodes are labeled from `0` to `n - 1`. Each edge is red or blue in this graph, and there could be self-edges and parallel edges.

You are given two arrays `redEdges` and `blueEdges` where:

- `redEdges[i] = [a_i, b_i]` indicates that there is a directed red edge from node a_i to node b_i in the graph, and
- `blueEdges[j] = [u_j, v_j]` indicates that there is a directed blue edge from node u_j to node v_j in the graph.

Return an array `answer` of length `n`, where each `answer[x]` is the length of the shortest path from node `0` to node `x` such that the edge colors alternate along the path, or `-1` if such a path does not exist.

Example 1:

```
Input: n = 3, redEdges = [[0,1],[1,2]], blueEdges = []
Output: [0,1,-1]
```

Example 2:

```
Input: n = 3, redEdges = [[0,1]], blueEdges = [[2,1]]
Output: [0,1,-1]
```

Constraints:

- `1 <= n <= 100`
- `0 <= redEdges.length, blueEdges.length <= 400`
- `redEdges[i].length == blueEdges[j].length == 2`
- `0 <=` a_i, b_i, u_j, v_j `< n`

SOLUTION (PYTHON 3)

Solution 1: BFS

How to think about it

Edges are red or blue and consecutive edges must differ, so a node may be visited twice with different incoming colors. The state is (node,last color). BFS from 0 with both virtual colors; the first time a node is reached is the shortest path. Adjacency is stored by color and the color is flipped on each hop so same-color edges are never taken.

The problem is essentially a shortest path problem, which we can consider solving using BFS.

First, we preprocess all the edges, categorizing all the edges by color and storing them in a multi-dimensional array g. Where g[0] stores all red edges, and g[1] stores all blue edges.

Next, we define the following data structures or variables:

- Queue q: used to store the currently searched node and the color of the current edge;
- Set vis: used to store the nodes that have been searched and the color of the current edge;
- Variable d: used to represent the current search level, i.e., the distance from the currently searched node to the starting point;
- Array ans: used to store the shortest distance from each node to the starting point. Initially, we initialize all elements in the ans array to -1, indicating that the distance from all nodes to the starting point is unknown.

We first enqueue the starting point 0 and the color of the starting edge 0 or 1, indicating that we start from the starting point and the current edge is red or blue.

Next, we start the BFS search. Each time we take out a node (i, c) from the queue, if the answer of the current node has not been updated, then we update the answer of the current node to the current level d, i.e., ans[i] = d. Then, we flip the color of the current edge c, i.e., if the current edge is red, we change it to blue, and vice versa. We take out all edges corresponding to the color, if the other end node j of the edge has not been searched, then we enqueue it.

After the search is over, return the answer array.

The time complexity is O(n + m), and the space complexity is O(n + m). Here, n and m are the number of nodes and edges, respectively.

Python 3

```
class Solution:
    def shortestAlternatingPaths(
        self, n: int, redEdges: List[List[int]], blueEdges: List[List[int]]
    ) -> List[int]:
        g = [defaultdict(list), defaultdict(list)]
        for i, j in redEdges:
            g[0][i].append(j)
        for i, j in blueEdges:
            g[1][i].append(j)
        ans = [-1] * n
        vis = set()
        q = deque([(0, 0), (0, 1)])
        d = 0
        while q:
            for _ in range(len(q)):
                i, c = q.popleft()
                if ans[i] == -1:
                    ans[i] = d
                vis.add((i, c))
                c ^= 1
                for j in g[c][i]:
                    if (j, c) not in vis:
                        q.append((j, c))
            d += 1
        return ans
```

PATTERN 17 · GRAPH BFS · PROBLEM 9 OF 20

1306. Jump Game III

Medium · Depth-First Search, Breadth-First Search, Array

leetcode.com/problems/jump-game-iii

PROBLEM

Given an array of non-negative integers `arr`, you are initially positioned at `start` index of the array. When you are at index `i`, you can jump to `i + arr[i]` or `i - arr[i]`, check if you can reach **any** index with value 0.

Notice that you can not jump outside of the array at any time.

Example 1:

```
Input: arr = [4,2,3,0,3,1,2], start = 5
Output: true
Explanation:
All possible ways to reach at index 3 with value 0 are:
index 5 -> index 4 -> index 1 -> index 3
index 5 -> index 6 -> index 4 -> index 1 -> index 3
```

Example 2:

```
Input: arr = [4,2,3,0,3,1,2], start = 0
Output: true
Explanation:
One possible way to reach at index 3 with value 0 is:
index 0 -> index 4 -> index 1 -> index 3
```

Example 3:

```
Input: arr = [3,0,2,1,2], start = 2
Output: false
Explanation: There is no way to reach at index 1 with value 0.
```

Constraints:

- `1 <= arr.length <= 5 * 10^4`
- `0 <= arr[i] < arr.length`
- `0 <= start < arr.length`

SOLUTION (PYTHON 3)

Solution 1: BFS

> **How to think about it**
>
> From start we jump to i ± arr[i] and ask whether a 0 is reachable. With $n \le 5 \times 10^4$, revisiting the same index loops forever. Each index needs to enter the queue at most once. The search is ordinary BFS on that graph: a dequeued 0 succeeds; otherwise we mark the cell visited (write -1) and enqueue the two in-range, unvisited jumps. The mark is the prune that keeps the work O(n).

We can use BFS to determine whether we can reach the index with a value of 0.

Define a queue q to store the currently reachable indices. Initially, enqueue the start index.

When the queue is not empty, take out the front index i of the queue. If arr[i] = 0, return `true`. Otherwise, mark the index i as visited. If i + arr[i] and i - arr[i] are within the array range and have not been visited, enqueue them and continue searching.

Finally, if the queue is empty, it means that we cannot reach the index with a value of 0, so return `false`.

The time complexity is O(n), and the space complexity is O(n). Where n is the length of the array.

Python 3

```python
class Solution:
    def canReach(self, arr: List[int], start: int) -> bool:
        q = deque([start])
        while q:
            i = q.popleft()
            if arr[i] == 0:
                return True
            x = arr[i]
            arr[i] = -1
            for j in (i + x, i - x):
                if 0 <= j < len(arr) and arr[j] >= 0:
                    q.append(j)
        return False
```

                stack.append(j)
    return zeros
```

433. Minimum Genetic Mutation

Medium · Breadth-First Search, Hash Table, String, Bidirectional Search

leetcode.com/problems/minimum-genetic-mutation

PROBLEM

A gene string can be represented by an 8-character long string, with choices from `'A'`, `'C'`, `'G'`, and `'T'`.

Suppose we need to investigate a mutation from a gene string `startGene` to a gene string `endGene` where one mutation is defined as one single character changed in the gene string.

- For example, `"AACCGGTT" --> "AACCGGTA"` is one mutation.

There is also a gene bank `bank` that records all the valid gene mutations. A gene must be in `bank` to make it a valid gene string.

Given the two gene strings `startGene` and `endGene` and the gene bank `bank`, return *the minimum number of mutations needed to mutate from* `startGene` *to* `endGene`. If there is no such a mutation, return `-1`.

Note that the starting point is assumed to be valid, so it might not be included in the bank.

Example 1:

```
Input: startGene = "AACCGGTT", endGene = "AACCGGTA", bank = ["AACCGGTA"]
Output: 1
```

Example 2:

```
Input: startGene = "AACCGGTT", endGene = "AAACGGTA", bank = ["AACCGGTA","AACCGCTA","AAACGGTA"]
Output: 2
```

Constraints:

- `0 <= bank.length <= 10`
- `startGene.length == endGene.length == bank[i].length == 8`
- `startGene`, `endGene`, and `bank[i]` consist of only the characters `['A', 'C', 'G', 'T']`.

SOLUTION (PYTHON 3)

Solution 1: BFS

How to think about it

A mutation flips one character and must land in the bank; we want the fewest steps. That is unweighted shortest path, so depth-first search does not give the minimum. BFS from the start. Each step scans unused bank strings that differ in exactly one position. The first time the end gene is dequeued is the answer; an empty queue means unreachable. The bank is tiny, so pairwise Hamming distance 1 is enough. A visited set prevents enqueueing a gene twice.

We define a queue `q` to store the current gene sequence and the number of changes, and a set `vis` to store the visited gene sequences. Initially, we add the starting gene sequence `start` to the queue `q` and the set `vis`.

Then, we continuously take out a gene sequence from the queue `q`. If this gene sequence equals the target gene sequence, we return the current number of changes. Otherwise, we iterate through the gene bank `bank`, calculate the difference value between the current gene sequence and the gene sequence in the gene bank. If the difference value is 1 and the gene sequence in the gene bank has not been visited, we add it to the queue `q` and the set `vis`.

If the queue `q` is empty, it means that the gene change cannot be completed, so we return -1.

The time complexity is $O(C \times n \times m)$, and the space complexity is $O(n \times m)$. Where n and m are the lengths of the gene sequence and the gene bank respectively, and C is the size of the character set of the gene sequence. In this problem, $C = 4$.

Python 3

```python
class Solution:
    def minMutation(self, startGene: str, endGene: str, bank: List[str]) -> int:
        q = deque([(startGene, 0)])
        vis = {startGene}
        while q:
            gene, depth = q.popleft()
            if gene == endGene:
                return depth
            for nxt in bank:
                diff = sum(a != b for a, b in zip(gene, nxt))
                if diff == 1 and nxt not in vis:
                    q.append((nxt, depth + 1))
                    vis.add(nxt)
        return -1
```

787. Cheapest Flights Within K Stops

Medium · Depth-First Search, Breadth-First Search, Graph, Dynamic Programming, Shortest Path, Heap (Priority Queue)

leetcode.com/problems/cheapest-flights-within-k-stops

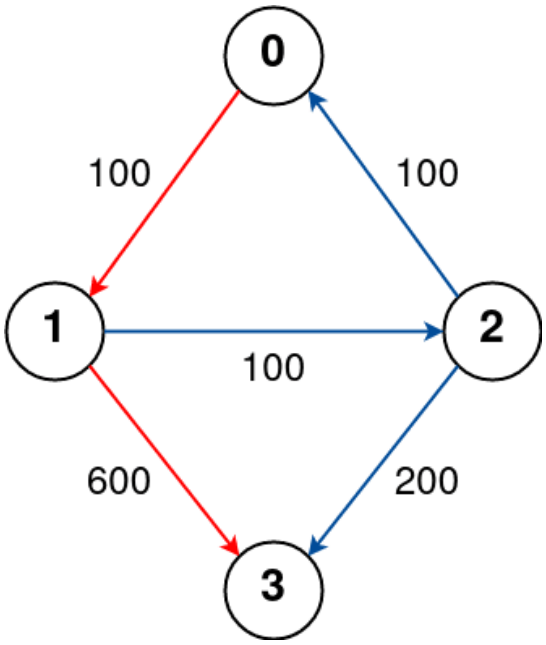
★ **TOP 10 PROBLEM** in Graph BFS: master this one first

PROBLEM

There are `n` cities connected by some number of flights. You are given an array `flights` where `flights[i] = [from`$_i$`, to`$_i$`, price`$_i$`]` indicates that there is a flight from city `from`$_i$ to city `to`$_i$ with cost `price`$_i$.

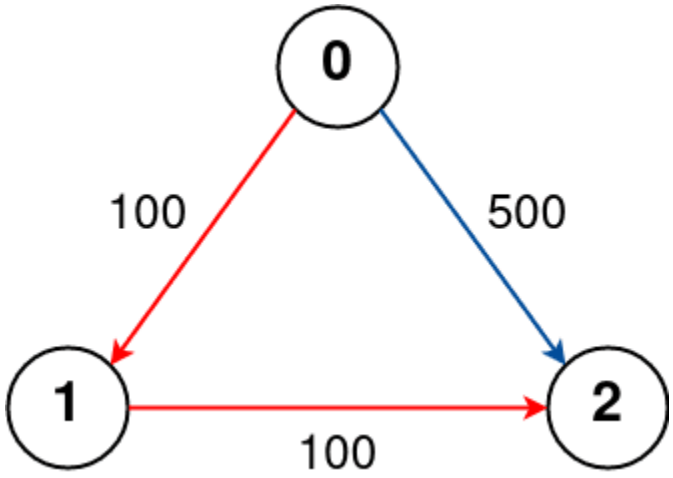
You are also given three integers `src`, `dst`, and `k`, return ***the cheapest price*** *from* `src` *to* `dst` *with at most* `k` *stops.* If there is no such route, return `-1`.

Example 1:



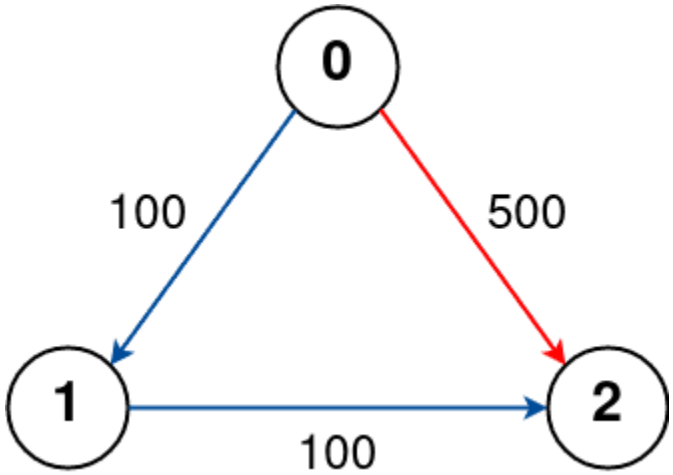
```
Input: n = 4, flights = [[0,1,100],[1,2,100],[2,0,100],[1,3,600],[2,3,200]], src = 0, dst = 3, k = 1
Output: 700
Explanation:
The graph is shown above.
The optimal path with at most 1 stop from city 0 to 3 is marked in red and has cost 100 + 600 = 700.
Note that the path through cities [0,1,2,3] is cheaper but is invalid because it uses 2 stops.
```

Example 2:



```
Input: n = 3, flights = [[0,1,100],[1,2,100],[0,2,500]], src = 0, dst = 2, k = 1
Output: 200
Explanation:
The graph is shown above.
The optimal path with at most 1 stop from city 0 to 2 is marked in red and has cost 100 + 100 = 200.
```

Example 3:



```
Input: n = 3, flights = [[0,1,100],[1,2,100],[0,2,500]], src = 0, dst = 2, k = 0
Output: 500
Explanation:
The graph is shown above.
The optimal path with no stops from city 0 to 2 is marked in red and has cost 500.
```

Constraints:

- $2 <= n <= 100$
- $0 <= flights.length <= (n * (n - 1) / 2)$
- $flights[i].length == 3$
- $0 <= from_i, to_i < n$
- $from_i != to_i$
- $1 <= price_i <= 10^4$
- There will not be any multiple flights between two cities.
- $0 <= src, dst, k < n$
- $src != dst$

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

Cheapest path with at most k stops. Dijkstra needs an extra “stops” dimension; Bellman-Ford with k+1 rounds is enough for n≤ 100. At most k stops means k+1 edges. Each round relaxes from a copy of the previous distances so one round is one edge. After k+1 rounds, infinite dist[dst] means unreachable.

Python 3

```python
class Solution:
    def findCheapestPrice(
        self, n: int, flights: List[List[int]], src: int, dst: int, k: int
    ) -> int:
        INF = 0x3F3F3F3F
        dist = [INF] * n
        dist[src] = 0
        for _ in range(k + 1):
            backup = dist.copy()
            for f, t, p in flights:
                dist[t] = min(dist[t], backup[f] + p)
        return -1 if dist[dst] == INF else dist[dst]
```

Complexity. Time: O(k * E), E = number of flights. Space: O(n).

Solution 2

How to think about it

Bellman-Ford scans every edge. Memoized dfs(u,k) is the min cost from u with k edges left: 0 at dst, inf when k runs out. The initial call uses k+1 edges. O(nk) states.

Python 3

```python
class Solution:
    def findCheapestPrice(
        self, n: int, flights: List[List[int]], src: int, dst: int, k: int
    ) -> int:
        @cache
        def dfs(u, k):
            if u == dst:
                return 0
            if k <= 0:
                return inf
            k -= 1
            ans = inf
            for v, p in g[u]:
                ans = min(ans, dfs(v, k) + p)
            return ans

        g = defaultdict(list)
        for u, v, p in flights:
            g[u].append((v, p))
        ans = dfs(src, k + 1)
        return -1 if ans >= inf else ans
```

PATTERN 17 · GRAPH BFS · PROBLEM 12 OF 20

934. Shortest Bridge

Medium · Depth-First Search, Breadth-First Search, Array, Matrix

leetcode.com/problems/shortest-bridge

★ **TOP 10 PROBLEM** in Graph BFS: master this one first

PROBLEM

You are given an `n x n` binary matrix `grid` where `1` represents land and `0` represents water.

An **island** is a 4-directionally connected group of `1`'s not connected to any other `1`'s. There are **exactly two islands** in `grid`.

You may change `0`'s to `1`'s to connect the two islands to form **one island**.

Return *the smallest number of `0`'s you must flip to connect the two islands*.

Example 1:

```
Input: grid = [[0,1],[1,0]]
Output: 1
```

Example 2:

```
Input: grid = [[0,1,0],[0,0,0],[0,0,1]]
Output: 2
```

Example 3:

```
Input: grid = [[1,1,1,1,1],[1,0,0,0,1],[1,0,1,0,1],[1,0,0,0,1],[1,1,1,1,1]]
Output: 1
```

Constraints:

- `n == grid.length == grid[i].length`
- `2 <= n <= 100`
- `grid[i][j]` is either `0` or `1`.
- There are exactly two islands in `grid`.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

There are exactly two islands; the fewest flips equal the shortest distance between them. DFS dumps one island into a queue and marks it visited, then BFS expands over water. The first time the other island is reached, the layer count is the answer.

Python 3

```
class Solution:
    def shortestBridge(self, grid: List[List[int]]) -> int:
        def dfs(i, j):
            q.append((i, j))
            grid[i][j] = 2
            for a, b in pairwise(dirs):
                x, y = i + a, j + b
                if 0 <= x < n and 0 <= y < n and grid[x][y] == 1:
                    dfs(x, y)

        n = len(grid)
        dirs = (-1, 0, 1, 0, -1)
        q = deque()
        i, j = next((i, j) for i in range(n) for j in range(n) if grid[i][j])
        dfs(i, j)
        ans = 0
        while 1:
            for _ in range(len(q)):
                i, j = q.popleft()
                for a, b in pairwise(dirs):
                    x, y = i + a, j + b
                    if 0 <= x < n and 0 <= y < n:
                        if grid[x][y] == 1:
                            return ans
                        if grid[x][y] == 0:
                            grid[x][y] = 2
                            q.append((x, y))
            ans += 1
```

Complexity. Time: O(n^2). Space: O(n^2).

1311. Get Watched Videos by Your Friends

Medium · Breadth-First Search, Graph, Array, Hash Table, Sorting

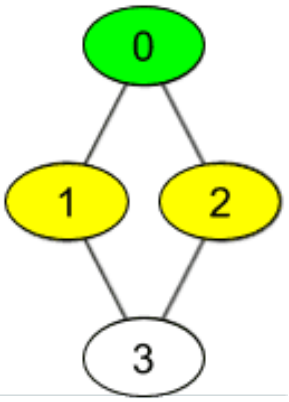
leetcode.com/problems/get-watched-videos-by-your-friends

PROBLEM

There are `n` people, each person has a unique *id* between `0` and `n-1`. Given the arrays `watchedVideos` and `friends`, where `watchedVideos[i]` and `friends[i]` contain the list of watched videos and the list of friends respectively for the person with `id = i`.

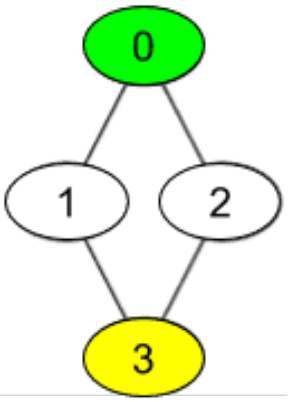
Level **1** of videos are all watched videos by your friends, level **2** of videos are all watched videos by the friends of your friends and so on. In general, the level `k` of videos are all watched videos by people with the shortest path **exactly** equal to `k` with you. Given your `id` and the `level` of videos, return the list of videos ordered by their frequencies (increasing). For videos with the same frequency order them alphabetically from least to greatest.

Example 1:



```
Input: watchedVideos = [["A","B"],["C"],["B","C"],["D"]], friends = [[1,2],[0,3],[0,3],[1,2]], id = 0, level = 1
Output: ["B","C"]
Explanation:
You have id = 0 (green color in the figure) and your friends are (yellow color in the figure):
Person with id = 1 -> watchedVideos = ["C"]
Person with id = 2 -> watchedVideos = ["B","C"]
The frequencies of watchedVideos by your friends are:
B -> 1
C -> 2
```

Example 2:



```
Input: watchedVideos = [["A","B"],["C"],["B","C"],["D"]], friends = [[1,2],[0,3],[0,3],[1,2]], id = 0, level = 2
Output: ["D"]
Explanation:
You have id = 0 (green color in the figure) and the only friend of your friends is the person with id = 3 (yellow color in the figure).
```

Constraints:

- `n == watchedVideos.length == friends.length`
- `2 <= n <= 100`
- `1 <= watchedVideos[i].length <= 100`
- `1 <= watchedVideos[i][j].length <= 8`
- `0 <= friends[i].length < n`
- `0 <= friends[i][j] < n`
- `0 <= id < n`
- `1 <= level < n`
- if `friends[i]` contains `j`, then `friends[j]` contains `i`

SOLUTION (PYTHON 3)

Solution 1: BFS

How to think about it

We need videos watched by friends exactly level hops away, ordered by frequency then name. Unbounded DFS does not stop on a precise layer and revisits people. level rounds of BFS from id leave exactly that layer in the queue. A counter tallies their videos; sorting by (cnt[v], v) produces the names. A visited set keeps a person from entering more than once.

We can use the Breadth-First Search (BFS) method to start from id and find all friends at a distance of level, then count the videos watched by these friends.

Specifically, we can use a queue q to store the friends at the current level. Initially, add id to the queue q. Use a hash table or a boolean array vis to record the friends that have already been visited. Then, perform level iterations, in each iteration dequeue all friends from the queue and enqueue their friends until all friends at distance level are found.

Next, we use a hash table cnt to count the videos watched by these friends and their frequencies. Finally, sort the key-value pairs in the hash table in ascending order by frequency, and if frequencies are the same, sort by video name in ascending order. Return the sorted list of video names.

Time complexity is $O(n + m + v \times \log v)$, and space complexity is $O(n + v)$. Here, n and m are the lengths of the arrays watchedVideos and friends, respectively, and v is the total number of videos watched by all friends.

Python 3

```python
class Solution:
    def watchedVideosByFriends(
        self,
        watchedVideos: List[List[str]],
        friends: List[List[int]],
        id: int,
        level: int,
    ) -> List[str]:
        q = deque([id])
        vis = {id}
        for _ in range(level):
            for _ in range(len(q)):
                i = q.popleft()
                for j in friends[i]:
                    if j not in vis:
                        vis.add(j)
                        q.append(j)
        cnt = Counter()
        for i in q:
            for v in watchedVideos[i]:
                cnt[v] += 1
        return sorted(cnt.keys(), key=lambda k: (cnt[k], k))
```

1765. Map of Highest Peak

Medium · Breadth-First Search, Array, Matrix

leetcode.com/problems/map-of-highest-peak

PROBLEM

You are given an integer matrix `isWater` of size `m x n` that represents a map of **land** and **water** cells.

- If `isWater[i][j] == 0`, cell `(i, j)` is a **land** cell.
- If `isWater[i][j] == 1`, cell `(i, j)` is a **water** cell.

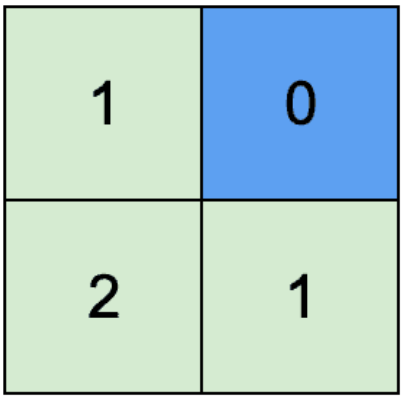
You must assign each cell a height in a way that follows these rules:

- The height of each cell must be non-negative.
- If the cell is a **water** cell, its height must be `0`.
- Any two adjacent cells must have an absolute height difference of **at most** `1`. A cell is adjacent to another cell if the former is directly north, east, south, or west of the latter (i.e., their sides are touching).

Find an assignment of heights such that the maximum height in the matrix is **maximized**.

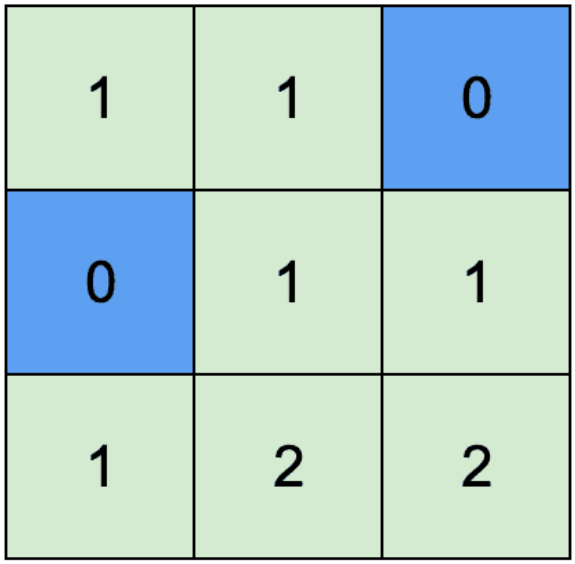
Return *an integer matrix* `height` *of size* `m x n` *where* `height[i][j]` *is cell* `(i, j)`*'s height. If there are multiple solutions, return* ***any*** *of them.*

Example 1:



```
Input: isWater = [[0,1],[0,0]]
Output: [[1,0],[2,1]]
Explanation: The image shows the assigned heights of each cell.
The blue cell is the water cell, and the green cells are the land cells.
```

Example 2:



```
Input: isWater = [[0,0,1],[1,0,0],[0,0,0]]
Output: [[1,1,0],[0,1,1],[1,2,2]]
Explanation: A height of 2 is the maximum possible height of any assignment.
Any height assignment that has a maximum height of 2 while still meeting the rules will also be
accepted.
```

Constraints:

- `m == isWater.length`
- `n == isWater[i].length`
- `1 <= m, n <= 1000`
- `isWater[i][j]` is `0` or `1`.
- There is at least **one** water cell.

Note: This question is the same as 542: https://leetcode.com/problems/01-matrix/

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

Water cells must be height 0, adjacent heights differ by at most 1, and land should be as high as possible. The height is the distance to the nearest water. Multi-source BFS: enqueue every water cell at 0, and set each unseen neighbour to the current height plus one. The distance field is the height map.

Python 3

```python
class Solution:
    def highestPeak(self, isWater: List[List[int]]) -> List[List[int]]:
        m, n = len(isWater), len(isWater[0])
        ans = [[-1] * n for _ in range(m)]
        q = deque()
        for i, row in enumerate(isWater):
            for j, v in enumerate(row):
                if v:
                    q.append((i, j))
                    ans[i][j] = 0
        while q:
            i, j = q.popleft()
            for a, b in pairwise((-1, 0, 1, 0, -1)):
                x, y = i + a, j + b
                if 0 <= x < m and 0 <= y < n and ans[x][y] == -1:
                    ans[x][y] = ans[i][j] + 1
                    q.append((x, y))
        return ans
```

Complexity. Time: O(m * n). Space: O(m * n).

Solution 2

> **How to think about it**
>
> Solution 2 is the same multi-source BFS, popping an explicit layer size. The algorithm and complexity are unchanged.

Python 3

```python
class Solution:
    def highestPeak(self, isWater: List[List[int]]) -> List[List[int]]:
        m, n = len(isWater), len(isWater[0])
        ans = [[-1] * n for _ in range(m)]
        q = deque()
        for i, row in enumerate(isWater):
            for j, v in enumerate(row):
                if v:
                    q.append((i, j))
                    ans[i][j] = 0
        while q:
            for _ in range(len(q)):
                i, j = q.popleft()
                for a, b in pairwise((-1, 0, 1, 0, -1)):
                    x, y = i + a, j + b
                    if 0 <= x < m and 0 <= y < n and ans[x][y] == -1:
                        ans[x][y] = ans[i][j] + 1
                        q.append((x, y))
        return ans
```

Complexity. Time: O(m * n). Space: O(m * n).

PATTERN 17 · GRAPH BFS · PROBLEM 15 OF 20

127. Word Ladder

Hard · Breadth-First Search, Hash Table, String, Bidirectional Search

leetcode.com/problems/word-ladder

★ **TOP 10 PROBLEM** in Graph BFS: master this one first

PROBLEM

A **transformation sequence** from word `beginWord` to word `endWord` using a dictionary `wordList` is a sequence of words `beginWord -> s1 -> s2 -> ... -> sk` such that:

- Every adjacent pair of words differs by a single letter.
- Every s_i for `1 <= i <= k` is in `wordList`. Note that `beginWord` does not need to be in `wordList`.
- s_k `== endWord`

Given two words, `beginWord` and `endWord`, and a dictionary `wordList`, return *the **number of words** in the **shortest transformation sequence** from* `beginWord` *to* `endWord`*, or* `0` *if no such sequence exists.*

Example 1:

```
Input: beginWord = "hit", endWord = "cog", wordList = ["hot","dot","dog","lot","log","cog"]
Output: 5
Explanation: One shortest transformation sequence is "hit" -> "hot" -> "dot" -> "dog" -> cog", which
is 5 words long.
```

Example 2:

```
Input: beginWord = "hit", endWord = "cog", wordList = ["hot","dot","dog","lot","log"]
Output: 0
Explanation: The endWord "cog" is not in wordList, therefore there is no valid transformation
sequence.
```

Constraints:

- `1 <= beginWord.length <= 10`
- `endWord.length == beginWord.length`
- `1 <= wordList.length <= 5000`
- `wordList[i].length == beginWord.length`
- `beginWord`, `endWord`, and `wordList[i]` consist of lowercase English letters.
- `beginWord != endWord`
- All the words in `wordList` are **unique**.

SOLUTIONS (PYTHON 3)

Solution 1: BFS

How to think about it

Find the shortest transformation; each step changes one letter and must stay in the word list. With up to 5000 words of length 10, enumerating paths is impossible. Unweighted shortest paths are BFS: try 26 letters at each position, enqueue hits, and remove them from the set so they are not visited twice.

BFS minimum step model. This problem can be solved with naive BFS, or it can be optimized with bidirectional BFS to reduce the search space and improve efficiency.

Bidirectional BFS is a common optimization method for BFS, with the main implementation ideas as follows:

1. Create two queues, q1 and q2, for "start -> end" and "end -> start" search directions, respectively.

2. Create two hash maps, m1 and m2, to record the visited nodes and their corresponding expansion times (steps).
3. During each search, prioritize the queue with fewer elements for search expansion. If a node visited from the other direction is found during the expansion, it means the shortest path has been found.
4. If one of the queues is empty, it means that the search in the current direction cannot continue, indicating that the start and end points are not connected, and there is no need to continue the search.

```
while q1 and q2:
    if len(q1) <= len(q2):
        # Prioritize the queue with fewer elements for expansion
        extend(m1, m2, q1)
    else:
        extend(m2, m1, q2)

def extend(m1, m2, q):
    # New round of expansion
    for _ in range(len(q)):
        p = q.popleft()
        step = m1[p]
        for t in next(p):
            if t in m1:
                # Already visited before
                continue
            if t in m2:
                # The other direction has been searched, indicating that a shortest path has been found
                return step + 1 + m2[t]
            q.append(t)
            m1[t] = step + 1
```

Python 3

```
class Solution:
    def ladderLength(self, beginWord: str, endWord: str, wordList: List[str]) -> int:
        words = set(wordList)
        q = deque([beginWord])
        ans = 1
        while q:
            ans += 1
            for _ in range(len(q)):
                s = q.popleft()
                s = list(s)
                for i in range(len(s)):
                    ch = s[i]
                    for j in range(26):
                        s[i] = chr(ord('a') + j)
                        t = ''.join(s)
                        if t not in words:
                            continue
                        if t == endWord:
                            return ans
                        q.append(t)
                        words.remove(t)
                    s[i] = ch
        return 0
```

Complexity. Time: O(N * L^2) (26 letters is a constant), N = number of words, L = word length. Space: O(N * L).

Solution 2: Bidirectional BFS

> **How to think about it**
>
> Solution 1's frontier can grow wide on a large list. Expanding from both ends and always growing the smaller side meets in the middle at the shortest length, and the search is usually smaller.

Search from both ends until the two sides meet.

Python 3

```
class Solution:
    def ladderLength(self, beginWord: str, endWord: str, wordList: List[str]) -> int:
        def extend(m1, m2, q):
            for _ in range(len(q)):
                s = q.popleft()
                step = m1[s]
                s = list(s)
                for i in range(len(s)):
                    ch = s[i]
                    for j in range(26):
                        s[i] = chr(ord('a') + j)
                        t = ''.join(s)
                        if t in m1 or t not in words:
                            continue
                        if t in m2:
                            return step + 1 + m2[t]
                        m1[t] = step + 1
                        q.append(t)
                    s[i] = ch
            return -1

        words = set(wordList)
        if endWord not in words:
            return 0
        q1, q2 = deque([beginWord]), deque([endWord])
        m1, m2 = {beginWord: 0}, {endWord: 0}
        while q1 and q2:
            t = extend(m1, m2, q1) if len(q1) <= len(q2) else extend(m2, m1, q2)
            if t != -1:
                return t + 1
        return 0
```

Complexity. Time: O(N * L^2) in the worst case, but much faster in practice (two searches meet in the middle). Space: O(N * L).

815. Bus Routes

Hard · Breadth-First Search, Array, Hash Table

leetcode.com/problems/bus-routes

★ **TOP 10 PROBLEM** in Graph BFS: master this one first

PROBLEM

You are given an array `routes` representing bus routes where `routes[i]` is a bus route that the i^{th} bus repeats forever.

- For example, if `routes[0] = [1, 5, 7]`, this means that the 0^{th} bus travels in the sequence `1 -> 5 -> 7 -> 1 -> 5 -> 7 -> 1 -> ...` forever.

You will start at the bus stop `source` (You are not on any bus initially), and you want to go to the bus stop `target`. You can travel between bus stops by buses only.

Return *the least number of buses you must take to travel from* `source` *to* `target`. Return `-1` if it is not possible.

Example 1:

```
Input: routes = [[1,2,7],[3,6,7]], source = 1, target = 6
Output: 2
Explanation: The best strategy is take the first bus to the bus stop 7, then take the second bus to the bus stop 6.
```

Example 2:

```
Input: routes = [[7,12],[4,5,15],[6],[15,19],[9,12,13]], source = 15, target = 12
Output: -1
```

Constraints:

- `1 <= routes.length <= 500.`
- `1 <= routes[i].length <= 10^5`
- All the values of `routes[i]` are **unique**.
- `sum(routes[i].length) <= 10^5`
- `0 <= routes[i][j] < 10^6`
- `0 <= source, target < 10^6`

SOLUTION (PYTHON 3)

Solution 1: BFS

How to think about it

Riding one bus reaches every stop on that route; we want the fewest rides. Walking stop-to-stop would expand the same bus many times. The right BFS layer is a transfer. Build a stop-to-routes index. The queue stores a stop and the ride count; each route is expanded once, enqueueing its unseen stops. Every bus is processed at most once.

First, we check if source and target are the same. If they are, we directly return 0.

Next, we use a hash table g to build a mapping from stops to bus routes. For each bus route, we traverse all the stops it passes through and map each stop to that bus route, i.e., g[stop] represents all bus routes passing through stop stop.

Then, we check if source and target are in the stop mapping. If they are not, we return -1.

We use a queue q to perform a breadth-first search (BFS). Each element in the queue is a tuple (stop, busCount), representing the current stop stop and the number of buses taken to reach the current stop busCount.

We initialize a set visBus to record the bus routes that have been visited and a set visStop to record the stops that have been visited. Then, we add source to visStop and (source, 0) to the queue q.

Next, we start the BFS. While the queue q is not empty, we take out the first element from the queue, which is the current stop stop and the number of buses taken to reach the current stop busCount.

If the current stop stop is the target stop target, we return the number of buses taken to reach the target stop busCount.

Otherwise, we traverse all bus routes passing through the current stop. For each bus route, we traverse all stops on that route. If a stop nextStop has not been visited, we add it to visStop and add (nextStop, busCount + 1) to the queue q.

Finally, if we cannot reach the target stop, we return -1.

The time complexity is O(L), and the space complexity is O(L), where L is the total number of stops on all bus routes.

Python 3

```python
class Solution:
    def numBusesToDestination(
        self, routes: List[List[int]], source: int, target: int
    ) -> int:
        if source == target:
            return 0
        g = defaultdict(list)
        for i, route in enumerate(routes):
            for stop in route:
                g[stop].append(i)
        if source not in g or target not in g:
            return -1
        q = [(source, 0)]
        vis_bus = set()
        vis_stop = {source}
        for stop, bus_count in q:
            if stop == target:
                return bus_count
            for bus in g[stop]:
                if bus not in vis_bus:
                    vis_bus.add(bus)
                    for next_stop in routes[bus]:
                        if next_stop not in vis_stop:
                            vis_stop.add(next_stop)
                            q.append((next_stop, bus_count + 1))
        return -1
```

                    previous[other] = bus
                    queue.append(other)
    return None
```

864. Shortest Path to Get All Keys

Hard · Bit Manipulation, Breadth-First Search, Array, Matrix

leetcode.com/problems/shortest-path-to-get-all-keys

★ **TOP 10 PROBLEM** in Graph BFS: master this one first

PROBLEM

You are given an `m x n` grid `grid` where:

- `'.'` is an empty cell.
- `'#'` is a wall.
- `'@'` is the starting point.
- Lowercase letters represent keys.
- Uppercase letters represent locks.

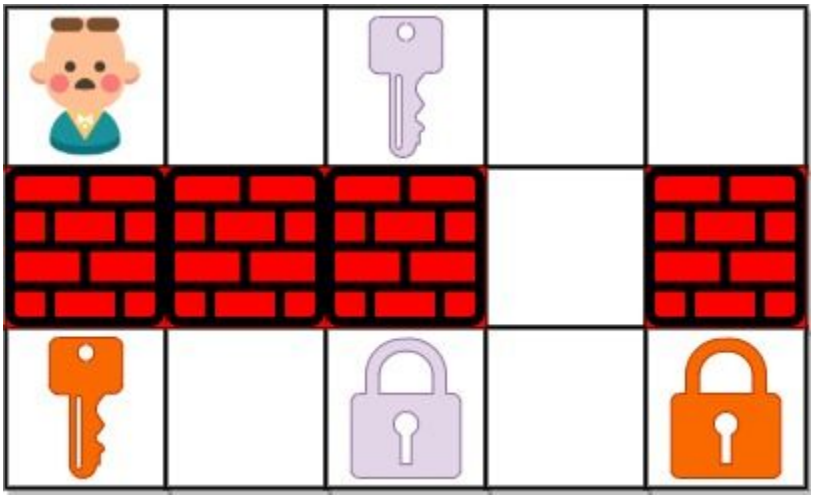
You start at the starting point and one move consists of walking one space in one of the four cardinal directions. You cannot walk outside the grid, or walk into a wall.

If you walk over a key, you can pick it up and you cannot walk over a lock unless you have its corresponding key.

For some `1 <= k <= 6`, there is exactly one lowercase and one uppercase letter of the first `k` letters of the English alphabet in the grid. This means that there is exactly one key for each lock, and one lock for each key; and also that the letters used to represent the keys and locks were chosen in the same order as the English alphabet.

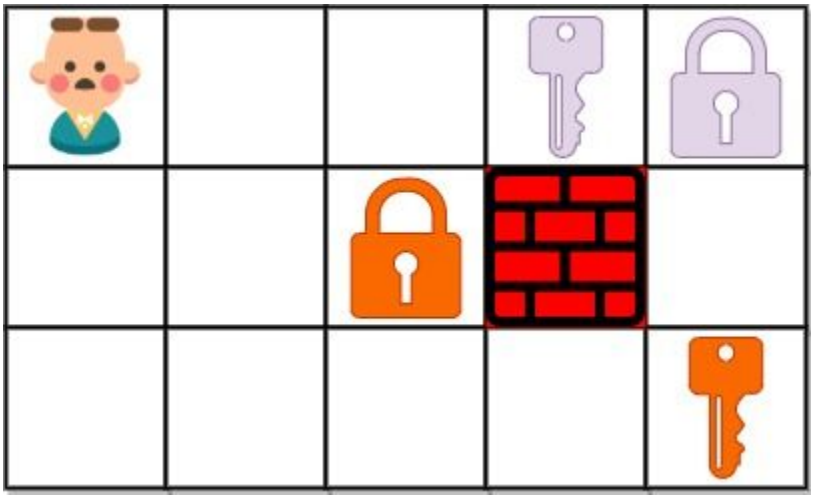
Return *the lowest number of moves to acquire all keys*. If it is impossible, return `-1`.

Example 1:



```
Input: grid = ["@.a..","###.#","b.A.B"]
Output: 8
Explanation: Note that the goal is to obtain all the keys not to open all the locks.
```

Example 2:



```
Input: grid = ["@..aA","..B#.","....b"]
Output: 6
```

Example 3:

```
Input: grid = ["@Aa"]
Output: -1
```

Constraints:

- `m == grid.length`
- `n == grid[i].length`
- `1 <= m, n <= 30`
- `grid[i][j]` is either an English letter, `'.'`, `'#'`, or `'@'`.
- There is exactly one `'@'` in the grid.
- The number of keys in the grid is in the range `[1, 6]`.
- Each key in the grid is **unique**.
- Each key in the grid has a matching lock.

SOLUTION (PYTHON 3)

Solution 1: State Compression + BFS

How to think about it

Collect every key; a lock blocks the path without its key. At most 6 keys on a 30× 30 grid, so (position, key mask) is a BFS state. (i,j,mask) is the cell and keys in hand. Walls and locked doors are skipped; a key sets a bit. The first full mask is the shortest path.

According to the problem description, we need to start from the initial position, move in four directions (up, down, left, right), collect all keys, and finally return the minimum number of moves required to collect all keys. If it is not possible to collect all keys, return -1.

First, we traverse the 2D grid to find the starting position (si, sj) and count the number of keys k.

Then, we can use Breadth-First Search (BFS) to solve this problem. Since the number of keys ranges from 1 to 6, we can use a binary number to represent the state of the keys, where the i-th bit being 1 indicates that the i-th key has been

collected, and 0 indicates that the i-th key has not been collected.

For example, in the following case, there are 4 bits set to 1, indicating that keys `'b', 'c', 'd', 'f'` have been collected.

```
1 0 1 1 1 0
^   ^ ^ ^
f   d c b
```

We define a queue q to store the current position and the state of the collected keys, i.e., (i, j, state), where (i, j) represents the current position, and state represents the state of the collected keys. The i-th bit of state being 1 indicates that the i-th key has been collected; otherwise, it indicates that the i-th key has not been collected.

Additionally, we define a hash table or array vis to record whether the current position and the state of the collected keys have been visited. If visited, there is no need to visit again. vis[i][j][state] indicates whether the position (i, j) and the state of the collected keys state have been visited.

We start from the initial position (si, sj), add it to the queue q, and set vis[si][sj][0] to true, indicating that the initial position and the state of the collected keys 0 have been visited.

During the BFS process, we take out a position (i, j, state) from the front of the queue and check whether the current position is the endpoint, i.e., whether the current position has collected all keys, which means the number of 1s in the binary representation of state is k. If so, we return the current number of steps as the answer.

Otherwise, we move from the current position in four directions (up, down, left, right). If we can move to the next position (x, y), we add (x, y, nxt) to the queue q, where nxt represents the state of the keys at the next position.

Here, (x, y) must first be within the grid range, i.e., $0 \le x < m$ and $0 \le y < n$. Secondly, if the position (x, y) is a wall, i.e., `grid[x][y] == '#'`, or the position (x, y) is a lock but we do not have the corresponding key, i.e., `grid[x][y] >= 'A' && grid[x][y] <= 'F' && (state >> (grid[x][y] - 'A') & 1) == 0)`, then we cannot move to the position (x, y)`. Otherwise, we can move to the position(x, y)`.

If the search ends and we have not collected all keys, return -1.

The time complexity is $O(m \times n \times 2^k)$, and the space complexity is $O(m \times n \times 2^k)$. Here, m and n are the number of rows and columns of the grid, respectively, and k is the number of keys.

Python 3

```python
class Solution:
    def shortestPathAllKeys(self, grid: List[str]) -> int:
        m, n = len(grid), len(grid[0])
        # Find the starting point (si, sj)
        si, sj = next((i, j) for i in range(m) for j in range(n) if grid[i][j] == '@')
        # Count the number of keys
        k = sum(v.islower() for row in grid for v in row)
        dirs = (-1, 0, 1, 0, -1)
        q = deque([(si, sj, 0)])
        vis = {(si, sj, 0)}
        ans = 0
        while q:
            for _ in range(len(q)):
                i, j, state = q.popleft()
                # If all keys are found, return the current step count
                if state == (1 << k) - 1:
                    return ans

                # Search in the four directions
                for a, b in pairwise(dirs):
                    x, y = i + a, j + b
                    nxt = state
                    # Within boundary limits
                    if 0 <= x < m and 0 <= y < n:
                        c = grid[x][y]
                        # It's a wall, or it's a lock but we don't have the key for it
                        if (
                            c == '#'
                            or c.isupper()
                            and (state & (1 << (ord(c) - ord('A')))) == 0
                        ):
                            continue
                        # It's a key
                        if c.islower():
                            # Update the state
                            nxt |= 1 << (ord(c) - ord('a'))
                        # If this state has not been visited, enqueue it
                        if (x, y, nxt) not in vis:
                            vis.add((x, y, nxt))
                            q.append((x, y, nxt))
            # Increment the step count
            ans += 1
        return -1
```

1568. Minimum Number of Days to Disconnect Island

Hard · Depth-First Search, Breadth-First Search, Array, Matrix, Articulation Point, Strongly Connected Component

leetcode.com/problems/minimum-number-of-days-to-disconnect-island

PROBLEM

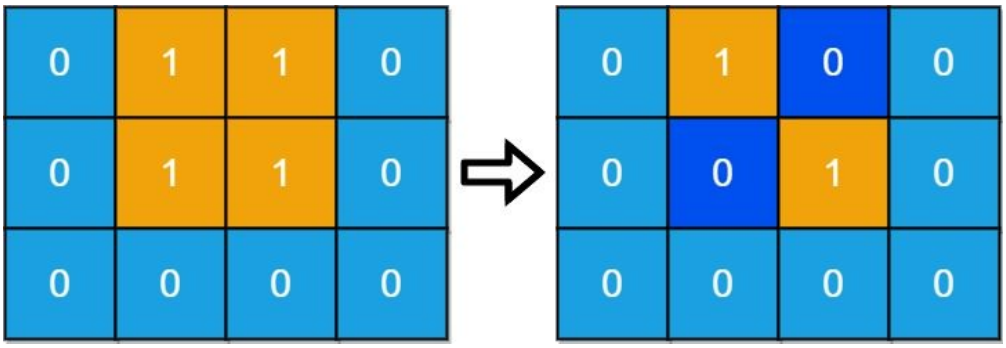
You are given an `m x n` binary grid `grid` where `1` represents land and `0` represents water. An **island** is a maximal **4-directionally** (horizontal or vertical) connected group of `1`'s.

The grid is said to be **connected** if we have **exactly one island**, otherwise is said **disconnected**.

In one day, we are allowed to change **any** single land cell `(1)` into a water cell `(0)`.

Return *the minimum number of days to disconnect the grid*.

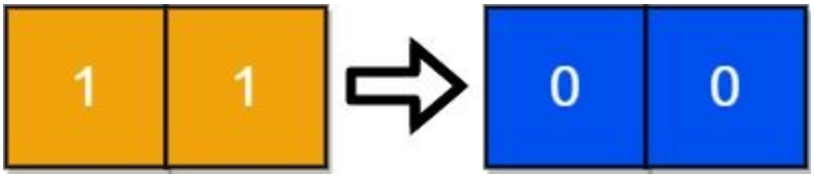
Example 1:



```
Input: grid = [[0,1,1,0],[0,1,1,0],[0,0,0,0]]

Output: 2
Explanation: We need at least 2 days to get a disconnected grid.
Change land grid[1][1] and grid[0][2] to water and get 2 disconnected island.
```

Example 2:



```
Input: grid = [[1,1]]
Output: 2
Explanation: Grid of full water is also disconnected ([[1,1]] -> [[0,0]]), 0 islands.
```

Constraints:

- `m == grid.length`
- `n == grid[i].length`
- `1 <= m, n <= 30`
- `grid[i][j]` is either `0` or `1`.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Each day one land cell may turn to water; we want the grid to stop containing exactly one island. The grid is small, and a stronger fact holds: any island can be split by removing at most two cells (for example two adjacent corner lands). Hence the answer is 0, 1, or 2. A DFS count that is not exactly one returns 0. Temporarily deleting each land cell and recounting returns 1 as soon as the island splits. Otherwise two deletions are required.

Python 3

```python
class Solution:
    def minDays(self, grid: List[List[int]]) -> int:
        if self.count(grid) != 1:
            return 0
        m, n = len(grid), len(grid[0])
        for i in range(m):
            for j in range(n):
                if grid[i][j] == 1:
                    grid[i][j] = 0
                    if self.count(grid) != 1:
                        return 1
                    grid[i][j] = 1
        return 2

    def count(self, grid):
        def dfs(i, j):
            grid[i][j] = 2
            for a, b in [[0, -1], [0, 1], [1, 0], [-1, 0]]:
                x, y = i + a, j + b
                if 0 <= x < m and 0 <= y < n and grid[x][y] == 1:
                    dfs(x, y)

        m, n = len(grid), len(grid[0])
        cnt = 0
        for i in range(m):
            for j in range(n):
                if grid[i][j] == 1:
                    dfs(i, j)
                    cnt += 1
        for i in range(m):
            for j in range(n):
                if grid[i][j] == 2:
                    grid[i][j] = 1
        return cnt
```

Complexity. Time: O((m * n)^2) (a full island count for every land cell). Space: O(m * n).

1293. Shortest Path in a Grid with Obstacles Elimination

Hard · Breadth-First Search, Array, Matrix

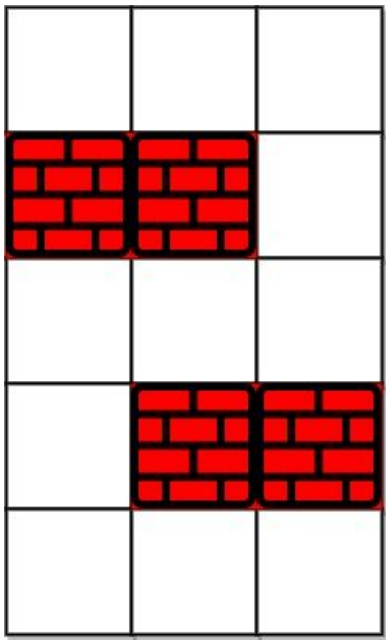
leetcode.com/problems/shortest-path-in-a-grid-with-obstacles-elimination

PROBLEM

You are given an `m x n` integer matrix `grid` where each cell is either `0` (empty) or `1` (obstacle). You can move up, down, left, or right from and to an empty cell in **one step**.

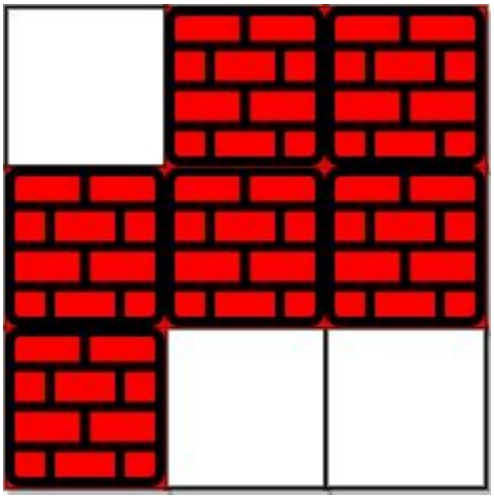
Return *the minimum number of **steps** to walk from the upper left corner* `(0, 0)` *to the lower right corner* `(m - 1, n - 1)` *given that you can eliminate **at most** `k` obstacles*. If it is not possible to find such walk return `-1`.

Example 1:



```
Input: grid = [[0,0,0],[1,1,0],[0,0,0],[0,1,1],[0,0,0]], k = 1
Output: 6
Explanation:
The shortest path without eliminating any obstacle is 10.
The shortest path with one obstacle elimination at position (3,2) is 6. Such path is (0,0) -> (0,1) -> (0,2) -> (1,2) -> (2,2) -> (3,2) -> (4,2).
```

Example 2:



```
Input: grid = [[0,1,1],[1,1,1],[1,0,0]], k = 1
Output: -1
Explanation: We need to eliminate at least two obstacles to find such a walk.
```

Constraints:

- `m == grid.length`
- `n == grid[i].length`
- `1 <= m, n <= 40`
- `1 <= k <= m * n`
- `grid[i][j]` is either `0` **or** `1`.
- `grid[0][0] == grid[m - 1][n - 1] == 0`

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Shortest path on a grid, with at most k obstacles removable. m,n ≤ 40, so a state includes remaining removals. BFS layers are steps; if k already covers the Manhattan detour we return that length. The queue stores (i,j,k left). Empty cells keep k; obstacles use k-1. The same cell with different remaining k is another state. The first time we reach the end is shortest.

Python 3

```python
class Solution:
    def shortestPath(self, grid: List[List[int]], k: int) -> int:
        m, n = len(grid), len(grid[0])
        if k >= m + n - 3:
            return m + n - 2
        q = deque([(0, 0, k)])
        vis = {(0, 0, k)}
        ans = 0
        while q:
            ans += 1
            for _ in range(len(q)):
                i, j, k = q.popleft()
                for a, b in [[0, -1], [0, 1], [1, 0], [-1, 0]]:
                    x, y = i + a, j + b
                    if 0 <= x < m and 0 <= y < n:
                        if x == m - 1 and y == n - 1:
                            return ans
                        if grid[x][y] == 0 and (x, y, k) not in vis:
                            q.append((x, y, k))
                            vis.add((x, y, k))
                        if grid[x][y] == 1 and k > 0 and (x, y, k - 1) not in vis:
                            q.append((x, y, k - 1))
                            vis.add((x, y, k - 1))
        return -1
```

Complexity. Time: O(m * n * k). Space: O(m * n * k).

PATTERN 17 · GRAPH BFS · PROBLEM 20 OF 20

126. Word Ladder II

Hard · Breadth-First Search, Hash Table, String, Backtracking, Bidirectional Search

leetcode.com/problems/word-ladder-ii

PROBLEM

A **transformation sequence** from word `beginWord` to word `endWord` using a dictionary `wordList` is a sequence of words `beginWord -> s1 -> s2 -> ... -> sk` such that:

- Every adjacent pair of words differs by a single letter.
- Every s_i for `1 <= i <= k` is in `wordList`. Note that `beginWord` does not need to be in `wordList`.
- s_k `== endWord`

Given two words, `beginWord` and `endWord`, and a dictionary `wordList`, return *all the **shortest transformation sequences** from* `beginWord` *to* `endWord`*, or an empty list if no such sequence exists. Each sequence should be returned as a list of the words* `[beginWord, s1, s2, ..., sk]`.

Example 1:

```
Input: beginWord = "hit", endWord = "cog", wordList = ["hot","dot","dog","lot","log","cog"]
Output: [["hit","hot","dot","dog","cog"],["hit","hot","lot","log","cog"]]
Explanation: There are 2 shortest transformation sequences:
"hit" -> "hot" -> "dot" -> "dog" -> "cog"
"hit" -> "hot" -> "lot" -> "log" -> "cog"
```

Example 2:

```
Input: beginWord = "hit", endWord = "cog", wordList = ["hot","dot","dog","lot","log"]
Output: []
Explanation: The endWord "cog" is not in wordList, therefore there is no valid transformation
sequence.
```

Constraints:

- `1 <= beginWord.length <= 5`
- `endWord.length == beginWord.length`
- `1 <= wordList.length <= 500`
- `wordList[i].length == beginWord.length`
- `beginWord`, `endWord`, and `wordList[i]` consist of lowercase English letters.
- `beginWord != endWord`
- All the words in `wordList` are **unique**.
- The **sum** of all shortest transformation sequences does not exceed 10^5.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

We need every shortest transformation, not just the length. Words have length at most 5 and the list at most 500, so the BFS depth is small, but the number of paths can be large. Unidirectional BFS expands level by level and records each word's predecessors. Only edges that keep the current distance are stored, so every recorded path is shortest. After the end word is reached, walk the predecessor sets backward to list them all.

Python 3

```
class Solution:
    def findLadders(
        self, beginWord: str, endWord: str, wordList: List[str]
    ) -> List[List[str]]:
        def dfs(path, cur):
            if cur == beginWord:
                ans.append(path[::-1])
                return
            for precursor in prev[cur]:
                path.append(precursor)
                dfs(path, precursor)
                path.pop()

        ans = []
        words = set(wordList)
        if endWord not in words:
            return ans
        words.discard(beginWord)
        dist = {beginWord: 0}
        prev = defaultdict(set)
        q = deque([beginWord])
        found = False
        step = 0
        while q and not found:
            step += 1
            for i in range(len(q), 0, -1):
                p = q.popleft()
                s = list(p)
                for i in range(len(s)):
                    ch = s[i]
                    for j in range(26):
                        s[i] = chr(ord('a') + j)
                        t = ''.join(s)
                        if dist.get(t, 0) == step:
                            prev[t].add(p)
                        if t not in words:
                            continue
                        prev[t].add(p)
                        words.discard(t)
                        q.append(t)
                        dist[t] = step
                        if endWord == t:
                            found = True
                    s[i] = ch
        if found:
            path = [endWord]
            dfs(path, endWord)
        return ans
```

Complexity. Time: O(N * L^2) for the search, plus the number of shortest paths times their length to list them. Space: O(N * L) plus the paths.

Matrix / Grid Traversal

20 problems · 4 Easy · 15 Medium · 1 Hard

THE IDEA

A grid is a graph: each cell has up to four neighbours. Use the four-direction list and a bounds check, then DFS or BFS as needed.

Signals: number of islands, flood fill, surrounded regions, spiral order, rotate image, set matrix zeroes, word search.

A TEMPLATE TO KEEP IN YOUR HANDS (PYTHON)

```
DIRS = ((1, 0), (-1, 0), (0, 1), (0, -1))
for dr, dc in DIRS:
    nr, nc = r + dr, c + dc
    if 0 <= nr < rows and 0 <= nc < cols and grid[nr][nc] == 1:
        visit(nr, nc)
```

463. Island Perimeter

Easy · Depth-First Search, Breadth-First Search, Array, Matrix

leetcode.com/problems/island-perimeter

★ **TOP 10 PROBLEM** in Matrix / Grid Traversal: master this one first

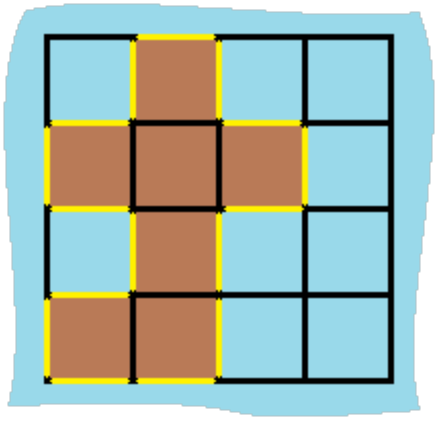
PROBLEM

You are given `row x col grid` representing a map where `grid[i][j] = 1` represents land and `grid[i][j] = 0` represents water.

Grid cells are connected **horizontally/vertically** (not diagonally). The `grid` is completely surrounded by water, and there is exactly one island (i.e., one or more connected land cells).

The island doesn't have "lakes", meaning the water inside isn't connected to the water around the island. One cell is a square with side length 1. The grid is rectangular, width and height don't exceed 100. Determine the perimeter of the island.

Example 1:



```
Input: grid = [[0,1,0,0],[1,1,1,0],[0,1,0,0],[1,1,0,0]]
Output: 16
Explanation: The perimeter is the 16 yellow stripes in the image above.
```

Example 2:

```
Input: grid = [[1]]
Output: 4
```

Example 3:

```
Input: grid = [[1,0]]
Output: 4
```

Constraints:

- `row == grid.length`
- `col == grid[i].length`
- `1 <= row, col <= 100`
- `grid[i][j]` is `0` or `1`.
- There is exactly one island in `grid`.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

The island is 4-connected; perimeter is 4 per land cell minus twice every shared edge. Checking all four neighbors needs bounds tests. Add 4 for each land cell; if the cell below or to the right is also land, that edge is shared, so subtract 2. Looking only down and right counts each inner edge once. No graph or DFS is required; one grid scan yields the perimeter.

Python 3

```python
class Solution:
    def islandPerimeter(self, grid: List[List[int]]) -> int:
        m, n = len(grid), len(grid[0])
        ans = 0
        for i in range(m):
            for j in range(n):
                if grid[i][j] == 1:
                    ans += 4
                    if i < m - 1 and grid[i + 1][j] == 1:
                        ans -= 2
                    if j < n - 1 and grid[i][j + 1] == 1:
                        ans -= 2
        return ans
```

Complexity. Time: O(m * n). Space: O(1).

```

766. Toeplitz Matrix

Easy · Array, Matrix

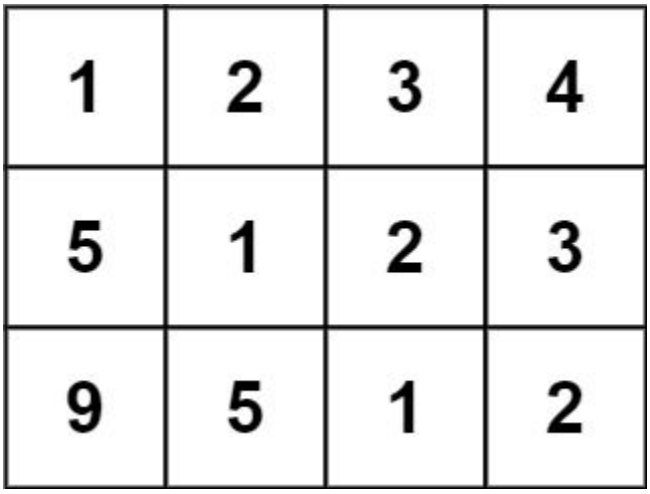
leetcode.com/problems/toeplitz-matrix

PROBLEM

Given an `m x n matrix`, return `true` *if the matrix is Toeplitz. Otherwise, return* `false`.

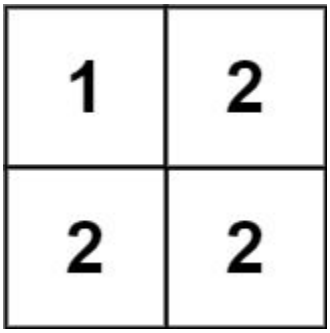
A matrix is **Toeplitz** if every diagonal from top-left to bottom-right has the same elements.

Example 1:



```
Input: matrix = [[1,2,3,4],[5,1,2,3],[9,5,1,2]]
Output: true
Explanation:
In the above grid, the diagonals are:
"[9]", "[5, 5]", "[1, 1, 1]", "[2, 2, 2]", "[3, 3]", "[4]".
In each diagonal all elements are the same, so the answer is True.
```

Example 2:



```
Input: matrix = [[1,2],[2,2]]
Output: false
Explanation:
The diagonal "[1, 2]" has different elements.
```

Constraints:

- `m == matrix.length`
- `n == matrix[i].length`
- `1 <= m, n <= 20`
- `0 <= matrix[i][j] <= 99`

Follow up:

- What if the `matrix` is stored on disk, and the memory is limited such that you can only load at most one row of the matrix into the memory at once?
- What if the `matrix` is so large that you can only load up a partial row into the memory at once?

SOLUTION (PYTHON 3)

Solution 1: Single Traversal

> **How to think about it**
>
> A Toeplitz matrix has equal diagonals, i.e. every cell equals its upper-left neighbor. The grid is at most 20× 20. Scan from (1,1); fail if matrix[i][j]≠ matrix[i-1][j-1]. The first row and column have no predecessor.

According to the problem description, the characteristic of a Toeplitz matrix is that each element is equal to the element in its upper left corner. Therefore, we only need to iterate through each element in the matrix and check if it is equal to the element in its upper left corner.

The time complexity is O(m × n), where m and n are the number of rows and columns of the matrix, respectively. The space complexity is O(1).

Python 3

```
class Solution:
    def isToeplitzMatrix(self, matrix: List[List[int]]) -> bool:
        m, n = len(matrix), len(matrix[0])
        for i in range(1, m):
            for j in range(1, n):
                if matrix[i][j] != matrix[i - 1][j - 1]:
                    return False
        return True
```

                return (r, c)
    return None
```

867. Transpose Matrix

Easy · Array, Matrix, Simulation

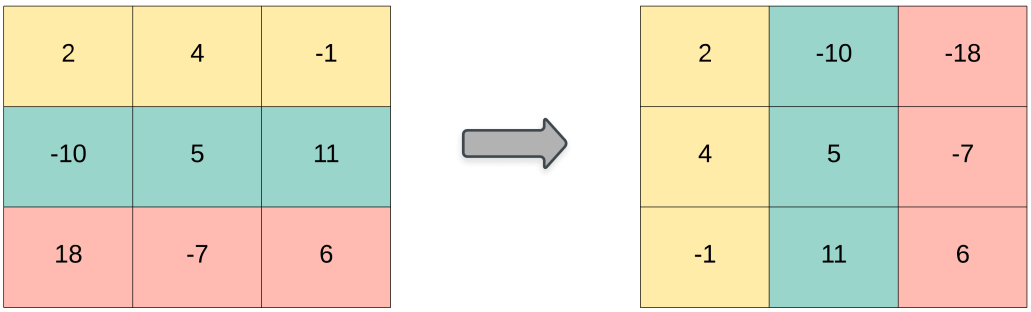
leetcode.com/problems/transpose-matrix

★ **TOP 10 PROBLEM** in Matrix / Grid Traversal: master this one first

PROBLEM

Given a 2D integer array `matrix`, return *the **transpose** of* `matrix`.

The **transpose** of a matrix is the matrix flipped over its main diagonal, switching the matrix's row and column indices.



Example 1:

```
Input: matrix = [[1,2,3],[4,5,6],[7,8,9]]
Output: [[1,4,7],[2,5,8],[3,6,9]]
```

Example 2:

```
Input: matrix = [[1,2,3],[4,5,6]]
Output: [[1,4],[2,5],[3,6]]
```

Constraints:

- `m == matrix.length`
- `n == matrix[i].length`
- `1 <= m, n <= 1000`
- `1 <= m * n <= 10^5`
- `-10^9 <= matrix[i][j] <= 10^9`

SOLUTION (PYTHON 3)

Solution 1: Simulation

How to think about it

A transpose swaps rows and columns. The matrix is small enough to build a new one; in-place swaps are unnecessary. zip over the matrix turns each column into a new row.

Let m be the number of rows and n be the number of columns in the matrix matrix. According to the definition of transpose, the transposed matrix ans will have n rows and m columns.

For any position (i, j) in ans, it corresponds to the position (j, i) in the matrix matrix. Therefore, we traverse each element in the matrix matrix and transpose it to the corresponding position in ans.

After the traversal, we return ans.

The time complexity is O(m × n), where m and n are the number of rows and columns in the matrix matrix, respectively. Ignoring the space consumption of the answer, the space complexity is O(1).

Python 3

```python
class Solution:
    def transpose(self, matrix: List[List[int]]) -> List[List[int]]:
        return [list(row) for row in zip(*matrix)]
```

# proportional to the number of stored cells.
# Time: O(k), k = non-zero cells.  Space: O(k).
def transpose_sparse(cells):
    result = {}
    for (row, col), value in cells.items():
        result[(col, row)] = value
    return result
```

54. Spiral Matrix

Medium · Array, Matrix, Simulation

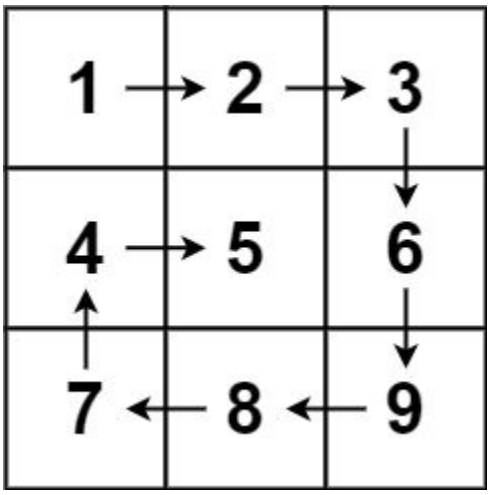
leetcode.com/problems/spiral-matrix

★ **TOP 10 PROBLEM** in Matrix / Grid Traversal: master this one first

PROBLEM

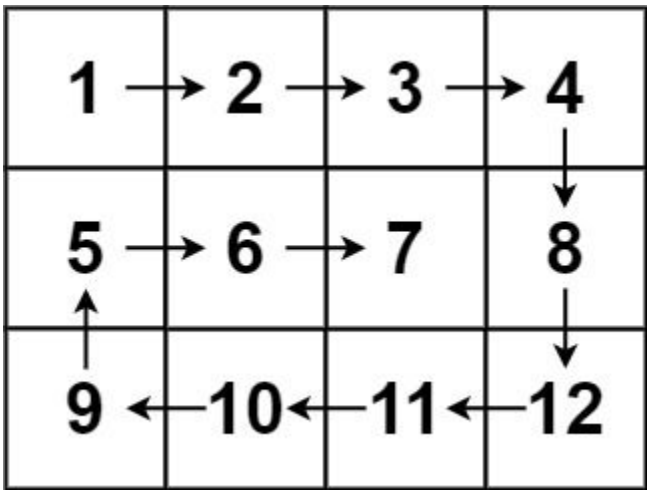
Given an `m x n matrix`, return *all elements of the* `matrix` *in spiral order*.

Example 1:



```
Input: matrix = [[1,2,3],[4,5,6],[7,8,9]]
Output: [1,2,3,6,9,8,7,4,5]
```

Example 2:



```
Input: matrix = [[1,2,3,4],[5,6,7,8],[9,10,11,12]]
Output: [1,2,3,4,8,12,11,10,9,5,6,7]
```

Constraints:

- `m == matrix.length`
- `n == matrix[i].length`
- `1 <= m, n <= 10`
- `-100 <= matrix[i][j] <= 100`

SOLUTIONS (PYTHON 3)

Solution 1: Simulation

> **How to think about it**
>
> The first idea is to peel layers: four loops per layer for top, right, bottom, left, then shrink the bounds. m, n ≤ 10 would pass, but a leftover single row or column is easy to get wrong. The waste is hand-managing four edges. A spiral is: keep the current direction, and turn right when the next cell is out of bounds or already visited. So we cycle four directions and mark visited cells in vis, taking m × n steps.

We can simulate the entire traversal process. We use i and j to represent the row and column of the current element being visited, and k to represent the current direction. We use an array or hash table vis to record whether each element has been visited. Each time we visit an element, we mark it as visited, then move one step forward in the current direction. If moving forward results in an out-of-bounds condition or the element has already been visited, we change direction and continue moving forward until the entire matrix has been traversed.

The time complexity is O(m × n), and the space complexity is O(m × n). Here, m and n are the number of rows and columns of the matrix, respectively.

Python 3

```python
class Solution:
    def spiralOrder(self, matrix: List[List[int]]) -> List[int]:
        m, n = len(matrix), len(matrix[0])
        dirs = (0, 1, 0, -1, 0)
        vis = [[False] * n for _ in range(m)]
        i = j = k = 0
        ans = []
        for _ in range(m * n):
            ans.append(matrix[i][j])
            vis[i][j] = True
            x, y = i + dirs[k], j + dirs[k + 1]
            if x < 0 or x >= m or y < 0 or y >= n or vis[x][y]:
                k = (k + 1) % 4
            i += dirs[k]
            j += dirs[k + 1]
        return ans
```

Solution 2: Simulation (Space Optimization)

> **How to think about it**
>
> Solution 1 already walks the matrix in linear time, but vis still costs O(mn) extra space. Values lie in [-100, 100], so the visit mark can be written back into the cell. What it lacks is an in-place mark: add 300 to a visited cell, and treat > 100 as seen. Subtract 300 afterwards. Extra space drops to O(1).

Notice that the range of matrix element values is [-100, 100]. Therefore, we can add a large value, such as 300, to the visited elements. This way, we only need to check if the visited element is greater than 100, without needing extra space to record whether it has been visited. If we need to restore the original values of the visited elements, we can traverse the matrix again after the traversal is complete and subtract 300 from all elements.

The time complexity is O(m × n), where m and n are the number of rows and columns of the matrix, respectively. The space complexity is O(1).

Python 3

```python
class Solution:
    def spiralOrder(self, matrix: List[List[int]]) -> List[int]:
        m, n = len(matrix), len(matrix[0])
        dirs = (0, 1, 0, -1, 0)
        i = j = k = 0
        ans = []
        for _ in range(m * n):
            ans.append(matrix[i][j])
            matrix[i][j] += 300
            x, y = i + dirs[k], j + dirs[k + 1]
            if x < 0 or x >= m or y < 0 or y >= n or matrix[x][y] > 100:
                k = (k + 1) % 4
            i += dirs[k]
            j += dirs[k + 1]
        for i in range(m):
            for j in range(n):
                matrix[i][j] -= 300
        return ans
```

PATTERN 18 · MATRIX / GRID TRAVERSAL · PROBLEM 8 OF 20

59. Spiral Matrix II

Medium · Array, Matrix, Simulation

leetcode.com/problems/spiral-matrix-ii

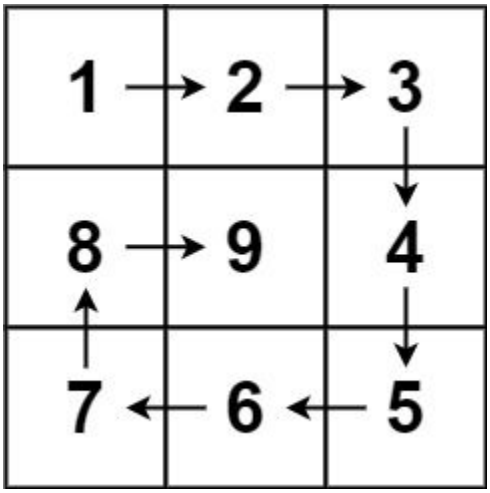
★ **TOP 10 PROBLEM** in Simulation / Array Rearrangement: master this one first

Also appears in pattern 36 Simulation / Array Rearrangement

PROBLEM

Given a positive integer `n`, generate an `n x n matrix` filled with elements from `1` to n^2 in spiral order.

Example 1:



```
Input: n = 3
Output: [[1,2,3],[8,9,4],[7,6,5]]
```

Example 2:

```
Input: n = 1
Output: [[1]]
```

Constraints:

- `1 <= n <= 20`

SOLUTION (PYTHON 3)

Solution 1: Simulation

How to think about it

The first idea is to fill by layers: four edges per layer, then shrink. n ≤ 20 would pass, with the same boundary bugs. The waste is hand-managing four edges. As in spiral read: keep the direction, turn right when the next cell is out of bounds or already filled. Empty cells are 0, filled cells are nonzero, so no extra vis. So cycle directions and write 1 through n^2.

We can directly simulate the process of generating the spiral matrix.

Define a 2D array ans to store the spiral matrix. Use i and j to represent the current row and column indices, and use k to represent the current direction index. dirs represents the mapping between direction indices and directions.

Starting from 1, fill each position in the matrix sequentially. After filling a position, calculate the row and column indices of the next position. If the next position is out of bounds or has already been filled, change the direction and then calculate the row and column indices of the next position.

The time complexity is $O(n^2)$, where n is the side length of the matrix. Ignoring the space consumption of the answer array, the space complexity is O(1).

Python 3

```
class Solution:
    def generateMatrix(self, n: int) -> List[List[int]]:
        ans = [[0] * n for _ in range(n)]
        dirs = (0, 1, 0, -1, 0)
        i = j = k = 0
        for v in range(1, n * n + 1):
            ans[i][j] = v
            x, y = i + dirs[k], j + dirs[k + 1]
            if x < 0 or x >= n or y < 0 or y >= n or ans[x][y]:
                k = (k + 1) % 4
            i, j = i + dirs[k], j + dirs[k + 1]
        return ans
```

48. Rotate Image

Medium · Array, Math, Matrix

leetcode.com/problems/rotate-image

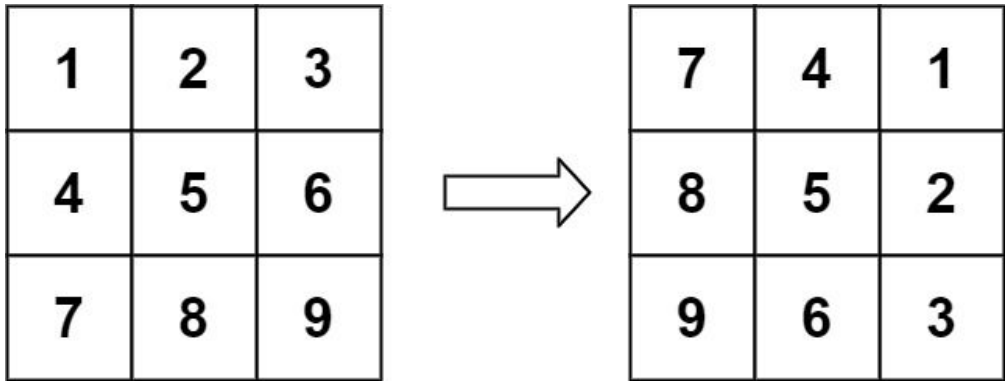
★ **TOP 10 PROBLEM** in Matrix / Grid Traversal: master this one first

PROBLEM

You are given an `n x n` 2D `matrix` representing an image, rotate the image by **90** degrees (clockwise).

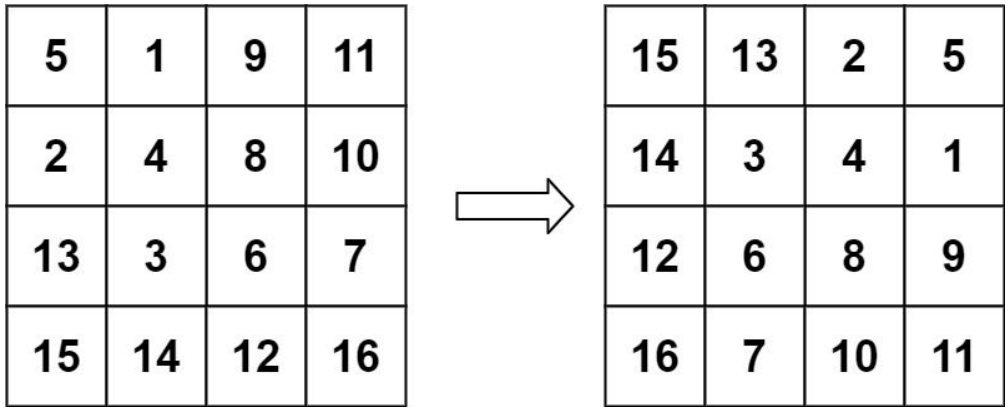
You have to rotate the image **in-place**, which means you have to modify the input 2D matrix directly. **DO NOT** allocate another 2D matrix and do the rotation.

Example 1:



```
Input: matrix = [[1,2,3],[4,5,6],[7,8,9]]
Output: [[7,4,1],[8,5,2],[9,6,3]]
```

Example 2:



```
Input: matrix = [[5,1,9,11],[2,4,8,10],[13,3,6,7],[15,14,12,16]]
Output: [[15,13,2,5],[14,3,4,1],[12,6,8,9],[16,7,10,11]]
```

Constraints:

- `n == matrix.length == matrix[i].length`
- `1 <= n <= 20`
- `-1000 <= matrix[i][j] <= 1000`

SOLUTION (PYTHON 3)

Solution 1: In-place Rotation

> **How to think about it**
>
> The first idea is a new matrix with matrix[j][n-1-i] ← matrix[i][j]. Correct, O(n^2) time and space. n ≤ 20 fits, but the problem requires in-place. The extra matrix is the bottleneck. A 90° clockwise turn factors into two in-place flips: reverse upside-down, then transpose across the main diagonal. (i, j) goes to (n-1-i, j), then to (j, n-1-i) — the target. Two rounds of swaps, O(1) extra space.

According to the problem requirements, we need to rotate matrix[i][j] to matrix[j][n - i - 1].

We can first flip the matrix upside down, i.e., swap matrix[i][j] with matrix[n - i - 1][j], and then flip the matrix along the main diagonal, i.e., swap matrix[i][j] with matrix[j][i]. This way, we can rotate matrix[i][j] to matrix[j][n - i - 1].

The time complexity is O(n^2), where n is the side length of the matrix. The space complexity is O(1).

Python 3

```
class Solution:
    def rotate(self, matrix: List[List[int]]) -> None:
        n = len(matrix)
        for i in range(n >> 1):
            for j in range(n):
                matrix[i][j], matrix[n - i - 1][j] = matrix[n - i - 1][j], matrix[i][j]
        for i in range(n):
            for j in range(i):
                matrix[i][j], matrix[j][i] = matrix[j][i], matrix[i][j]
```

```

PATTERN 18 · MATRIX / GRID TRAVERSAL · PROBLEM 10 OF 20

73. Set Matrix Zeroes

Medium · Array, Hash Table, Matrix

leetcode.com/problems/set-matrix-zeroes

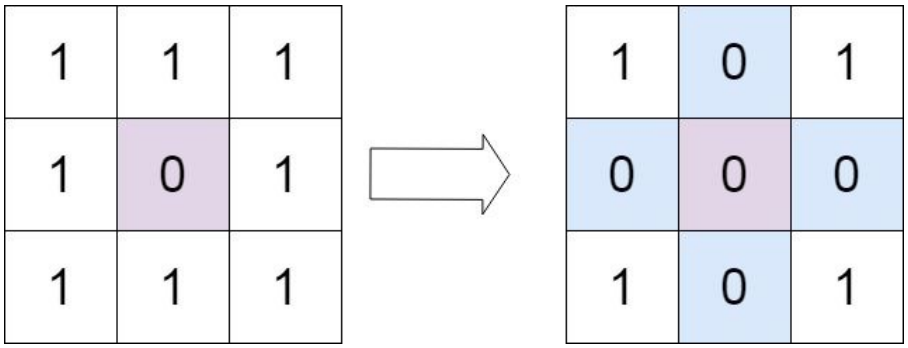
★ **TOP 10 PROBLEM** in Matrix / Grid Traversal: master this one first

PROBLEM

Given an `m x n` integer matrix `matrix`, if an element is `0`, set its entire row and column to `0`'s.

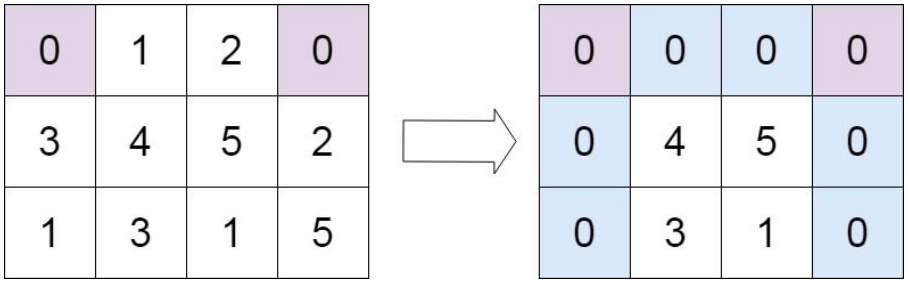
You must do it in place.

Example 1:



```
Input: matrix = [[1,1,1],[1,0,1],[1,1,1]]
Output: [[1,0,1],[0,0,0],[1,0,1]]
```

Example 2:



```
Input: matrix = [[0,1,2,0],[3,4,5,2],[1,3,1,5]]
Output: [[0,0,0,0],[0,4,5,0],[0,3,1,0]]
```

Constraints:

- `m == matrix.length`
- `n == matrix[0].length`
- `1 <= m, n <= 200`
- -2^{31} `<= matrix[i][j] <=` $2^{31} - 1$

Follow up:

- A straightforward solution using `O(mn)` space is probably a bad idea.
- A simple improvement uses `O(m + n)` space, but still not the best solution.
- Could you devise a constant space solution?

SOLUTIONS (PYTHON 3)

Solution 1: Array Mark

> **How to think about it**
>
> Zeroing a whole row and column as soon as we see a 0 wipes zeros we have not scanned yet, and we cannot tell original zeros from new ones. Copying an O(mn) matrix works, but the follow-up rejects that space. m,n ≤ 200, so two scans are fine. Record which rows and columns must be zeroed, then rewrite. An m-length row mark and an n-length column mark suffice: first pass only flags, second pass writes zeros. Extra space drops from O(mn) to O(m+n), still not the constant-space follow-up.

We use arrays `rows` and `cols` to mark the rows and columns to be cleared.

Then traverse the matrix again, and clear the elements in the rows and columns marked in `rows` and `cols`.

The time complexity is O(m× n), and the space complexity is O(m+n). Where m and n are the number of rows and columns of the matrix respectively.

Python 3

```python
class Solution:
    def setZeroes(self, matrix: List[List[int]]) -> None:
        m, n = len(matrix), len(matrix[0])
        row = [False] * m
        col = [False] * n
        for i in range(m):
            for j in range(n):
                if matrix[i][j] == 0:
                    row[i] = col[j] = True
        for i in range(m):
            for j in range(n):
                if row[i] or col[j]:
                    matrix[i][j] = 0
```

Solution 2: Mark in Place

> **How to think about it**
>
> Method 1 still spends O(m+n) on mark arrays. The follow-up wants O(1) extra space, and the first row and first column can play the role of row and col. Those strips are both data and marks, so we save with i0, j0 whether they themselves must be zeroed, update the interior, and only then clear the first row and column — otherwise the marks get overwritten too early.

In the first method, we use an additional array to mark the rows and columns to be cleared. In fact, we can also use the first row and first column of the matrix to mark them, without creating an additional array.

Since the first row and the first column are used to mark, their values may change due to the mark, so we need additional variables i0, j0 to mark whether the first row and the first column need to be cleared.

The time complexity is O(m× n), and the space complexity is O(1). Where m and n are the number of rows and columns of the matrix respectively.

Python 3

```python
class Solution:
    def setZeroes(self, matrix: List[List[int]]) -> None:
        m, n = len(matrix), len(matrix[0])
        i0 = any(v == 0 for v in matrix[0])
        j0 = any(matrix[i][0] == 0 for i in range(m))
        for i in range(1, m):
            for j in range(1, n):
                if matrix[i][j] == 0:
                    matrix[i][0] = matrix[0][j] = 0
        for i in range(1, m):
            for j in range(1, n):
                if matrix[i][0] == 0 or matrix[0][j] == 0:
                    matrix[i][j] = 0
        if i0:
            for j in range(n):
                matrix[0][j] = 0
        if j0:
            for i in range(m):
                matrix[i][0] = 0
```

498. Diagonal Traverse

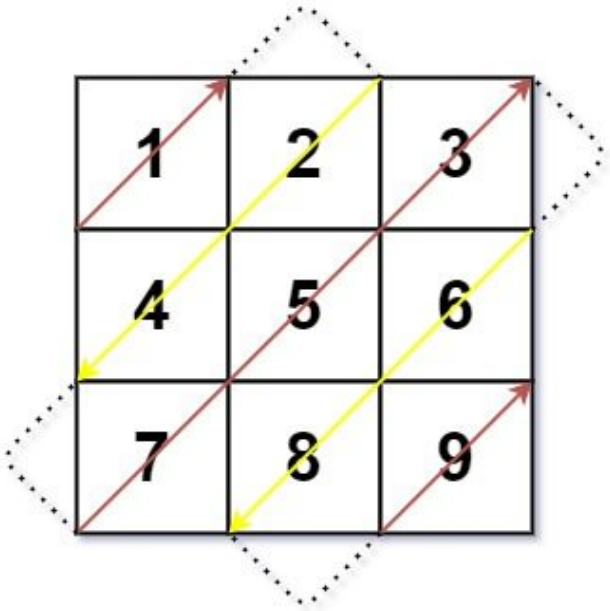
Medium · Array, Matrix, Simulation

leetcode.com/problems/diagonal-traverse

PROBLEM

Given an `m x n` matrix `mat`, return *an array of all the elements of the array in a diagonal order*.

Example 1:



```
Input: mat = [[1,2,3],[4,5,6],[7,8,9]]
Output: [1,2,4,7,5,3,6,8,9]
```

Example 2:

```
Input: mat = [[1,2],[3,4]]
Output: [1,2,3,4]
```

Constraints:

- `m == mat.length`
- `n == mat[i].length`
- `1 <= m, n <= 10^4`
- `1 <= m * n <= 10^4`
- `-10^5 <= mat[i][j] <= 10^5`

SOLUTION (PYTHON 3)

Solution 1: Fixed Point Traversal

How to think about it

Traverse the matrix in zigzag diagonals. Simulating a direction and bouncing off edges needs many boundary cases. There are m+n-1 diagonals, each with a closed-form start. Diagonal k is collected top-right to bottom-left, starting at (0,k) when k<n and (k-n+1,n-1) otherwise. Even k is reversed to match the required zigzag. Always walking down-left and flipping on even k avoids switching a direction vector on the border.

For each round k, we fix the starting point from the top-right and traverse diagonally to the bottom-left to get t. If k is even, we reverse t.

The time complexity is O(m × n), and the space complexity is O(1). Ignoring the space used for the answer.

Python 3

```python
class Solution:
    def findDiagonalOrder(self, mat: List[List[int]]) -> List[int]:
        m, n = len(mat), len(mat[0])
        ans = []
        for k in range(m + n - 1):
            t = []
            i = 0 if k < n else k - n + 1
            j = k if k < n else n - 1
            while i < m and j >= 0:
                t.append(mat[i][j])
                i += 1
                j -= 1
            if k % 2 == 0:
                t = t[::-1]
            ans.extend(t)
        return ans
```

289. Game of Life

Medium · Array, Matrix, Simulation

leetcode.com/problems/game-of-life

★ **TOP 10 PROBLEM** in Matrix / Grid Traversal, Simulation / Array Rearrangement: master this one first

Also appears in pattern 36 Simulation / Array Rearrangement

PROBLEM

According to Wikipedia's article: "The **Game of Life**, also known simply as **Life**, is a cellular automaton devised by the British mathematician John Horton Conway in 1970."

The board is made up of an `m x n` grid of cells, where each cell has an initial state: **live** (represented by a `1`) or **dead** (represented by a `0`). Each cell interacts with its eight neighbors (horizontal, vertical, diagonal) using the following four rules (taken from the above Wikipedia article):

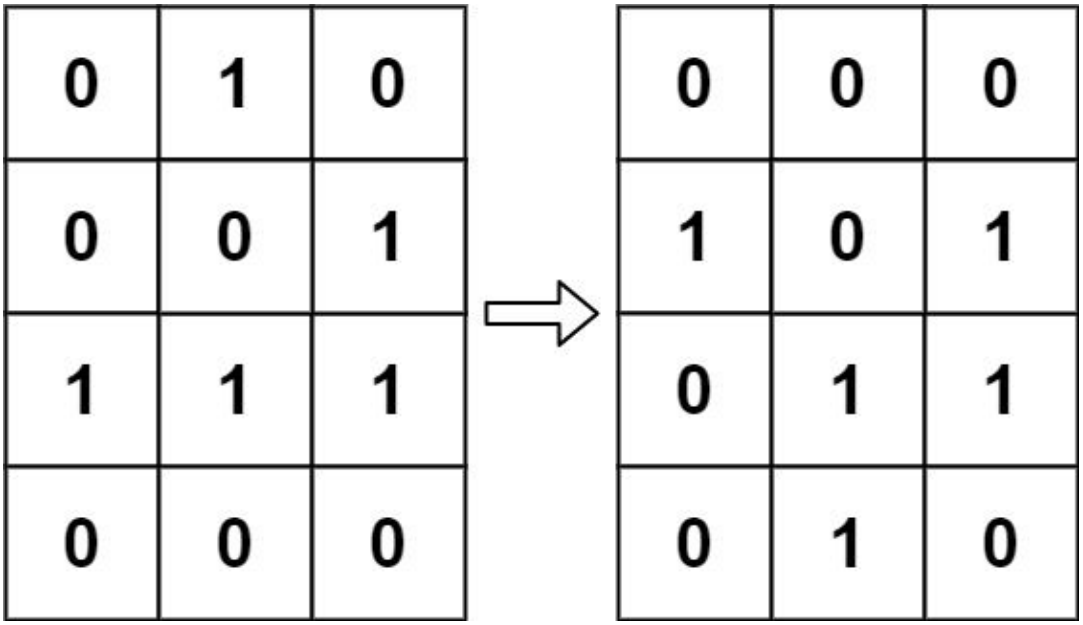
1. Any live cell with fewer than two live neighbors dies as if caused by under-population.
2. Any live cell with two or three live neighbors lives on to the next generation.
3. Any live cell with more than three live neighbors dies, as if by over-population.
4. Any dead cell with exactly three live neighbors becomes a live cell, as if by reproduction.

The next state of the board is determined by applying the above rules simultaneously to every cell in the current state of the `m x n` grid `board`. In this process, births and deaths occur **simultaneously**.

Given the current state of the `board`, **update** the `board` to reflect its next state.

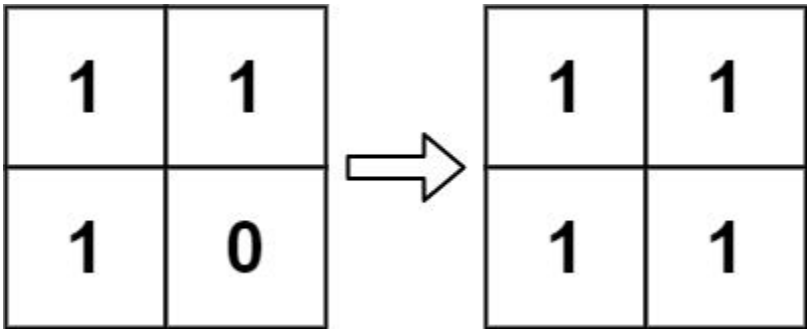
Note that you do not need to return anything.

Example 1:



```
Input: board = [[0,1,0],[0,0,1],[1,1,1],[0,0,0]]
Output: [[0,0,0],[1,0,1],[0,1,1],[0,1,0]]
```

Example 2:



```
Input: board = [[1,1],[1,0]]
Output: [[1,1],[1,1]]
```

Constraints:

- `m == board.length`
- `n == board[i].length`
- `1 <= m, n <= 25`
- `board[i][j]` is `0` or `1`.

Follow up:

- Could you solve it in-place? Remember that the board needs to be updated simultaneously: You cannot update some cells first and then use their updated values to update other cells.
- In this question, we represent the board using a 2D array. In principle, the board is infinite, which would cause problems when the active area encroaches upon the border of the array (i.e., live cells reach the border). How would you address these problems?

SOLUTION (PYTHON 3)

Solution 1: In-place marking

How to think about it

The next state depends on the current eight neighbors; writing immediately would spoil cells not yet processed. Use sentinels: live-to-dead as 2, dead-to-live as -1, and treat positives as live when counting. A second pass maps 2 to 0 and -1 to 1, all in place.

Let's define two new states. State 2 indicates that the living cell becomes dead in the next state, and state -1 indicates that the dead cell becomes alive in the next state. Therefore, for the current grid we are traversing, if the grid is greater than 0, it means that the current grid is a living cell, otherwise it is a dead cell.

So we can traverse the entire board, for each grid, count the number of living neighbors around the grid, and use the variable live to represent it. If the current grid is a living cell, then when live < 2 or live > 3, the next state of the current grid is a dead cell, that is, state 2; if the current grid is a dead cell, then when live = 3, the next state of the current grid is an active cell, that is, state -1.

Finally, we traverse the board again, and update the grid with state 2 to a dead cell, and update the grid with state -1 to an active cell.

The time complexity is $O(m \times n)$, where m and n are the number of rows and columns of the board, respectively. We need to traverse the entire board. And the space complexity is $O(1)$.

Python 3

```python
class Solution:
    def gameOfLife(self, board: List[List[int]]) -> None:
        m, n = len(board), len(board[0])
        for i in range(m):
            for j in range(n):
                live = -board[i][j]
                for x in range(i - 1, i + 2):
                    for y in range(j - 1, j + 2):
                        if 0 <= x < m and 0 <= y < n and board[x][y] > 0:
                            live += 1
                if board[i][j] and (live < 2 or live > 3):
                    board[i][j] = 2
                if board[i][j] == 0 and live == 3:
                    board[i][j] = -1
        for i in range(m):
            for j in range(n):
                if board[i][j] == 2:
                    board[i][j] = 0
                elif board[i][j] == -1:
                    board[i][j] = 1
```

694. Number of Distinct Islands

Medium · Depth-First Search, Breadth-First Search, Union Find, Array, Hash Table, Matrix, Sorting, Hash Function

leetcode.com/problems/number-of-distinct-islands

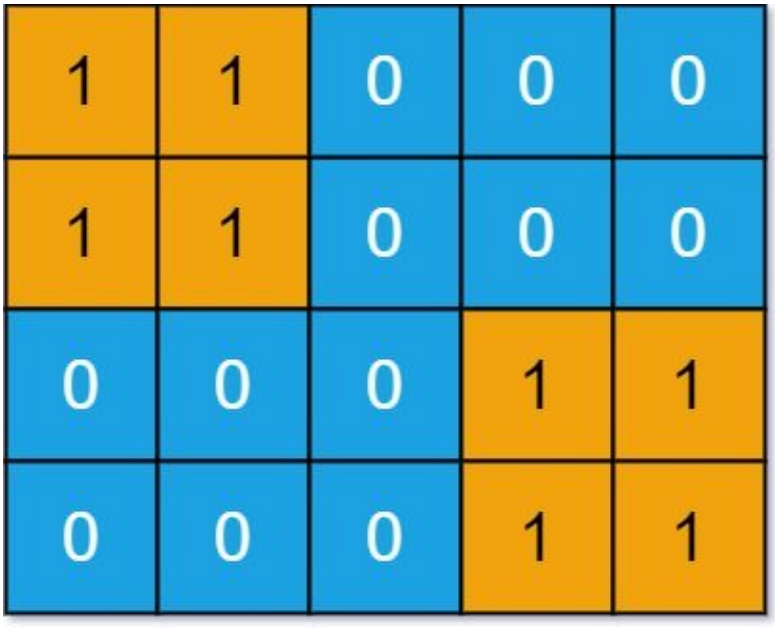
PROBLEM

You are given an `m x n` binary matrix `grid`. An island is a group of `1`'s (representing land) connected **4-directionally** (horizontal or vertical.) You may assume all four edges of the grid are surrounded by water.

An island is considered to be the same as another if and only if one island can be translated (and not rotated or reflected) to equal the other.

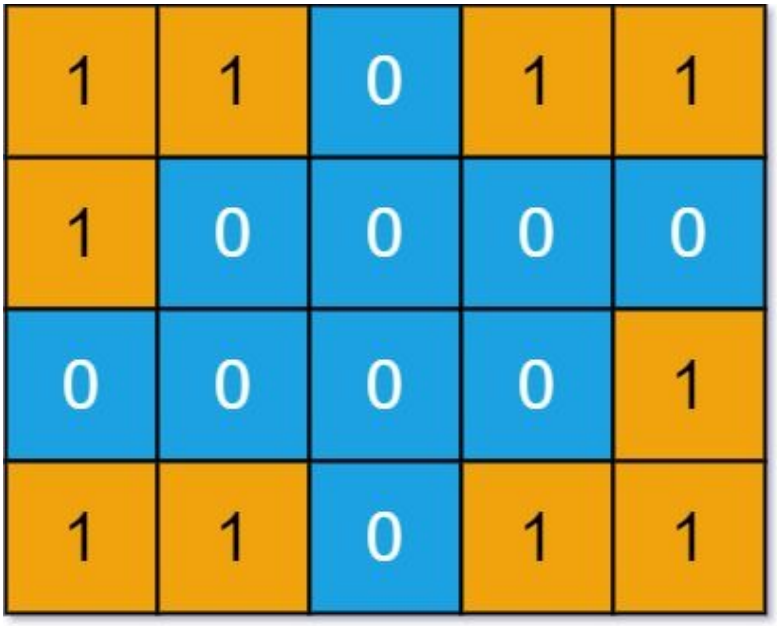
Return *the number of **distinct** islands*.

Example 1:



```
Input: grid = [[1,1,0,0,0],[1,1,0,0,0],[0,0,0,1,1],[0,0,0,1,1]]
Output: 1
```

Example 2:



```
Input: grid = [[1,1,0,1,1],[1,0,0,0,0],[0,0,0,0,1],[1,1,0,1,1]]
Output: 3
```

Constraints:

- `m == grid.length`
- `n == grid[i].length`
- `1 <= m, n <= 50`
- `grid[i][j]` is either `0` or `1`.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Islands are equal iff a translation matches them; rotation does not count. Absolute coordinates need a common origin. DFS records both the step direction and the backtrack. Distinct shapes yield distinct strings; a set of those strings is the answer. Mark land as 0 when visited.

Python 3

```
class Solution:
    def numDistinctIslands(self, grid: List[List[int]]) -> int:
        def dfs(i: int, j: int, k: int):
            grid[i][j] = 0
            path.append(str(k))
            dirs = (-1, 0, 1, 0, -1)
            for h in range(1, 5):
                x, y = i + dirs[h - 1], j + dirs[h]
                if 0 <= x < m and 0 <= y < n and grid[x][y]:
                    dfs(x, y, h)
            path.append(str(-k))

        paths = set()
        path = []
        m, n = len(grid), len(grid[0])
        for i, row in enumerate(grid):
            for j, x in enumerate(row):
                if x:
                    dfs(i, j, 0)
                    paths.add("".join(path))
                    path.clear()
        return len(paths)
```

Complexity. Time: O(m * n). Space: O(m * n).

PATTERN 18 · MATRIX / GRID TRAVERSAL · PROBLEM 19 OF 20

1706. Where Will the Ball Fall

Medium · Array, Matrix, Simulation

leetcode.com/problems/where-will-the-ball-fall

Also appears in pattern 22 Dynamic Programming - 2D / Grid

PROBLEM

You have a 2-D `grid` of size `m x n` representing a box, and you have `n` balls. The box is open on the top and bottom sides.

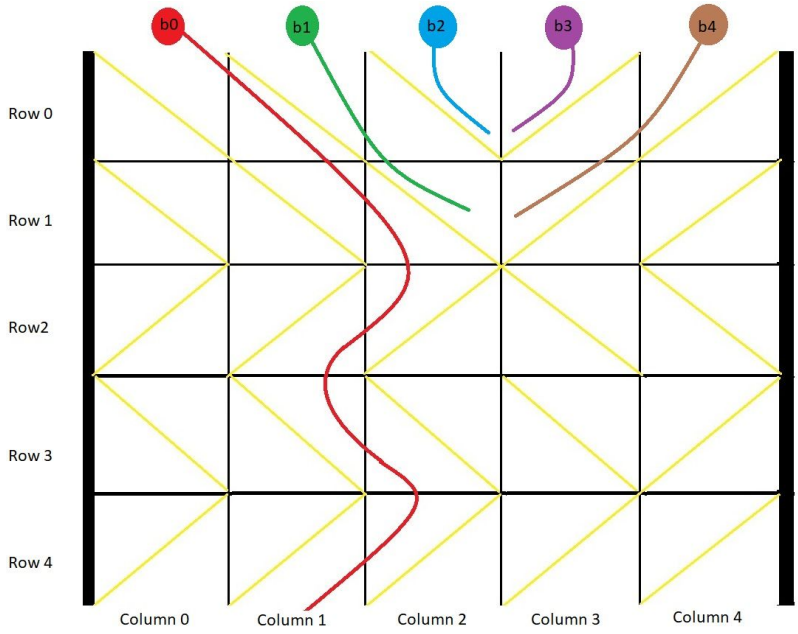
Each cell in the box has a diagonal board spanning two corners of the cell that can redirect a ball to the right or to the left.

- A board that redirects the ball to the right spans the top-left corner to the bottom-right corner and is represented in the grid as `1`.
- A board that redirects the ball to the left spans the top-right corner to the bottom-left corner and is represented in the grid as `-1`.

We drop one ball at the top of each column of the box. Each ball can get stuck in the box or fall out of the bottom. A ball gets stuck if it hits a "V" shaped pattern between two boards or if a board redirects the ball into either wall of the box.

Return *an array* `answer` *of size* `n` *where* `answer[i]` *is the column that the ball falls out of at the bottom after dropping the ball from the* `i`th *column at the top, or* `-1` *if the ball gets stuck in the box.*

Example 1:



```
Input: grid = [[1,1,1,-1,-1],[1,1,1,-1,-1],[-1,-1,-1,1,1],[1,1,1,1,-1],[-1,-1,-1,-1,-1]]
Output: [1,-1,-1,-1,-1]
Explanation: This example is shown in the photo.
Ball b0 is dropped at column 0 and falls out of the box at column 1.
Ball b1 is dropped at column 1 and will get stuck in the box between column 2 and 3 and row 1.
Ball b2 is dropped at column 2 and will get stuck on the box between column 2 and 3 and row 0.
Ball b3 is dropped at column 3 and will get stuck on the box between column 2 and 3 and row 0.
Ball b4 is dropped at column 4 and will get stuck on the box between column 2 and 3 and row 1.
```

Example 2:

```
Input: grid = [[-1]]
Output: [-1]
Explanation: The ball gets stuck against the left wall.
```

Example 3:

```
Input: grid = [[1,1,1,1,1,1],[-1,-1,-1,-1,-1,-1],[1,1,1,1,1,1],[-1,-1,-1,-1,-1,-1]]
Output: [0,1,2,3,4,-1]
```

Constraints:

- `m == grid.length`
- `n == grid[i].length`
- `1 <= m, n <= 100`
- `grid[i][j]` is `1` or `-1`.

SOLUTION (PYTHON 3)

Solution 1: Case Analysis + DFS

How to think about it

A ball is dropped from every top cell and boards steer it left or right. The grid is small enough to simulate each ball independently. A ball gets stuck in four cases: it is on the border and the board pushes it out, or two neighbouring boards form a V. Otherwise it slides diagonally to the next row. Let dfs(i,j) be the exit column from (i,j): return -1 if stuck, otherwise recurse to (i+1,j± 1). Reaching row m returns the current column.

We can use DFS to simulate the movement of the ball. Design a function dfs(i, j), which represents the column where the ball will fall when it starts from row i and column j. The ball will get stuck in the following cases:

1. The ball is in the leftmost column, and the cell's diagonal directs the ball to the left.
2. The ball is in the rightmost column, and the cell's diagonal directs the ball to the right.
3. The cell's diagonal directs the ball to the right, and the adjacent cell to the right directs the ball to the left.
4. The cell's diagonal directs the ball to the left, and the adjacent cell to the left directs the ball to the right.

If any of the above conditions are met, we can determine that the ball will get stuck and return -1. Otherwise, we can continue to recursively find the next position of the ball. Finally, if the ball reaches the last row, we can return the current column index.

The time complexity is O(m × n), and the space complexity is O(m). Here, m and n are the number of rows and columns of the grid, respectively.

Python 3

```python
class Solution:
    def findBall(self, grid: List[List[int]]) -> List[int]:
        def dfs(i: int, j: int) -> int:
            if i == m:
                return j
            if j == 0 and grid[i][j] == -1:
                return -1
            if j == n - 1 and grid[i][j] == 1:
                return -1
            if grid[i][j] == 1 and grid[i][j + 1] == -1:
                return -1
            if grid[i][j] == -1 and grid[i][j - 1] == 1:
                return -1
            return dfs(i + 1, j + 1) if grid[i][j] == 1 else dfs(i + 1, j - 1)

        m, n = len(grid), len(grid[0])
        return [dfs(0, j) for j in range(n)]
```

980. Unique Paths III

Hard · Bit Manipulation, Array, Backtracking, Hamiltonian Path, Matrix

leetcode.com/problems/unique-paths-iii

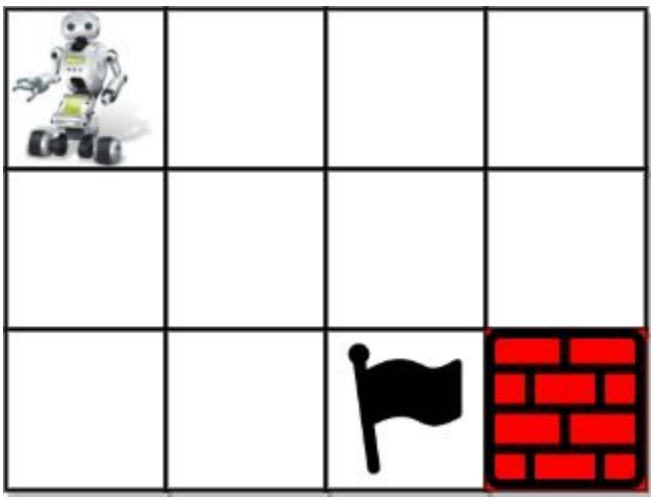
PROBLEM

You are given an `m x n` integer array `grid` where `grid[i][j]` could be:

- `1` representing the starting square. There is exactly one starting square.
- `2` representing the ending square. There is exactly one ending square.
- `0` representing empty squares we can walk over.
- `-1` representing obstacles that we cannot walk over.

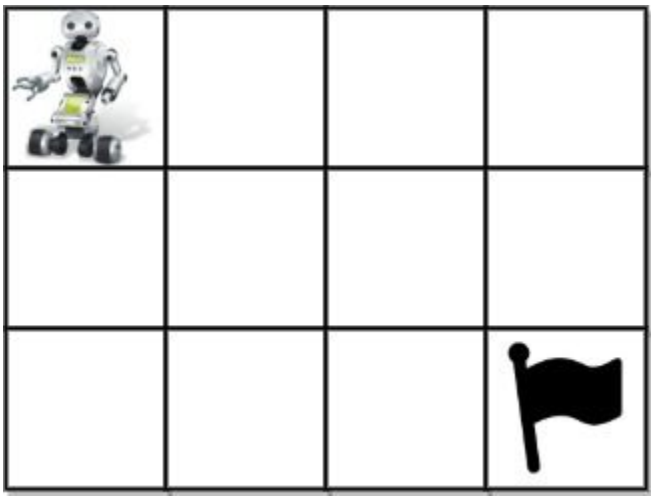
Return *the number of 4-directional walks from the starting square to the ending square, that walk over every non-obstacle square exactly once*.

Example 1:



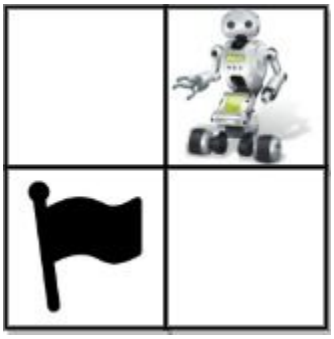
```
Input: grid = [[1,0,0,0],[0,0,0,0],[0,0,2,-1]]
Output: 2
Explanation: We have the following two paths:
1. (0,0),(0,1),(0,2),(0,3),(1,3),(1,2),(1,1),(1,0),(2,0),(2,1),(2,2)
2. (0,0),(1,0),(2,0),(2,1),(1,1),(0,1),(0,2),(0,3),(1,3),(1,2),(2,2)
```

Example 2:



```
Input: grid = [[1,0,0,0],[0,0,0,0],[0,0,0,2]]
Output: 4
Explanation: We have the following four paths:
1. (0,0),(0,1),(0,2),(0,3),(1,3),(1,2),(1,1),(1,0),(2,0),(2,1),(2,2),(2,3)
2. (0,0),(0,1),(1,1),(1,0),(2,0),(2,1),(2,2),(1,2),(0,2),(0,3),(1,3),(2,3)
3. (0,0),(1,0),(2,0),(2,1),(2,2),(1,2),(1,1),(0,1),(0,2),(0,3),(1,3),(2,3)
4. (0,0),(1,0),(2,0),(2,1),(1,1),(0,1),(0,2),(0,3),(1,3),(1,2),(2,2),(2,3)
```

Example 3:



```
Input: grid = [[0,1],[2,0]]
Output: 0
Explanation: There is no path that walks over every empty square exactly once.
Note that the starting and ending square can be anywhere in the grid.
```

Constraints:

- `m == grid.length`
- `n == grid[i].length`
- `1 <= m, n <= 20`
- `1 <= m * n <= 20`
- `-1 <= grid[i][j] <= 2`
- There is exactly one starting cell and one ending cell.

SOLUTION (PYTHON 3)

Solution 1: Backtracking

How to think about it

Walk from start to end visiting every empty cell exactly once. At most 20 cells, so backtracking fits. Count empties and find the start, then DFS in four directions with a visited set. A path that lands on the end counts only when the step count equals the number of empties plus one.

We can first traverse the entire grid, find the starting point (x, y), and count the number of blank spaces cnt.

Next, we can start searching from the starting point to get all the path numbers. We design a function dfs(i, j, k) to indicate that the path number is k and the starting point is (i, j).

In the function, we first determine whether the current cell is the end point. If it is, we determine whether k is equal to cnt + 1. If it is, the current path is a valid path, and 1 is returned, otherwise 0 is returned.

If the current cell is not the end point, we enumerate the four adjacent cells of the current cell. If the adjacent cell has not been visited, we mark the adjacent cell as visited, and then continue to search the path number from the adjacent cell. After the search is completed, we mark the adjacent cell as unvisited. After the search is completed, we return the sum of the path numbers of all adjacent cells.

Finally, we return the path number from the starting point, that is, dfs(x, y, 1).

The time complexity is $O(3^{m \times n})$, and the space complexity is $O(m \times n)$. Where m and n are the number of rows and columns of the grid, respectively.

Python 3

```python
class Solution:
    def uniquePathsIII(self, grid: List[List[int]]) -> int:
        def dfs(i: int, j: int, k: int) -> int:
            if grid[i][j] == 2:
                return int(k == cnt + 1)
            ans = 0
            for a, b in pairwise(dirs):
                x, y = i + a, j + b
                if 0 <= x < m and 0 <= y < n and (x, y) not in vis and grid[x][y] != -1:
                    vis.add((x, y))
                    ans += dfs(x, y, k + 1)
                    vis.remove((x, y))
            return ans

        m, n = len(grid), len(grid[0])
        start = next((i, j) for i in range(m) for j in range(n) if grid[i][j] == 1)
        dirs = (-1, 0, 1, 0, -1)
        cnt = sum(row.count(0) for row in grid)
        vis = {start}
        return dfs(*start, 0)
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

Built on the solutions above: helper functions, then the function for each follow-up. No tests and no restating of the question.

```python
# FOLLOW-UPS (answered below, in this order):

PATTERN 19 · HEAP / PRIORITY QUEUE · PROBLEM 1 OF 20

1046. Last Stone Weight

Easy · Array, Heap (Priority Queue)

leetcode.com/problems/last-stone-weight

★ **TOP 10 PROBLEM** in Heap / Priority Queue, Two Heaps: master this one first

Also appears in pattern 37 Two Heaps

PROBLEM

You are given an array of integers `stones` where `stones[i]` is the weight of the i^{th} stone.

We are playing a game with the stones. On each turn, we choose the **heaviest two stones** and smash them together. Suppose the heaviest two stones have weights `x` and `y` with `x <= y`. The result of this smash is:

- If `x == y`, both stones are destroyed, and
- If `x != y`, the stone of weight `x` is destroyed, and the stone of weight `y` has new weight `y - x`.

At the end of the game, there is **at most one** stone left.

Return *the weight of the last remaining stone*. If there are no stones left, return `0`.

Example 1:

```
Input: stones = [2,7,4,1,8,1]
Output: 1
Explanation:
We combine 7 and 8 to get 1 so the array converts to [2,4,1,1,1] then,
we combine 2 and 4 to get 2 so the array converts to [2,1,1,1] then,
we combine 2 and 1 to get 1 so the array converts to [1,1,1] then,
we combine 1 and 1 to get 0 so the array converts to [1] then that's the value of the last stone.
```

Example 2:

```
Input: stones = [1]
Output: 1
```

Constraints:

- `1 <= stones.length <= 30`
- `1 <= stones[i] <= 1000`

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Each smash uses the two heaviest stones. Scanning for the maximum every time repeats comparisons; a heap extracts them in logarithmic time. Negating the weights turns a min-heap into a max-heap. Pop y≥ x and push y-x when they differ, until fewer than two stones remain. An empty heap is 0; otherwise the answer is the negated top.

Python 3

```python
class Solution:
    def lastStoneWeight(self, stones: List[int]) -> int:
        h = [-x for x in stones]
        heapify(h)
        while len(h) > 1:
            y, x = -heappop(h), -heappop(h)
            if x != y:
                heappush(h, x - y)
        return 0 if not h else -h[0]
```

Complexity. Time: O(n log n). Space: O(n).

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

Built on the solutions above: helper functions, then the function for each follow-up. No tests and no restating of the question.

```
# FOLLOW-UPS (answered below, in this order):
# 1. Return the weight of every smash, in order
# 2. Choose which stones to smash to leave the SMALLEST
# possible remainder (Last Stone Weight II)

# ============================================================
# FOLLOW-UP 1: Return the weight of every smash, in order
# ============================================================

# ---- follow-up 1: function ----
# Answer: Same max-heap (negated weights); record what is
# left after each smash.
# Time: O(n log n).  Space: O(n).
import heapq

def smash_log(stones):
    heap = [-s for s in stones]
    heapq.heapify(heap)
    log = []
    while len(heap) > 1:
        first = -heapq.heappop(heap)
        second = -heapq.heappop(heap)
        left = first - second
        log.append((first, second, left))
        if left > 0:
            heapq.heappush(heap, -left)
    return log

# ============================================================
# FOLLOW-UP 2: Choose which stones to smash to leave the
# SMALLEST possible remainder (Last Stone Weight II)
# ============================================================

# ---- follow-up 2: function ----
# Answer: Smashing amounts to splitting the stones into
# two groups and subtracting their totals, so the best
# remainder is the smallest difference between two groups:
# a subset-sum table up to half of the total.
# Time: O(n * S), S = half of the total.  Space: O(S).
def last_stone_weight_min(stones):
    total = 0
    for s in stones:
        total += s

                reachable[amount] = True
    best = 0
    for amount in range(half + 1):
        if reachable[amount]:
            best = amount
    return total - 2 * best
```

703. Kth Largest Element in a Stream

Easy · Tree, Design, Binary Search Tree, Binary Tree, Data Stream, Heap (Priority Queue)

leetcode.com/problems/kth-largest-element-in-a-stream

★ **TOP 10 PROBLEM** in Heap / Priority Queue, Two Heaps: master this one first

Also appears in pattern 37 Two Heaps

PROBLEM

You are part of a university admissions office and need to keep track of the `kth` highest test score from applicants in real-time. This helps to determine cut-off marks for interviews and admissions dynamically as new applicants submit their scores.

You are tasked to implement a class which, for a given integer `k`, maintains a stream of test scores and continuously returns the `k`th highest test score **after** a new score has been submitted. More specifically, we are looking for the `k`th highest score in the sorted list of all scores.

Implement the `KthLargest` class:

- `KthLargest(int k, int[] nums)` Initializes the object with the integer `k` and the stream of test scores `nums`.
- `int add(int val)` Adds a new test score `val` to the stream and returns the element representing the k^{th} largest element in the pool of test scores so far.

Example 1:

Input:
["KthLargest", "add", "add", "add", "add", "add"]
[[3, [4, 5, 8, 2]], [3], [5], [10], [9], [4]]

Output: [null, 4, 5, 5, 8, 8]

Explanation:

KthLargest kthLargest = new KthLargest(3, [4, 5, 8, 2]);
kthLargest.add(3); // return 4
kthLargest.add(5); // return 5
kthLargest.add(10); // return 5
kthLargest.add(9); // return 8
kthLargest.add(4); // return 8

Example 2:

Input:
["KthLargest", "add", "add", "add", "add"]
[[4, [7, 7, 7, 7, 8, 3]], [2], [10], [9], [9]]

Output: [null, 7, 7, 7, 8]

Explanation:

KthLargest kthLargest = new KthLargest(4, [7, 7, 7, 7, 8, 3]);

kthLargest.add(2); // return 7

kthLargest.add(10); // return 7

kthLargest.add(9); // return 7

kthLargest.add(9); // return 8

Constraints:

- `0 <= nums.length <= 10^4`
- `1 <= k <= nums.length + 1`

- -10^4 <= nums[i] <= 10^4
- -10^4 <= val <= 10^4
- At most 10^4 calls will be made to add.

SOLUTION (PYTHON 3)

Solution 1: Priority Queue (Min Heap)

How to think about it

We insert into a stream and must report the k-th largest after each add. Sorting or scanning the whole history on every query is too heavy when both n and the query count reach 10^4. Only the current top k values matter; anything smaller can never be the answer. In a size-k min-heap the top is the smallest of those k, i.e. the k-th largest overall. Push each new value and pop if the heap grows past k. Seeding from nums uses the same add. Each update is O(log k).

We maintain a priority queue (min heap) minQ.

Initially, we add the elements of the array nums to minQ one by one, ensuring that the size of minQ does not exceed k. The time complexity is O(n × log k).

Each time a new element is added, if the size of minQ exceeds k, we pop the top element of the heap to ensure that the size of minQ is k. The time complexity is O(log k).

In this way, the elements in minQ are the largest k elements in the array nums, and the top element of the heap is the k^{th} largest element.

The space complexity is O(k).

Python 3

```
class KthLargest:

    def __init__(self, k: int, nums: List[int]):
        self.k = k
        self.min_q = []
        for x in nums:
            self.add(x)

    def add(self, val: int) -> int:
        heappush(self.min_q, val)
        if len(self.min_q) > self.k:
            heappop(self.min_q)
        return self.min_q[0]

# Your KthLargest object will be instantiated and called as such:
# obj = KthLargest(k, nums)
# param_1 = obj.add(val)
```

PATTERN 19 · HEAP / PRIORITY QUEUE · PROBLEM 3 OF 20

1337. The K Weakest Rows in a Matrix

Easy · Array, Binary Search, Matrix, Sorting, Heap (Priority Queue)

leetcode.com/problems/the-k-weakest-rows-in-a-matrix

★ **TOP 10 PROBLEM** in Heap / Priority Queue, K-way Merge: master this one first

Also appears in pattern 38 K-way Merge

PROBLEM

You are given an `m x n` binary matrix `mat` of `1`'s (representing soldiers) and `0`'s (representing civilians). The soldiers are positioned **in front** of the civilians. That is, all the `1`'s will appear to the **left** of all the `0`'s in each row.

A row `i` is **weaker** than a row `j` if one of the following is true:

- The number of soldiers in row `i` is less than the number of soldiers in row `j`.
- Both rows have the same number of soldiers and `i < j`.

Return *the indices of the* `k` ***weakest*** *rows in the matrix ordered from weakest to strongest*.

Example 1:

```
Input: mat =
[[1,1,0,0,0],
 [1,1,1,1,0],
 [1,0,0,0,0],
 [1,1,0,0,0],
 [1,1,1,1,1]],
k = 3
Output: [2,0,3]
Explanation:
The number of soldiers in each row is:
- Row 0: 2
- Row 1: 4
- Row 2: 1
- Row 3: 2
- Row 4: 5
The rows ordered from weakest to strongest are [2,0,3,1,4].
```

Example 2:

```
Input: mat =
[[1,0,0,0],
 [1,1,1,1],
 [1,0,0,0],
 [1,0,0,0]],
k = 2
Output: [0,2]
Explanation:
The number of soldiers in each row is:
- Row 0: 1
- Row 1: 4
- Row 2: 1
- Row 3: 1
The rows ordered from weakest to strongest are [0,2,3,1].
```

Constraints:

- `m == mat.length`
- `n == mat[i].length`
- `2 <= n, m <= 100`

- `1 <= k <= m`
- `matrix[i][j]` is either 0 or 1.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Rows are ordered by soldier count, then by index; we keep the first k. Ones sit left of zeros, so the count is the first zero. Bisecting the reversed row for 0 yields that count; sorting row indices by it and slicing k entries is the answer.

Python 3

```
class Solution:
    def kWeakestRows(self, mat: List[List[int]], k: int) -> List[int]:
        m, n = len(mat), len(mat[0])
        ans = [n - bisect_right(row[::-1], 0) for row in mat]
        idx = list(range(m))
        idx.sort(key=lambda i: ans[i])
        return idx[:k]
```

Complexity. Time: O(m * log n + m * log m). Space: O(m).

2558. Take Gifts From the Richest Pile

Easy · Array, Simulation, Heap (Priority Queue)

leetcode.com/problems/take-gifts-from-the-richest-pile

★ **TOP 10 PROBLEM** in Two Heaps: master this one first

Also appears in pattern 37 Two Heaps

PROBLEM

You are given an integer array `gifts` denoting the number of gifts in various piles. Every second, you do the following:

- Choose the pile with the maximum number of gifts.
- If there is more than one pile with the maximum number of gifts, choose any.
- Reduce the number of gifts in the pile to the floor of the square root of the original number of gifts in the pile.

Return *the number of gifts remaining after* `k` *seconds.*

Example 1:

```
Input: gifts = [25,64,9,4,100], k = 4
Output: 29
Explanation:
The gifts are taken in the following way:
- In the first second, the last pile is chosen and 10 gifts are left behind.
- Then the second pile is chosen and 8 gifts are left behind.
- After that the first pile is chosen and 5 gifts are left behind.
- Finally, the last pile is chosen again and 3 gifts are left behind.
The final remaining gifts are [5,8,9,4,3], so the total number of gifts remaining is 29.
```

Example 2:

```
Input: gifts = [1,1,1,1], k = 4
Output: 4
Explanation:
In this case, regardless which pile you choose, you have to leave behind 1 gift in each pile.
That is, you can't take any pile with you.
So, the total gifts remaining are 4.
```

Constraints:

- `1 <= gifts.length <= 10^3`
- `1 <= gifts[i] <= 10^9`
- `1 <= k <= 10^3`

SOLUTION (PYTHON 3)

Solution 1: Priority Queue (Max Heap)

How to think about it

Each step replaces the richest pile with floor(√(·)), k times, then sums what remains. Scanning for the max each time works for the limits, but a heap yields it directly. A max-heap pops the top and pushes its integer square root, k times, then sums the heap. Python stores negations.

We can store the array gifts in a max heap, and then loop k times, each time taking out the top element of the heap, taking the square root of it, and putting the result back into the heap.

Finally, we add up all the elements in the heap as the answer.

The time complexity is O(n + k × log n), and the space complexity is O(n). Here, n is the length of the array gifts.

Python 3

```
class Solution:
    def pickGifts(self, gifts: List[int], k: int) -> int:
        h = [-v for v in gifts]
        heapify(h)
        for _ in range(k):
            heapreplace(h, -int(sqrt(-h[0])))
        return -sum(h)
```

PATTERN 19 · HEAP / PRIORITY QUEUE · PROBLEM 7 OF 20

973. K Closest Points to Origin

Medium · Geometry, Array, Math, Divide and Conquer, Quickselect, Sorting, Heap (Priority Queue), K-D Tree

leetcode.com/problems/k-closest-points-to-origin

★ **TOP 10 PROBLEM** in Heap / Priority Queue: master this one first

Also appears in pattern 38 K-way Merge

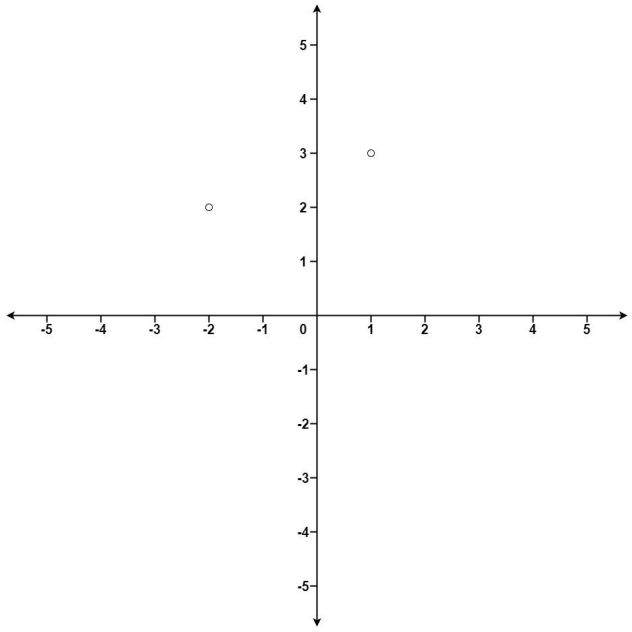
PROBLEM

Given an array of `points` where `points[i] = [x_i, y_i]` represents a point on the **X-Y** plane and an integer `k`, return the `k` closest points to the origin `(0, 0)`.

The distance between two points on the **X-Y** plane is the Euclidean distance (i.e., $\sqrt{(x_1 - x_2)^2 + (y_1 - y_2)^2}$).

You may return the answer in **any order**. The answer is **guaranteed** to be **unique** (except for the order that it is in).

Example 1:



```
Input: points = [[1,3],[-2,2]], k = 1
Output: [[-2,2]]
Explanation:
The distance between (1, 3) and the origin is sqrt(10).
The distance between (-2, 2) and the origin is sqrt(8).
Since sqrt(8) < sqrt(10), (-2, 2) is closer to the origin.
We only want the closest k = 1 points from the origin, so the answer is just [[-2,2]].
```

Example 2:

```
Input: points = [[3,3],[5,-1],[-2,4]], k = 2
Output: [[3,3],[-2,4]]
Explanation: The answer [[-2,4],[3,3]] would also be accepted.
```

Constraints:

- $1 <= k <= points.length <= 10^4$
- $-10^4 <= x_i, y_i <= 10^4$

SOLUTIONS (PYTHON 3)

Solution 1: Custom Sorting

> **How to think about it**
>
> Find the k points closest to the origin. Sorting by Euclidean distance and taking the first k is O(nlog n), which is fine for n≤ 10^4.

We sort all points by their distance from the origin in ascending order, and then take the first k points.

The time complexity is O(n log n), and the space complexity is O(log n). Here, n is the length of the array points.

Python 3

```
class Solution:
    def kClosest(self, points: List[List[int]], k: int) -> List[List[int]]:
        points.sort(key=lambda p: hypot(p[0], p[1]))
        return points[:k]
```

Solution 2: Priority Queue (Max Heap)

> **How to think about it**
>
> A full sort also orders the farthest n-k points. A max-heap of size k keeps only the current closest k, in O(nlog k) time.

We can use a priority queue (max heap) to maintain the k closest points to the origin.

The time complexity is O(n × log k), and the space complexity is O(k). Here, n is the length of the array points.

Python 3

```
class Solution:
    def kClosest(self, points: List[List[int]], k: int) -> List[List[int]]:
        max_q = []
        for i, (x, y) in enumerate(points):
            dist = math.hypot(x, y)
            heappush(max_q, (-dist, i))
            if len(max_q) > k:
                heappop(max_q)
        return [points[i] for _, i in max_q]
```

Solution 3: Binary Search

> **How to think about it**
>
> The heap still pays a logarithm. The number of points is monotone in the distance, so binary-search a threshold until at least k points lie inside, then collect every point whose distance is at most that critical value.

We notice that as the distance increases, the number of points increases as well. There exists a critical value such that the number of points before this value is less than or equal to k, and the number of points after this value is greater than k.

Therefore, we can use binary search to enumerate the distance. In each binary search iteration, we count the number of points whose distance is less than or equal to the current distance. If the count is greater than or equal to k, it indicates that the critical value is on the left side, so we set the right boundary equal to the current distance; otherwise, the critical value is on the right side, so we set the left boundary equal to the current distance plus one.

After the binary search is finished, we just need to return the points whose distance is less than or equal to the left boundary.

The time complexity is O(n × log M), and the space complexity is O(n). Here, n is the length of the array points, and M is the maximum value of the distance.

Python 3

```
class Solution:
    def kClosest(self, points: List[List[int]], k: int) -> List[List[int]]:
        dist = [x * x + y * y for x, y in points]
        l, r = 0, max(dist)
        while l < r:
            mid = (l + r) >> 1
            cnt = sum(d <= mid for d in dist)
            if cnt >= k:
                r = mid
            else:
                l = mid + 1
        return [points[i] for i, d in enumerate(dist) if d <= l]
```

PATTERN 19 · HEAP / PRIORITY QUEUE · PROBLEM 8 OF 20

621. Task Scheduler

Medium · Greedy, Array, Hash Table, Counting, Sorting, Heap (Priority Queue)

leetcode.com/problems/task-scheduler

★ **TOP 10 PROBLEM** in Heap / Priority Queue, Greedy: master this one first

Also appears in pattern 21 Greedy, 37 Two Heaps

PROBLEM

You are given an array of CPU `tasks`, each labeled with a letter from A to Z, and a number `n`. Each CPU interval can be idle or allow the completion of one task. Tasks can be completed in any order, but there's a constraint: there has to be a gap of **at least** `n` intervals between two tasks with the same label.

Return the **minimum** number of CPU intervals required to complete all tasks.

Example 1:

Input: tasks = ["A","A","A","B","B","B"], n = 2

Output: 8

Explanation: A possible sequence is: A -> B -> idle -> A -> B -> idle -> A -> B.

After completing task A, you must wait two intervals before doing A again. The same applies to task B. In the 3rd interval, neither A nor B can be done, so you idle. By the 4th interval, you can do A again as 2 intervals have passed.

Example 2:

Input: tasks = ["A","C","A","B","D","B"], n = 1

Output: 6

Explanation: A possible sequence is: A -> B -> C -> D -> A -> B.

With a cooling interval of 1, you can repeat a task after just one other task.

Example 3:

Input: tasks = ["A","A","A", "B","B","B"], n = 3

Output: 10

Explanation: A possible sequence is: A -> B -> idle -> idle -> A -> B -> idle -> idle -> A -> B.

There are only two types of tasks, A and B, which need to be separated by 3 intervals. This leads to idling twice between repetitions of these tasks.

Constraints:

- `1 <= tasks.length <= 10^4`
- `tasks[i]` is an uppercase English letter.
- `0 <= n <= 100`

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Identical tasks must be at least n apart. Simulating the timeline is unnecessary once the bottleneck task is known. The most frequent count x builds (x-1) full gaps plus s tasks of that count at the end. If the total number of tasks is larger, idle slots fill, so the answer is max(m, (x-1)(n+1)+s).

Python 3

```
class Solution:
    def leastInterval(self, tasks: List[str], n: int) -> int:
        cnt = Counter(tasks)
        x = max(cnt.values())
        s = sum(v == x for v in cnt.values())
        return max(len(tasks), (x - 1) * (n + 1) + s)
```

Complexity. Time: O(n). Space: O(C), C = 26 task types.

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

Built on the solutions above: helper functions, then the function for each follow-up. No tests and no restating of the question.

            schedule.append("idle")
        if waiting and waiting[0][0] <= time:
            ready_time, left, task = waiting.popleft()
            heapq.heappush(heap, (left, task))
    return schedule
```

451. Sort Characters By Frequency

Medium · Hash Table, String, Bucket Sort, Counting, Sorting, Heap (Priority Queue)

leetcode.com/problems/sort-characters-by-frequency

PROBLEM

Given a string `s`, sort it in **decreasing order** based on the **frequency** of the characters. The **frequency** of a character is the number of times it appears in the string.

Return *the sorted string*. If there are multiple answers, return *any of them*.

Example 1:

```
Input: s = "tree"
Output: "eert"
Explanation: 'e' appears twice while 'r' and 't' both appear once.
So 'e' must appear before both 'r' and 't'. Therefore "eetr" is also a valid answer.
```

Example 2:

```
Input: s = "cccaaa"
Output: "aaaccc"
Explanation: Both 'c' and 'a' appear three times, so both "cccaaa" and "aaaccc" are valid answers.
Note that "cacaca" is incorrect, as the same characters must be together.
```

Example 3:

```
Input: s = "Aabb"
Output: "bbAa"
Explanation: "bbaA" is also a valid answer, but "Aabb" is incorrect.
Note that 'A' and 'a' are treated as two different characters.
```

Constraints:

- `1 <= s.length <= 5 * 10^5`
- `s` consists of uppercase and lowercase English letters and digits.

SOLUTION (PYTHON 3)

Solution 1: Hash Table + Sorting

> **How to think about it**
>
> Characters must be rewritten in decreasing frequency; ties may break arbitrarily. A bucket per count needs a bound on the count; the alphabet is small, so sorting the key–value pairs is enough. Count with a hash map, sort by frequency descending, and repeat each character v times. We sort distinct characters, not the whole string, so the log factor follows the alphabet size.

We use a hash table cnt to count the occurrences of each character in the string s. Then, we sort the key-value pairs in cnt in descending order by the number of occurrences. Finally, we concatenate the characters according to the sorted order.

The time complexity is O(n + k × log k), and the space complexity is O(n + k), where n is the length of the string s, and k is the number of distinct characters.

Python 3

```python
class Solution:
    def frequencySort(self, s: str) -> str:
        cnt = Counter(s)
        return ''.join(c * v for c, v in sorted(cnt.items(), key=lambda x: -x[1]))
```

1167. Minimum Cost to Connect Sticks

Medium · Greedy, Array, Heap (Priority Queue)

leetcode.com/problems/minimum-cost-to-connect-sticks

Also appears in pattern 38 K-way Merge

PROBLEM

You have some number of sticks with positive integer lengths. These lengths are given as an array `sticks`, where `sticks[i]` is the length of the i^{th} stick.

You can connect any two sticks of lengths `x` and `y` into one stick by paying a cost of `x + y`. You must connect all the sticks until there is only one stick remaining.

Return *the minimum cost of connecting all the given sticks into one stick in this way*.

Example 1:

```
Input: sticks = [2,4,3]
Output: 14
Explanation: You start with sticks = [2,4,3].
1. Combine sticks 2 and 3 for a cost of 2 + 3 = 5. Now you have sticks = [5,4].
2. Combine sticks 5 and 4 for a cost of 5 + 4 = 9. Now you have sticks = [9].
There is only one stick left, so you are done. The total cost is 5 + 9 = 14.
```

Example 2:

```
Input: sticks = [1,8,3,5]
Output: 30
Explanation: You start with sticks = [1,8,3,5].
1. Combine sticks 1 and 3 for a cost of 1 + 3 = 4. Now you have sticks = [4,8,5].
2. Combine sticks 4 and 5 for a cost of 4 + 5 = 9. Now you have sticks = [9,8].
3. Combine sticks 9 and 8 for a cost of 9 + 8 = 17. Now you have sticks = [17].
There is only one stick left, so you are done. The total cost is 4 + 9 + 17 = 30.
```

Example 3:

```
Input: sticks = [5]
Output: 0
Explanation: There is only one stick, so you don't need to do anything. The total cost is 0.
```

Constraints:

- `1 <= sticks.length <= 10^4`
- `1 <= sticks[i] <= 10^4`

SOLUTION (PYTHON 3)

Solution 1: Greedy + Priority Queue (Min Heap)

> **How to think about it**
>
> The cost of joining two sticks is their sum, and the new stick is merged again, so longer sticks are charged repeatedly. Always joining the two shortest lengths limits how often large values reappear. A min-heap pops two sticks, pushes their sum, and accumulates the cost until one stick remains.

We can use a greedy approach, each time choosing the shortest two sticks to connect, which ensures the minimum cost of connection.

Therefore, we can use a priority queue (min heap) to maintain the current stick lengths. Each time, we take out two sticks from the priority queue to connect, then put the connected stick back into the priority queue, until there is only one stick left

in the priority queue.

The time complexity is O(n × log n), and the space complexity is O(n). Here, n is the length of the array `sticks`.

Python 3

```
class Solution:
    def connectSticks(self, sticks: List[int]) -> int:
        heapify(sticks)
        ans = 0
        while len(sticks) > 1:
            z = heappop(sticks) + heappop(sticks)
            ans += z
            heappush(sticks, z)
        return ans
```

```

```
        for i in range(k):
            group += heapq.heappop(heap)
        total += group
        heapq.heappush(heap, group)
    return total
```

1642. Furthest Building You Can Reach

Medium · Greedy, Array, Heap (Priority Queue)

leetcode.com/problems/furthest-building-you-can-reach

★ **TOP 10 PROBLEM** in Heap / Priority Queue, Two Heaps: master this one first

Also appears in pattern 37 Two Heaps

PROBLEM

You are given an integer array `heights` representing the heights of buildings, some `bricks`, and some `ladders`.

You start your journey from building `0` and move to the next building by possibly using bricks or ladders.

While moving from building `i` to building `i+1` (**0-indexed**),

- If the current building's height is **greater than or equal** to the next building's height, you do **not** need a ladder or bricks.
- If the current building's height is **less than** the next building's height, you can either use **one ladder** or `(h[i+1] - h[i])` **bricks**.

Return the furthest building index (0-indexed) you can reach if you use the given ladders and bricks optimally.

Example 1:

```
Input: heights = [4,2,7,6,9,14,12], bricks = 5, ladders = 1
Output: 4
Explanation: Starting at building 0, you can follow these steps:
- Go to building 1 without using ladders nor bricks since 4 >= 2.
- Go to building 2 using 5 bricks. You must use either bricks or ladders because 2 < 7.
- Go to building 3 without using ladders nor bricks since 7 >= 6.
- Go to building 4 using your only ladder. You must use either bricks or ladders because 6 < 9.
It is impossible to go beyond building 4 because you do not have any more bricks or ladders.
```

Example 2:

```
Input: heights = [4,12,2,7,3,18,20,3,19], bricks = 10, ladders = 2
Output: 7
```

Example 3:

```
Input: heights = [14,3,19,3], bricks = 17, ladders = 0
Output: 3
```

Constraints:

- 1 <= heights.length <= 10^5
- 1 <= heights[i] <= 10^6
- 0 <= bricks <= 10^9
- 0 <= ladders <= heights.length

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Only upward climbs cost bricks or ladders, and ladders should cover the largest climbs. The input can be large, so the choice must be online. A min-heap stores climbs currently covered by ladders. When the heap exceeds the ladder count, pay the smallest climb with bricks. If bricks run out, stop. If bricks last the whole way, we reach the last building.

Python 3

```python
class Solution:
    def furthestBuilding(self, heights: List[int], bricks: int, ladders: int) -> int:
        h = []
        for i, a in enumerate(heights[:-1]):
            b = heights[i + 1]
            d = b - a
            if d > 0:
                heappush(h, d)
                if len(h) > ladders:
                    bricks -= heappop(h)
                    if bricks < 0:
                        return i
        return len(heights) - 1
```

Complexity. Time: O(n log L), L = number of ladders. Space: O(L).

        heapq.heappush(heap, (climb, i))
```

```
        if len(heap) > ladders:
            smallest, position = heapq.heappop(heap)
            bricks -= smallest
        if bricks < 0:
            return reached, sorted(p for c, p in heap)
        reached = i + 1
    return reached, sorted(p for c, p in heap)
```

PATTERN 19 · HEAP / PRIORITY QUEUE · PROBLEM 13 OF 20

1834. Single-Threaded CPU

Medium · Array, Sorting, Heap (Priority Queue)

leetcode.com/problems/single-threaded-cpu

★ **TOP 10 PROBLEM** in Two Heaps: master this one first

Also appears in pattern 37 Two Heaps

PROBLEM

You are given `n` tasks labeled from `0` to `n - 1` represented by a 2D integer array `tasks`, where `tasks[i] = [enqueueTime`$_i$`, processingTime`$_i$`]` means that the `i`□□□□□□th task will be available to process at `enqueueTime`$_i$ and will take `processingTime`$_i$ to finish processing.

You have a single-threaded CPU that can process **at most one** task at a time and will act in the following way:

- If the CPU is idle and there are no available tasks to process, the CPU remains idle.
- If the CPU is idle and there are available tasks, the CPU will choose the one with the **shortest processing time**. If multiple tasks have the same shortest processing time, it will choose the task with the smallest index.
- Once a task is started, the CPU will **process the entire task** without stopping.
- The CPU can finish a task then start a new one instantly.

Return the order in which the CPU will process the tasks.

Example 1:

```
Input: tasks = [[1,2],[2,4],[3,2],[4,1]]
Output: [0,2,3,1]
Explanation: The events go as follows:
- At time = 1, task 0 is available to process. Available tasks = {0}.
- Also at time = 1, the idle CPU starts processing task 0. Available tasks = {}.
- At time = 2, task 1 is available to process. Available tasks = {1}.
- At time = 3, task 2 is available to process. Available tasks = {1, 2}.
- Also at time = 3, the CPU finishes task 0 and starts processing task 2 as it is the shortest.
Available tasks = {1}.
- At time = 4, task 3 is available to process. Available tasks = {1, 3}.
- At time = 5, the CPU finishes task 2 and starts processing task 3 as it is the shortest. Available
tasks = {1}.
- At time = 6, the CPU finishes task 3 and starts processing task 1. Available tasks = {}.
- At time = 10, the CPU finishes task 1 and becomes idle.
```

Example 2:

```
Input: tasks = [[7,10],[7,12],[7,5],[7,4],[7,2]]
Output: [4,3,2,0,1]
Explanation: The events go as follows:
- At time = 7, all the tasks become available. Available tasks = {0,1,2,3,4}.
- Also at time = 7, the idle CPU starts processing task 4. Available tasks = {0,1,2,3}.
- At time = 9, the CPU finishes task 4 and starts processing task 3. Available tasks = {0,1,2}.
- At time = 13, the CPU finishes task 3 and starts processing task 2. Available tasks = {0,1}.
- At time = 18, the CPU finishes task 2 and starts processing task 0. Available tasks = {1}.
- At time = 28, the CPU finishes task 0 and starts processing task 1. Available tasks = {}.
- At time = 40, the CPU finishes task 1 and becomes idle.
```

Constraints:

- `1 <= tasks.length <= 10`^{5}
- `tasks[i] = [enqueueTime`$_i$`, processingTime`$_i$`]`
- `1 <= enqueueTime`$_i$`, processingTime`$_i$ `<= 10`^{9}

SOLUTION (PYTHON 3)

Solution 1: Sorting + Priority Queue (Min Heap)

> **How to think about it**
>
> An idle CPU picks the arrived task with the shortest processing time (then smallest index). Scanning every task each time is $O(n^2)$. With $n \le 10^5$ this will not pass. Sort by enqueue time and keep arrived tasks in a min-heap of (processingTime,index). Advance time to the next arrival or to the finish of the heap top, then push newly available tasks. The heap implements the scheduling rule directly.

First, we sort the tasks by `enqueueTime` in ascending order. Next, we use a priority queue (min heap) to maintain the currently executable tasks. The elements in the queue are `(processingTime, index)`, which represent the execution time and the index of the task. We also use a variable t to represent the current time, initially set to 0.

Next, we simulate the execution process of the tasks.

If the current queue is empty, it means there are no executable tasks at the moment. We update t to the larger value between the `enqueueTime` of the next task and the current time t. Then, we add all tasks with `enqueueTime` less than or equal to t to the queue.

Then, we take out a task from the queue, add its index to the answer array, and update t to the sum of the current time t and the execution time of the current task.

We repeat the above process until the queue is empty and all tasks have been added to the queue.

The time complexity is $O(n \times \log n)$, where n is the number of tasks.

Python 3

```python
class Solution:
    def getOrder(self, tasks: List[List[int]]) -> List[int]:
        for i, task in enumerate(tasks):
            task.append(i)
        tasks.sort()
        ans = []
        q = []
        n = len(tasks)
        i = t = 0
        while q or i < n:
            if not q:
                t = max(t, tasks[i][0])
            while i < n and tasks[i][0] <= t:
                heappush(q, (tasks[i][1], tasks[i][2]))
                i += 1
            pt, j = heappop(q)
            ans.append(j)
            t += pt
        return ans
```

```

PATTERN 19 · HEAP / PRIORITY QUEUE · PROBLEM 14 OF 20

2542. Maximum Subsequence Score

Medium · Greedy, Array, Sorting, Heap (Priority Queue)

leetcode.com/problems/maximum-subsequence-score

Also appears in pattern 37 Two Heaps

PROBLEM

You are given two **0-indexed** integer arrays `nums1` and `nums2` of equal length `n` and a positive integer `k`. You must choose a **subsequence** of indices from `nums1` of length `k`.

For chosen indices $i_0, i_1, ..., i_{k-1}$, your **score** is defined as:

- The sum of the selected elements from `nums1` multiplied with the **minimum** of the selected elements from `nums2`.
- It can defined simply as: $(nums1[i_0] + nums1[i_1] + ... + nums1[i_{k-1}]) * \min(nums2[i_0], nums2[i_1], ..., nums2[i_{k-1}])$.

Return *the **maximum** possible score.*

A **subsequence** of indices of an array is a set that can be derived from the set $\{0, 1, ..., n-1\}$ by deleting some or no elements.

Example 1:

```
Input: nums1 = [1,3,3,2], nums2 = [2,1,3,4], k = 3
Output: 12
Explanation:
The four possible subsequence scores are:
- We choose the indices 0, 1, and 2 with score = (1+3+3) * min(2,1,3) = 7.
- We choose the indices 0, 1, and 3 with score = (1+3+2) * min(2,1,4) = 6.
- We choose the indices 0, 2, and 3 with score = (1+3+2) * min(2,3,4) = 12.
- We choose the indices 1, 2, and 3 with score = (3+3+2) * min(1,3,4) = 8.
Therefore, we return the max score, which is 12.
```

Example 2:

```
Input: nums1 = [4,2,3,1,1], nums2 = [7,5,10,9,6], k = 1
Output: 30
Explanation:
Choosing index 2 is optimal: nums1[2] * nums2[2] = 3 * 10 = 30 is the maximum possible score.
```

Constraints:

- `n == nums1.length == nums2.length`
- `1 <= n <=` 10^5
- `0 <= nums1[i], nums2[j] <=` 10^5
- `1 <= k <= n`

SOLUTION (PYTHON 3)

Solution 1: Sorting + Priority Queue (Min Heap)

How to think about it

A score is the sum of k chosen nums1 values times the minimum of the matching nums2 values. Enumerating k-subsets is impossible. If the minimum is fixed as a, we may only pick among indices with nums2≥ a. Scanning pairs in decreasing nums2 makes the current a the minimum, and all earlier pairs remain eligible. A min-heap keeps the k largest nums1 values; when it fills, multiply the sum by a and evict the smallest to make room.

Sort nums2 and nums1 in descending order according to nums2, then traverse from front to back, maintaining a min heap. The heap stores elements from nums1, and the number of elements in the heap does not exceed k. At the same time, maintain a variable s representing the sum of the elements in the heap, and continuously update the answer during the traversal process.

The time complexity is O(n × log n), and the space complexity is O(n). Here, n is the length of the array nums1.

Python 3

```python
class Solution:
    def maxScore(self, nums1: List[int], nums2: List[int], k: int) -> int:
        nums = sorted(zip(nums2, nums1), reverse=True)
        q = []
        ans = s = 0
        for a, b in nums:
            s += b
            heappush(q, b)
            if len(q) == k:
                ans = max(ans, s * a)
                s -= heappop(q)
        return ans
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

            total -= value
        if len(heap) == k and total * nums2[i] > best[0]:
            best = (total * nums2[i], sorted(index for value, index in heap))
    return best

# ========================================================
# FOLLOW-UP 2: You may choose AT MOST k indices (not
# exactly k)
# ========================================================

# ---- follow-up 2: function ----
# Answer: The same sweep, but evaluate the score whenever
# the heap holds at least one number, not only when it
# holds exactly k.
# Time: O(n log n).  Space: O(k).
```

```python
import heapq

def best_score_at_most_k(nums1, nums2, k):
    order = sorted(range(len(nums1)), key=lambda i: -nums2[i])
    heap = []
    total = 0
    best = 0
    for i in order:
        heapq.heappush(heap, nums1[i])
        total += nums1[i]
        if len(heap) > k:
            total -= heapq.heappop(heap)
        if total * nums2[i] > best:
            best = total * nums2[i]
    return best
```

1985. Find the Kth Largest Integer in the Array

Medium · Array, String, Divide and Conquer, Quickselect, Sorting, Heap (Priority Queue)

leetcode.com/problems/find-the-kth-largest-integer-in-the-array

PROBLEM

You are given an array of strings `nums` and an integer `k`. Each string in `nums` represents an integer without leading zeros.

Return *the string that represents the* k^{th} ***largest integer*** *in* `nums`.

Note: Duplicate numbers should be counted distinctly. For example, if `nums` is `["1","2","2"]`, `"2"` is the first largest integer, `"2"` is the second-largest integer, and `"1"` is the third-largest integer.

Example 1:

```
Input: nums = ["3","6","7","10"], k = 4
Output: "3"
Explanation:
The numbers in nums sorted in non-decreasing order are ["3","6","7","10"].
The 4th largest integer in nums is "3".
```

Example 2:

```
Input: nums = ["2","21","12","1"], k = 3
Output: "2"
Explanation:
The numbers in nums sorted in non-decreasing order are ["1","2","12","21"].
The 3rd largest integer in nums is "2".
```

Example 3:

```
Input: nums = ["0","0"], k = 2
Output: "0"
Explanation:
The numbers in nums sorted in non-decreasing order are ["0","0"].
The 2nd largest integer in nums is "0".
```

Constraints:

- `1 <= k <= nums.length <=` 10^4
- `1 <= nums[i].length <= 100`
- `nums[i]` consists of only digits.
- `nums[i]` will not have any leading zeros.

SOLUTION (PYTHON 3)

Solution 1: Sorting or Quickselect

> **How to think about it**
>
> The entries are decimal strings and must not be compared lexicographically. After parsing as integers we want the k-th largest; a heap selection is enough. nlargest(k,·) keyed by int returns that element at position k-1.

We can sort the strings in the nums array in descending order as integers, and then take the k-th element. Alternatively, we can use the quickselect algorithm to find the k-th largest integer.

The time complexity is O(n × log n) or O(n), where n is the length of the nums array. The space complexity is O(log n) or O(1).

Python 3

```
class Solution:
    def kthLargestNumber(self, nums: List[str], k: int) -> str:
        return nlargest(k, nums, key=lambda x: int(x))[k - 1]
```

    heap = []
    for text in nums:
        heapq.heappush(heap, (len(text), text))
        if len(heap) > k:
            heapq.heappop(heap)
    return heap[0][1]
```

PATTERN 19 · HEAP / PRIORITY QUEUE · PROBLEM 16 OF 20

692. Top K Frequent Words

Medium · Trie, Array, Hash Table, String, Bucket Sort, Counting, Sorting, Heap (Priority Queue)

leetcode.com/problems/top-k-frequent-words

PROBLEM

Given an array of strings `words` and an integer `k`, return *the* `k` *most frequent strings*.

Return the answer **sorted** by **the frequency** from highest to lowest. Sort the words with the same frequency by their **lexicographical order**.

Example 1:

```
Input: words = ["i","love","leetcode","i","love","coding"], k = 2
Output: ["i","love"]
Explanation: "i" and "love" are the two most frequent words.
Note that "i" comes before "love" due to a lower alphabetical order.
```

Example 2:

```
Input: words = ["the","day","is","sunny","the","the","the","sunny","is","is"], k = 4
Output: ["the","is","sunny","day"]
Explanation: "the", "is", "sunny" and "day" are the four most frequent words, with the number of
occurrence being 4, 3, 2 and 1 respectively.
```

Constraints:

- `1 <= words.length <= 500`
- `1 <= words[i].length <= 10`
- `words[i]` consists of lowercase English letters.
- `k` is in the range `[1, The number of unique words[i]]`

Follow-up: Could you solve it in `O(n log(k))` time and `O(n)` extra space?

SOLUTION (PYTHON 3)

Solution 1: Hash Table + Sorting

> **How to think about it**
>
> Return the k most frequent words, breaking ties lexicographically. A heap is O(nlog k), but a full sort is fine here. Count, sort keys by (-count, word), and take the first k.

We can use a hash table cnt to record the frequency of each word. Then, we sort the key-value pairs in the hash table by value, and if the values are the same, we sort by key.

Finally, we take the first k keys.

The time complexity is O(n × log n), and the space complexity is O(n). Here, n is the number of words.

Python 3

```python
class Solution:
    def topKFrequent(self, words: List[str], k: int) -> List[str]:
        cnt = Counter(words)
        return sorted(cnt, key=lambda x: (-cnt[x], x))[:k]
```

        for i in range(min(k, len(pairs))):
            result.append(pairs[i][1])
        return result
```

PATTERN 19 · HEAP / PRIORITY QUEUE · PROBLEM 17 OF 20

1845. Seat Reservation Manager

Medium · Design, Heap (Priority Queue)

leetcode.com/problems/seat-reservation-manager

Also appears in pattern 37 Two Heaps

PROBLEM

Design a system that manages the reservation state of `n` seats that are numbered from `1` to `n`.

Implement the `SeatManager` class:

- `SeatManager(int n)` Initializes a `SeatManager` object that will manage `n` seats numbered from `1` to `n`. All seats are initially available.
- `int reserve()` Fetches the **smallest-numbered** unreserved seat, reserves it, and returns its number.
- `void unreserve(int seatNumber)` Unreserves the seat with the given `seatNumber`.

Example 1:

```
Input
["SeatManager", "reserve", "reserve", "unreserve", "reserve", "reserve", "reserve", "reserve",
"unreserve"]
[[5], [], [], [2], [], [], [], [], [5]]
Output
[null, 1, 2, null, 2, 3, 4, 5, null]

Explanation
SeatManager seatManager = new SeatManager(5); // Initializes a SeatManager with 5 seats.
seatManager.reserve(); // All seats are available, so return the lowest numbered seat, which is 1.
seatManager.reserve(); // The available seats are [2,3,4,5], so return the lowest of them, which is 2.
seatManager.unreserve(2); // Unreserve seat 2, so now the available seats are [2,3,4,5].
seatManager.reserve(); // The available seats are [2,3,4,5], so return the lowest of them, which is 2.
seatManager.reserve(); // The available seats are [3,4,5], so return the lowest of them, which is 3.
seatManager.reserve(); // The available seats are [4,5], so return the lowest of them, which is 4.
seatManager.reserve(); // The only available seat is seat 5, so return 5.
seatManager.unreserve(5); // Unreserve seat 5, so now the available seats are [5].
```

Constraints:

- $1 <= n <= 10^5$
- $1 <= seatNumber <= n$
- For each call to `reserve`, it is guaranteed that there will be at least one unreserved seat.
- For each call to `unreserve`, it is guaranteed that `seatNumber` will be reserved.
- At most 10^5 calls **in total** will be made to `reserve` and `unreserve`.

SOLUTION (PYTHON 3)

Solution 1: Priority Queue (Min-Heap)

> **How to think about it**
>
> We must always reserve the smallest free seat and later release seats. Scanning a boolean array for the minimum free index is O(n) per call. Store free seat numbers in a min-heap: reserve pops the top, unreserve pushes the number back. Both updates are logarithmic.

We define a priority queue (min-heap) q to store all the available seat numbers. Initially, we add all seat numbers from 1 to n into q.

When calling the `reserve` method, we pop the top element from q, which is the smallest available seat number.

When calling the `unreserve` method, we add the seat number back into q.

In terms of time complexity, the initialization time complexity is O(n) or O(n × log n), and the time complexity of the `reserve` and `unreserve` methods is both O(log n). The space complexity is O(n).

Python 3

```
class SeatManager:
    def __init__(self, n: int):
        self.q = list(range(1, n + 1))

    def reserve(self) -> int:
        return heappop(self.q)

    def unreserve(self, seatNumber: int) -> None:
        heappush(self.q, seatNumber)

# Your SeatManager object will be instantiated and called as such:
# obj = SeatManager(n)
# param_1 = obj.reserve()
# obj.unreserve(seatNumber)
```

2462. Total Cost to Hire K Workers

Medium · Array, Two Pointers, Simulation, Heap (Priority Queue)

leetcode.com/problems/total-cost-to-hire-k-workers

Also appears in pattern 37 Two Heaps

PROBLEM

You are given a **0-indexed** integer array `costs` where `costs[i]` is the cost of hiring the i^{th} worker.

You are also given two integers `k` and `candidates`. We want to hire exactly `k` workers according to the following rules:

- You will run `k` sessions and hire exactly one worker in each session.
- In each hiring session, choose the worker with the lowest cost from either the first `candidates` workers or the last `candidates` workers. Break the tie by the smallest index.
  - For example, if `costs = [3,2,7,7,1,2]` and `candidates = 2`, then in the first hiring session, we will choose the 4^{th} worker because they have the lowest cost `[3,2,7,7,1,2]`.
  - In the second hiring session, we will choose 1^{st} worker because they have the same lowest cost as 4^{th} worker but they have the smallest index `[3,2,7,7,2]`. Please note that the indexing may be changed in the process.
- If there are fewer than candidates workers remaining, choose the worker with the lowest cost among them. Break the tie by the smallest index.
- A worker can only be chosen once.

Return *the total cost to hire exactly* `k` *workers.*

Example 1:

```
Input: costs = [17,12,10,2,7,2,11,20,8], k = 3, candidates = 4
Output: 11
Explanation: We hire 3 workers in total. The total cost is initially 0.
- In the first hiring round we choose the worker from [17,12,10,2,7,2,11,20,8]. The lowest cost is 2,
and we break the tie by the smallest index, which is 3. The total cost = 0 + 2 = 2.
- In the second hiring round we choose the worker from [17,12,10,7,2,11,20,8]. The lowest cost is 2
(index 4). The total cost = 2 + 2 = 4.
- In the third hiring round we choose the worker from [17,12,10,7,11,20,8]. The lowest cost is 7
(index 3). The total cost = 4 + 7 = 11. Notice that the worker with index 3 was common in the first and
last four workers.
The total hiring cost is 11.
```

Example 2:

```
Input: costs = [1,2,4,1], k = 3, candidates = 3
Output: 4
Explanation: We hire 3 workers in total. The total cost is initially 0.
- In the first hiring round we choose the worker from [1,2,4,1]. The lowest cost is 1, and we break the
tie by the smallest index, which is 0. The total cost = 0 + 1 = 1. Notice that workers with index 1 and
2 are common in the first and last 3 workers.
- In the second hiring round we choose the worker from [2,4,1]. The lowest cost is 1 (index 2). The
total cost = 1 + 1 = 2.
- In the third hiring round there are less than three candidates. We choose the worker from the
remaining workers [2,4]. The lowest cost is 2 (index 0). The total cost = 2 + 2 = 4.
The total hiring cost is 4.
```

Constraints:

- `1 <= costs.length <= 10^5`
- `1 <= costs[i] <= 10^5`
- `1 <= k, candidates <= costs.length`

SOLUTION (PYTHON 3)

Solution 1: Priority Queue (Min Heap)

> **How to think about it**
>
> Each of k hires picks the cheapest among the first and last candidates workers; n≤ 10^5. If those two sides cover the array, just take the k global minima. Otherwise a heap holds both sides (with indices). After popping, push the next unused worker from that side. Stop refilling when the two pointers cross.

First, we check if candidates × 2 is greater than or equal to n. If it is, we directly return the sum of the costs of the first k smallest workers.

Otherwise, we use a min heap pq to maintain the costs of the first candidates workers and the last candidates workers.

We first add the costs and corresponding indices of the first candidates workers to the min heap pq, and then add the costs and corresponding indices of the last candidates workers to the min heap pq. We use two pointers l and r to point to the indices of the front and back candidates, initially l = candidates, r = n - candidates - 1.

Then we perform k iterations, each time taking the worker with the smallest cost from the min heap pq and adding its cost to the answer. If l > r, it means that all the front and back candidates have been selected, and we skip directly. Otherwise, if the index of the current worker is less than l, it means it is a worker from the front, we add the cost and index of the l-th worker to the min heap pq, and then increment l; otherwise, we add the cost and index of the r-th worker to the min heap pq, and then decrement r.

After the loop ends, we return the answer.

The time complexity is O(n × log n), and the space complexity is O(n). Where n is the length of the array costs.

Python 3

```python
class Solution:
    def totalCost(self, costs: List[int], k: int, candidates: int) -> int:
        n = len(costs)
        if candidates * 2 >= n:
            return sum(sorted(costs)[:k])
        pq = []
        for i, c in enumerate(costs[:candidates]):
            heappush(pq, (c, i))
        for i in range(n - candidates, n):
            heappush(pq, (costs[i], i))
        heapify(pq)
        l, r = candidates, n - candidates - 1
        ans = 0
        for _ in range(k):
            c, i = heappop(pq)
            ans += c
            if l > r:
                continue
            if i < l:
                heappush(pq, (costs[l], l))
                l += 1
            else:
                heappush(pq, (costs[r], r))
                r -= 1
        return ans
```

leetcode.com/problems/maximum-performance-of-a-team

★ **TOP 10 PROBLEM** in Two Heaps: master this one first

Also appears in pattern 37 Two Heaps

PROBLEM

You are given two integers `n` and `k` and two integer arrays `speed` and `efficiency` both of length `n`. There are `n` engineers numbered from `1` to `n`. `speed[i]` and `efficiency[i]` represent the speed and efficiency of the i^{th} engineer respectively.

Choose **at most** `k` different engineers out of the `n` engineers to form a team with the maximum **performance**.

The performance of a team is the sum of its engineers' speeds multiplied by the minimum efficiency among its engineers.

Return *the maximum performance of this team*. Since the answer can be a huge number, return it **modulo** $10^9 + 7$.

Example 1:

```
Input: n = 6, speed = [2,10,3,1,5,8], efficiency = [5,4,3,9,7,2], k = 2
Output: 60
Explanation:
We have the maximum performance of the team by selecting engineer 2 (with speed=10 and efficiency=4)
and engineer 5 (with speed=5 and efficiency=7). That is, performance = (10 + 5) * min(4, 7) = 60.
```

Example 2:

```
Input: n = 6, speed = [2,10,3,1,5,8], efficiency = [5,4,3,9,7,2], k = 3
Output: 68
Explanation:
This is the same example as the first but k = 3. We can select engineer 1, engineer 2 and engineer 5 to
get the maximum performance of the team. That is, performance = (2 + 10 + 5) * min(5, 4, 7) = 68.
```

Example 3:

```
Input: n = 6, speed = [2,10,3,1,5,8], efficiency = [5,4,3,9,7,2], k = 4
Output: 72
```

Constraints:

- $1 <= k <= n <= 10^5$
- `speed.length == n`
- `efficiency.length == n`
- $1 <= speed[i] <= 10^5$
- $1 <= efficiency[i] <= 10^8$

SOLUTION (PYTHON 3)

Solution 1

How to think about it

A team of at most k people scores (sum of speeds) times (minimum efficiency). n ≤ 10^5 forbids subsets. Scanning engineers from high efficiency to low makes the current efficiency the team's floor; we only keep the k fastest so far. A min-heap drops the slowest when the size hits k, and the speed sum times the current efficiency updates the answer.

Python 3

```
class Solution:
    def maxPerformance(
        self, n: int, speed: List[int], efficiency: List[int], k: int
    ) -> int:
        t = sorted(zip(speed, efficiency), key=lambda x: -x[1])
        ans = tot = 0
        mod = 10**9 + 7
        h = []
        for s, e in t:
            tot += s
            ans = max(ans, tot * e)
            heappush(h, s)
            if len(h) == k:
                tot -= heappop(h)
        return ans % mod
```

Complexity. Time: O(n log n). Space: O(n).

1882. Process Tasks Using Servers

Medium · Array, Heap (Priority Queue)

leetcode.com/problems/process-tasks-using-servers

★ **TOP 10 PROBLEM** in Heap / Priority Queue: master this one first

Also appears in pattern 37 Two Heaps

PROBLEM

You are given two **0-indexed** integer arrays `servers` and `tasks` of lengths `n` and `m` respectively. `servers[i]` is the **weight** of the `i`$^{\square\square\square\square\square\square th}$ server, and `tasks[j]` is the **time needed** to process the `j`$^{\square\square\square\square\square\square th}$ task **in seconds**.

Tasks are assigned to the servers using a **task queue**. Initially, all servers are free, and the queue is **empty**.

At second `j`, the `j`th task is **inserted** into the queue (starting with the `0`th task being inserted at second `0`). As long as there are free servers and the queue is not empty, the task in the front of the queue will be assigned to a free server with the **smallest weight**, and in case of a tie, it is assigned to a free server with the **smallest index**.

If there are no free servers and the queue is not empty, we wait until a server becomes free and immediately assign the next task. If multiple servers become free at the same time, then multiple tasks from the queue will be assigned **in order of insertion** following the weight and index priorities above.

A server that is assigned task `j` at second `t` will be free again at second `t + tasks[j]`.

Build an array `ans` of length `m`, where `ans[j]` is the **index** of the server the `j`$^{\square\square\square\square\square\square th}$ task will be assigned to.

Return *the array* `ans`.

Example 1:

```
Input: servers = [3,3,2], tasks = [1,2,3,2,1,2]
Output: [2,2,0,2,1,2]
Explanation: Events in chronological order go as follows:
- At second 0, task 0 is added and processed using server 2 until second 1.
- At second 1, server 2 becomes free. Task 1 is added and processed using server 2 until second 3.
- At second 2, task 2 is added and processed using server 0 until second 5.
- At second 3, server 2 becomes free. Task 3 is added and processed using server 2 until second 5.
- At second 4, task 4 is added and processed using server 1 until second 5.
- At second 5, all servers become free. Task 5 is added and processed using server 2 until second 7.
```

Example 2:

```
Input: servers = [5,1,4,3,2], tasks = [2,1,2,4,5,2,1]
Output: [1,4,1,4,1,3,2]
Explanation: Events in chronological order go as follows:
- At second 0, task 0 is added and processed using server 1 until second 2.
- At second 1, task 1 is added and processed using server 4 until second 2.
- At second 2, servers 1 and 4 become free. Task 2 is added and processed using server 1 until second
4.
- At second 3, task 3 is added and processed using server 4 until second 7.
- At second 4, server 1 becomes free. Task 4 is added and processed using server 1 until second 9.
- At second 5, task 5 is added and processed using server 3 until second 7.
- At second 6, task 6 is added and processed using server 2 until second 7.
```

Constraints:

- `servers.length == n`
- `tasks.length == m`
- `1 <= n, m <= 2 * 10`^{5}
- `1 <= servers[i], tasks[j] <= 2 * 10`^{5}

SOLUTION (PYTHON 3)

Solution 1: Priority Queue (Min-Heap)

How to think about it

Tasks arrive at times 0,1,2,…. A free server with the smallest weight (then smallest index) is chosen; if none is free we wait for the earliest one. Scanning all servers per task is too slow. An idle heap stores (weight,index); a busy heap stores (free time,weight,index). At task j move finished servers back, or if none are idle take the earliest busy server and chain the new task onto it. A chained free time is a sum of task lengths and reaches 4×10^{10}, so that field is a 64-bit integer.

We use a min-heap idle to maintain all idle servers, where each element is a tuple (x, i) representing the i-th server with weight x. We use another min-heap busy to maintain all busy servers, where each element is a tuple (w, s, i) representing the i-th server that will be idle at time w with weight s. Initially, we add all servers to idle.

Next, we iterate through all tasks. For the j-th task, we first remove all servers from busy that will be idle at or before time j and add them to idle. Then we take the server with the smallest weight from idle, add it to busy, and assign it to the j-th task. If idle is empty, we take the server with the earliest idle time from busy, add it to busy, and assign it to the j-th task.

After iterating through all tasks, we obtain the answer array ans.

The time complexity is O((n + m) log n), where n is the number of servers and m is the number of tasks. The space complexity is O(n). Here, n and m are the number of servers and tasks, respectively.

```python
class Solution:
    def assignTasks(self, servers: List[int], tasks: List[int]) -> List[int]:
        idle = [(x, i) for i, x in enumerate(servers)]
        heapify(idle)
        busy = []
        ans = []
        for j, t in enumerate(tasks):
            while busy and busy[0][0] <= j:
                _, s, i = heappop(busy)
                heappush(idle, (s, i))
            if idle:
                s, i = heappop(idle)
                heappush(busy, (j + t, s, i))
            else:
                w, s, i = heappop(busy)
                heappush(busy, (w + t, s, i))
            ans.append(i)
        return ans
```

PATTERN 20 · INTERVALS (MERGE / INSERT / OVERLAP) · PROBLEM 1 OF 20

56. Merge Intervals

Medium · Array, Sorting, Quick Sort

leetcode.com/problems/merge-intervals

★ **TOP 10 PROBLEM** in Intervals (Merge / Insert / Overlap), Sorting: master this one first

Also appears in pattern 23 Sorting

PROBLEM

Given an array of `intervals` where `intervals[i] = [start_i, end_i]`, merge all overlapping intervals, and return *an array of the non-overlapping intervals that cover all the intervals in the input*.

Example 1:

```
Input: intervals = [[1,3],[2,6],[8,10],[15,18]]
Output: [[1,6],[8,10],[15,18]]
Explanation: Since intervals [1,3] and [2,6] overlap, merge them into [1,6].
```

Example 2:

```
Input: intervals = [[1,4],[4,5]]
Output: [[1,5]]
Explanation: Intervals [1,4] and [4,5] are considered overlapping.
```

Example 3:

```
Input: intervals = [[4,7],[1,4]]
Output: [[1,7]]
Explanation: Intervals [1,4] and [4,7] are considered overlapping.
```

Constraints:

- `1 <= intervals.length <= 10^4`
- `intervals[i].length == 2`
- `0 <= start_i <= end_i <= 10^4`

SOLUTIONS (PYTHON 3)

Solution 1: Sorting + One-pass Traversal

How to think about it

The first idea is to pick an interval and scan the rest for overlaps, merging until nothing changes. Correct, but worst-case $O(n^2)$ with a messy merge order. $n \le 10^4$ is tight. The waste is locating overlaps in unsorted input. After sorting by left endpoint, an interval can overlap only the interval we have not closed yet—later starts are larger, so they cannot skip over the middle and overlap again. So we sort, then scan once, keeping st, ed as the interval under merge.

We can sort the intervals in ascending order by the left endpoint, and then traverse the intervals for merging operations.

The specific merging operation is as follows.

First, we add the first interval to the answer. Then, we consider each subsequent interval in turn:

- If the right endpoint of the last interval in the answer array is less than the left endpoint of the current interval, it means that the two intervals will not overlap, so we can directly add the current interval to the end of the answer array;
- Otherwise, it means that the two intervals overlap. We need to use the right endpoint of the current interval to update the right endpoint of the last interval in the answer array, setting it to the larger of the two.

Finally, we return the answer array.

The time complexity is $O(n \times \log n)$, and the space complexity is $O(\log n)$. Here, n is the number of intervals.

Python 3

```python
class Solution:
    def merge(self, intervals: List[List[int]]) -> List[List[int]]:
        intervals.sort()
        ans = []
        st, ed = intervals[0]
        for s, e in intervals[1:]:
            if ed < s:
                ans.append([st, ed])
                st, ed = s, e
            else:
                ed = max(ed, e)
        ans.append([st, ed])
        return ans
```

Solution 2

How to think about it

Solution 1 is already O(n log n) and correct. It still keeps a separate st, ed, writes only when the interval closes, and appends once more at the end. What it lacks is storing the current interval in the answer: put the first interval into ans immediately, then either extend ans[-1]'s right end or append. Fewer variables, no final flush.

Python 3

```python
class Solution:
    def merge(self, intervals: List[List[int]]) -> List[List[int]]:
        intervals.sort()
        ans = [intervals[0]]
        for s, e in intervals[1:]:
            if ans[-1][1] < s:
                ans.append([s, e])
            else:
                ans[-1][1] = max(ans[-1][1], e)
        return ans
```

Solution 3

How to think about it

Solution 2 already mutates the last interval in the answer. The loop is still "look at one, patch if needed." What it lacks is merging by groups: fix left l, eat every overlapping interval in an inner loop while stretching r, then push [l, r] once. Already-written answers are never rewritten.

Python 3 (written for this guide: the doocs page has no Python 3 version of this solution)

```python
class Solution:
    def merge(self, intervals: List[List[int]]) -> List[List[int]]:
        intervals.sort(key=lambda x: x[0])
        n = len(intervals)
        result = []
        i = 0
        while i < n:
            left, right = intervals[i]
            i += 1
            while i < n and right >= intervals[i][0]:
                right = max(right, intervals[i][1])
                i += 1
            result.append([left, right])
        return result
```

Complexity. Time: O(n log n). Space: O(log n) for the sort (plus the output).

PATTERN 20 · INTERVALS (MERGE / INSERT / OVERLAP) · PROBLEM 2 OF 20

57. Insert Interval

Medium · Array

leetcode.com/problems/insert-interval

★ **TOP 10 PROBLEM** in Intervals (Merge / Insert / Overlap): master this one first

PROBLEM

You are given an array of non-overlapping intervals `intervals` where `intervals[i] = [start`$_i$`, end`$_i$`]` represent the start and the end of the i^{th} interval and `intervals` is sorted in ascending order by `start`$_i$. You are also given an interval `newInterval = [start, end]` that represents the start and end of another interval.

Two intervals are considered overlapping if they share **at least** one point.

Insert `newInterval` into `intervals` such that `intervals` is still sorted in ascending order by `start`$_i$ and `intervals` still does not have any overlapping intervals (merge overlapping intervals if necessary).

Return `intervals` *after the insertion*.

Note that you don't need to modify `intervals` in-place. You can make a new array and return it.

Example 1:

```
Input: intervals = [[1,3],[6,9]], newInterval = [2,5]
Output: [[1,5],[6,9]]
```

Example 2:

```
Input: intervals = [[1,2],[3,5],[6,7],[8,10],[12,16]], newInterval = [4,8]
Output: [[1,2],[3,10],[12,16]]
Explanation: Because the new interval [4,8] overlaps with [3,5],[6,7],[8,10].
```

Constraints:

- `0 <= intervals.length <= 10`^{4}
- `intervals[i].length == 2`
- `0 <= start`$_i$ `<= end`$_i$ `<= 10`^{5}
- `intervals` is sorted by `start`$_i$ in **ascending** order.
- `newInterval.length == 2`
- `0 <= start <= end <= 10`^{5}

SOLUTIONS (PYTHON 3)

Solution 1: Sorting + Interval Merging

How to think about it

The first idea is to insert newInterval into the list and reuse ordinary interval merging. n ≤ 10^4, so an O(n log n) sort will pass. The list is already sorted and non-overlapping, but reusing merge-intervals is the least extra code: append, sort, merge. Correct; it just ignores the given order.

We can first add the new interval `newInterval` to the interval list `intervals`, and then merge according to the regular method of interval merging.

The time complexity is O(n × log n), and the space complexity is O(n). Here, n is the number of intervals.

Python 3

```python
class Solution:
    def insert(
        self, intervals: List[List[int]], newInterval: List[int]
    ) -> List[List[int]]:
        def merge(intervals: List[List[int]]) -> List[List[int]]:
            intervals.sort()
            ans = [intervals[0]]
            for s, e in intervals[1:]:
                if ans[-1][1] < s:
                    ans.append([s, e])
                else:
                    ans[-1][1] = max(ans[-1][1], e)
            return ans

        intervals.append(newInterval)
        return merge(intervals)
```

Solution 2: One-pass Traversal

> **How to think about it**
>
> Solution 1 sorts again and throws away the existing order, paying an extra log n. What it lacks is a single pass: write a current interval if it lies entirely left of the new one; if it lies entirely right, insert the new interval first; otherwise widen the new interval's ends. Append at the end if it was never inserted. Linear, no sort.

We can traverse the interval list `intervals`, let the current interval be `interval`, and there are three situations for each interval:

- The current interval is on the right side of the new interval, that is, newInterval[1] < interval[0]. At this time, if the new interval has not been added, then add the new interval to the answer, and then add the current interval to the answer.
- The current interval is on the left side of the new interval, that is, interval[1] < newInterval[0]. At this time, add the current interval to the answer.
- Otherwise, it means that the current interval and the new interval intersect. We take the minimum of the left endpoint of the current interval and the left endpoint of the new interval, and the maximum of the right endpoint of the current interval and the right endpoint of the new interval, as the left and right endpoints of the new interval, and then continue to traverse the interval list.

After the traversal, if the new interval has not been added, then add the new interval to the answer.

The time complexity is O(n), where n is the number of intervals. Ignoring the space consumption of the answer array, the space complexity is O(1).

Python 3

```python
class Solution:
    def insert(
        self, intervals: List[List[int]], newInterval: List[int]
    ) -> List[List[int]]:
        st, ed = newInterval
        ans = []
        insert = False
        for s, e in intervals:
            if ed < s:
                if not insert:
                    ans.append([st, ed])
                    insert = True
                ans.append([s, e])
            elif e < st:
                ans.append([s, e])
            else:
                st = min(st, s)
                ed = max(ed, e)
        if not insert:
            ans.append([st, ed])
        return ans
```

435. Non-overlapping Intervals

Medium · Greedy, Array, Dynamic Programming, Sorting

leetcode.com/problems/non-overlapping-intervals

★ **TOP 10 PROBLEM** in Intervals (Merge / Insert / Overlap): master this one first

Also appears in pattern 21 Greedy

PROBLEM

Given an array of intervals `intervals` where `intervals[i] = [start_i, end_i]`, return *the minimum number of intervals you need to remove to make the rest of the intervals non-overlapping*.

Note that intervals which only touch at a point are **non-overlapping**. For example, `[1, 2]` and `[2, 3]` are non-overlapping.

Example 1:

```
Input: intervals = [[1,2],[2,3],[3,4],[1,3]]
Output: 1
Explanation: [1,3] can be removed and the rest of the intervals are non-overlapping.
```

Example 2:

```
Input: intervals = [[1,2],[1,2],[1,2]]
Output: 2
Explanation: You need to remove two [1,2] to make the rest of the intervals non-overlapping.
```

Example 3:

```
Input: intervals = [[1,2],[2,3]]
Output: 0
Explanation: You don't need to remove any of the intervals since they're already non-overlapping.
```

Constraints:

- `1 <= intervals.length <= 10^5`
- `intervals[i].length == 2`
- `-5 * 10^4 <= start_i < end_i <= 5 * 10^4`

SOLUTION (PYTHON 3)

Solution 1: Sorting + Greedy

How to think about it

Removing the fewest intervals so the rest are disjoint is the same as keeping the largest set of non-overlapping intervals. Subset search is too large. Sort by right endpoint and keep an interval when it starts at or after the last kept end. The earliest finish leaves the most room, which is why we sort by the right end. The answer starts at n and decreases once per kept interval: total minus the size of a maximum compatible set.

We first sort the intervals in ascending order by their right boundary. We use a variable pre to record the right boundary of the previous interval and a variable ans to record the number of intervals that need to be removed. Initially, ans = intervals.length.

Then we iterate through the intervals. For each interval:

- If the left boundary of the current interval is greater than or equal to pre, it means that this interval does not need to be removed. We directly update pre to the right boundary of the current interval and decrement ans by one;
- Otherwise, it means that this interval needs to be removed, and we do not need to update pre and ans.

Finally, we return ans.

The time complexity is O(n × log n), and the space complexity is O(log n), where n is the number of intervals.

Python 3

```python
class Solution:
    def eraseOverlapIntervals(self, intervals: List[List[int]]) -> int:
        intervals.sort(key=lambda x: x[1])
        ans = len(intervals)
        pre = -inf
        for l, r in intervals:
            if pre <= l:
                ans -= 1
                pre = r
        return ans
```

# and add the best total over intervals that end before it
# starts (found with a binary search).
# Time: O(n log n).  Space: O(n).
import bisect

def max_weight_schedule(intervals):
    # intervals are (start, end, weight)
    ordered = sorted(intervals, key=lambda x: x[1])
    ends = [x[1] for x in ordered]
    best = [0] * (len(ordered) + 1)
    for i in range(1, len(ordered) + 1):
        start, end, weight = ordered[i - 1]
        before = bisect.bisect_right(ends, start, 0, i - 1)
```

```
        take = weight + best[before]
        best[i] = take if take > best[i - 1] else best[i - 1]
    return best[len(ordered)]
```

452. Minimum Number of Arrows to Burst Balloons

Medium · Greedy, Array, Sorting

leetcode.com/problems/minimum-number-of-arrows-to-burst-balloons

★ **TOP 10 PROBLEM** in Intervals (Merge / Insert / Overlap): master this one first

Also appears in pattern 21 Greedy

PROBLEM

There are some spherical balloons taped onto a flat wall that represents the XY-plane. The balloons are represented as a 2D integer array `points` where `points[i] = [x_start, x_end]` denotes a balloon whose **horizontal diameter** stretches between x_{start} and x_{end}. You do not know the exact y-coordinates of the balloons.

Arrows can be shot up **directly vertically** (in the positive y-direction) from different points along the x-axis. A balloon with x_{start} and x_{end} is **burst** by an arrow shot at x if $x_{start} <= x <= x_{end}$. There is **no limit** to the number of arrows that can be shot. A shot arrow keeps traveling up infinitely, bursting any balloons in its path.

Given the array `points`, return *the **minimum** number of arrows that must be shot to burst all balloons*.

Example 1:

```
Input: points = [[10,16],[2,8],[1,6],[7,12]]
Output: 2
Explanation: The balloons can be burst by 2 arrows:
- Shoot an arrow at x = 6, bursting the balloons [2,8] and [1,6].
- Shoot an arrow at x = 11, bursting the balloons [10,16] and [7,12].
```

Example 2:

```
Input: points = [[1,2],[3,4],[5,6],[7,8]]
Output: 4
Explanation: One arrow needs to be shot for each balloon for a total of 4 arrows.
```

Example 3:

```
Input: points = [[1,2],[2,3],[3,4],[4,5]]
Output: 2
Explanation: The balloons can be burst by 2 arrows:
- Shoot an arrow at x = 2, bursting the balloons [1,2] and [2,3].
- Shoot an arrow at x = 4, bursting the balloons [3,4] and [4,5].
```

Constraints:

- $1 <= points.length <= 10^5$
- `points[i].length == 2`
- $-2^{31} <= x_{start} < x_{end} <= 2^{31} - 1$

SOLUTION (PYTHON 3)

Solution 1

How to think about it

One arrow bursts every balloon covering that x-coordinate; we want the fewest arrows. This is piercing all intervals with the fewest points. Sort by the right end. The current arrow sits on the last burst balloon's right end; if the next left end is past that point, shoot again and move the pin. Pinning the rightmost point of a kept interval covers as many later balloons as possible; sorting by the right end makes that greedy choice optimal.

Python 3

```python
class Solution:
    def findMinArrowShots(self, points: List[List[int]]) -> int:
        ans, last = 0, -inf
        for a, b in sorted(points, key=lambda x: x[1]):
            if a > last:
                ans += 1
                last = b
        return ans
```

Complexity. Time: O(n log n). Space: O(log n) for the sort.

    arrows = 0
    last_shot = None
    for x in sorted(xs):
        if last_shot is None or x - r > last_shot:
            arrows += 1
            last_shot = x + r
    return arrows
```

986. Interval List Intersections

Medium · Array, Two Pointers, Sweep Line

leetcode.com/problems/interval-list-intersections

★ **TOP 10 PROBLEM** in Intervals (Merge / Insert / Overlap): master this one first

PROBLEM

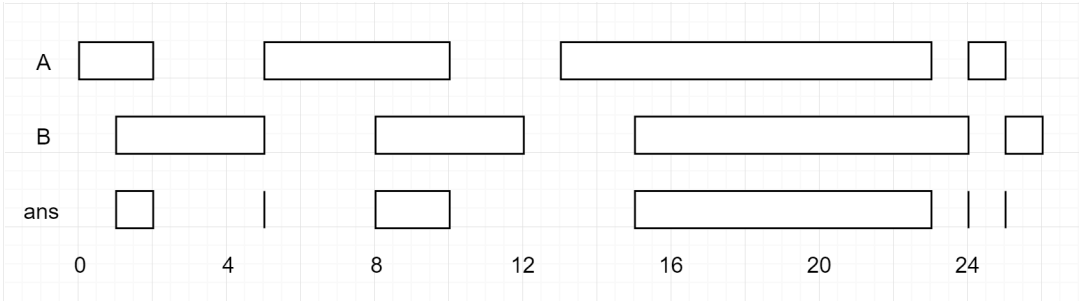
You are given two lists of closed intervals, `firstList` and `secondList`, where `firstList[i] = [start`$_i$`, end`$_i$`]` and `secondList[j] = [start`$_j$`, end`$_j$`]`. Each list of intervals is pairwise **disjoint** and in **sorted order**.

Return *the intersection of these two interval lists*.

A **closed interval** `[a, b]` (with `a <= b`) denotes the set of real numbers `x` with `a <= x <= b`.

The **intersection** of two closed intervals is a set of real numbers that are either empty or represented as a closed interval. For example, the intersection of `[1, 3]` and `[2, 4]` is `[2, 3]`.

Example 1:



```
Input: firstList = [[0,2],[5,10],[13,23],[24,25]], secondList = [[1,5],[8,12],[15,24],[25,26]]
Output: [[1,2],[5,5],[8,10],[15,23],[24,24],[25,25]]
```

Example 2:

```
Input: firstList = [[1,3],[5,9]], secondList = []
Output: []
```

Constraints:

- `0 <= firstList.length, secondList.length <= 1000`
- `firstList.length + secondList.length >= 1`
- $0 \le start_i < end_i \le 10^9$
- $end_i < start_{i+1}$
- $0 \le start_j < end_j \le 10^9$
- $end_j < start_{j+1}$

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Two lists of closed intervals are each sorted and internally disjoint; we want every intersection. Two pointers hold the current intervals. Their overlap is $[\max(s_1,s_2),\min(e_1,e_2)]$ and is recorded when nonempty. Advance the pointer whose interval ends first.

Python 3

```
class Solution:
    def intervalIntersection(
        self, firstList: List[List[int]], secondList: List[List[int]]
    ) -> List[List[int]]:
        i = j = 0
        ans = []
        while i < len(firstList) and j < len(secondList):
            s1, e1, s2, e2 = *firstList[i], *secondList[j]
            l, r = max(s1, s2), min(e1, e2)
            if l <= r:
                ans.append([l, r])
            if e1 < e2:
                i += 1
            else:
                j += 1
        return ans
```

Complexity. Time: O(m + n). Space: O(1) extra (the output is O(m + n)).

PATTERN 20 · INTERVALS (MERGE / INSERT / OVERLAP) · PROBLEM 6 OF 20

729. My Calendar I

Medium · Design, Segment Tree, Array, Binary Search, Ordered Set

leetcode.com/problems/my-calendar-i

★ **TOP 10 PROBLEM** in Segment Tree: master this one first

Also appears in pattern 40 Segment Tree

PROBLEM

You are implementing a program to use as your calendar. We can add a new event if adding the event will not cause a **double booking**.

A **double booking** happens when two events have some non-empty intersection (i.e., some moment is common to both events.).

The event can be represented as a pair of integers `startTime` and `endTime` that represents a booking on the half-open interval `[startTime, endTime)`, the range of real numbers `x` such that `startTime <= x < endTime`.

Implement the `MyCalendar` class:

- `MyCalendar()` Initializes the calendar object.
- `boolean book(int startTime, int endTime)` Returns `true` if the event can be added to the calendar successfully without causing a **double booking**. Otherwise, return `false` and do not add the event to the calendar.

Example 1:

```
Input
["MyCalendar", "book", "book", "book"]
[[], [10, 20], [15, 25], [20, 30]]
Output
[null, true, false, true]

Explanation
MyCalendar myCalendar = new MyCalendar();
myCalendar.book(10, 20); // return True
myCalendar.book(15, 25); // return False, It can not be booked because time 15 is already booked by
another event.
myCalendar.book(20, 30); // return True, The event can be booked, as the first event takes every time
less than 20, but not including 20.
```

Constraints:

- $0 <= start < end <= 10^9$
- At most `1000` calls will be made to `book`.

SOLUTION (PYTHON 3)

Solution 1: Ordered Set

How to think about it

Bookings must not overlap; endpoints reach 10^9 and there are about 1000 calls. A linear scan works, but an ordered map finds the conflict in a log. Sorted by end time, the only interval that can meet [start,end) is the first whose end is greater than start. If that start is still less than end, they overlap. Store end↦start. bisect_right(start) yields that candidate; insert on success. O(log n) per book.

We can use an ordered set to store the schedule. An ordered set can perform insert, delete, and search operations in O(log n) time. The elements in the ordered set are sorted by the endTime of the schedule in ascending order.

When calling the book(start, end) method, we search for the first schedule in the ordered set with an end time greater than start. If it exists and its start time is less than end, it means there is a double booking, and we return false. Otherwise, we insert end as the key and start as the value into the ordered set and return true.

The time complexity is O(n × log n), and the space complexity is O(n). Here, n is the number of schedules.

Python 3

```
class MyCalendar:

    def __init__(self):
        self.sd = SortedDict()

    def book(self, start: int, end: int) -> bool:
        idx = self.sd.bisect_right(start)
        if idx < len(self.sd) and self.sd.values()[idx] < end:
            return False
        self.sd[end] = start
        return True

# Your MyCalendar object will be instantiated and called as such:
# obj = MyCalendar()
# param_1 = obj.book(start,end)
```

Medium · Design, Segment Tree, Array, Binary Search, Ordered Set, Prefix Sum

leetcode.com/problems/my-calendar-ii

★ **TOP 10 PROBLEM** in Intervals (Merge / Insert / Overlap): master this one first

Also appears in pattern 40 Segment Tree

PROBLEM

You are implementing a program to use as your calendar. We can add a new event if adding the event will not cause a **triple booking**.

A **triple booking** happens when three events have some non-empty intersection (i.e., some moment is common to all the three events.).

The event can be represented as a pair of integers `startTime` and `endTime` that represents a booking on the half-open interval `[startTime, endTime)`, the range of real numbers `x` such that `startTime <= x < endTime`.

Implement the `MyCalendarTwo` class:

- `MyCalendarTwo()` Initializes the calendar object.
- `boolean book(int startTime, int endTime)` Returns `true` if the event can be added to the calendar successfully without causing a **triple booking**. Otherwise, return `false` and do not add the event to the calendar.

Example 1:

```
Input
["MyCalendarTwo", "book", "book", "book", "book", "book", "book"]
[[], [10, 20], [50, 60], [10, 40], [5, 15], [5, 10], [25, 55]]
Output
[null, true, true, true, false, true, true]

Explanation
MyCalendarTwo myCalendarTwo = new MyCalendarTwo();
myCalendarTwo.book(10, 20); // return True, The event can be booked.
myCalendarTwo.book(50, 60); // return True, The event can be booked.
myCalendarTwo.book(10, 40); // return True, The event can be double booked.
myCalendarTwo.book(5, 15); // return False, The event cannot be booked, because it would result in a
triple booking.
myCalendarTwo.book(5, 10); // return True, The event can be booked, as it does not use time 10 which is
already double booked.
myCalendarTwo.book(25, 55); // return True, The event can be booked, as the time in [25, 40) will be
double booked with the third event, the time [40, 50) will be single booked, and the time [50, 55) will
be double booked with the second event.
```

Constraints:

- `0 <= start < end <= 10^9`
- At most `1000` calls will be made to `book`.

SOLUTIONS (PYTHON 3)

Solution 1: Difference Array

How to think about it

Double booking is allowed, triple is not. Endpoints reach 10^9 with 1000 calls. Checking every pair plus a second list of doubles is clumsy. Coverage is a difference array: +1 at start, -1 at end. A prefix scan over sorted times rejects a booking if the sum exceeds 2, then rolls the two updates back. A sorted map stands in for the huge timeline. Each book scans the keys in O(n), total $O(n^2)$, which is fine for 1000 calls.

We can use the concept of a difference array to record the booking status at each time point. Then, we traverse all the time points and count the booking status at the current time point. If the number of bookings exceeds 2, we return false. Otherwise, we return true.

The time complexity is $O(n^2)$, and the space complexity is $O(n)$, where n is the number of bookings.

Python 3

```
class MyCalendarTwo:

    def __init__(self):
        self.sd = SortedDict()

    def book(self, startTime: int, endTime: int) -> bool:
        self.sd[startTime] = self.sd.get(startTime, 0) + 1
        self.sd[endTime] = self.sd.get(endTime, 0) - 1
        s = 0
        for v in self.sd.values():
            s += v
            if s > 2:
                self.sd[startTime] -= 1
                self.sd[endTime] += 1
                return False
        return True

# Your MyCalendarTwo object will be instantiated and called as such:
# obj = MyCalendarTwo()
# param_1 = obj.book(startTime,endTime)
```

Solution 2: Segment Tree

> **How to think about it**
>
> Solution 1 rescans every breakpoint. Range add plus range-max is a lazy segment tree. The universe is 10^9, so nodes are created on demand and store the max coverage. Query [start,end); reject if the max is already 2, otherwise add one. O(log n) per book.

A segment tree divides the entire interval into multiple non-contiguous subintervals, with the number of subintervals not exceeding log(width). To update the value of an element, only log(width) intervals need to be updated, and these intervals are all contained within a larger interval that includes the element. When modifying intervals, a **lazy mark** is used to ensure efficiency.

- Each node of the segment tree represents an interval;
- The segment tree has a unique root node representing the entire statistical range, such as [1, N];
- Each leaf node of the segment tree represents a unit interval of length 1, [x, x];
- For each internal node [l, r], its left child is [l, mid] and its right child is [mid + 1, r], where mid = floor((l + r) / 2) (i.e., floor division).

For this problem, the segment tree nodes maintain the following information:

1. The maximum number of bookings within the interval v
2. Lazy mark add

Since the time range is 10^9, which is very large, we use dynamic node creation.

The time complexity is $O(n \times \log n)$, and the space complexity is $O(n)$. Here, n is the number of bookings.

Python 3

```
class Node:
    def __init__(self, l: int, r: int):
        self.left = None
        self.right = None
        self.l = l
        self.r = r
        self.mid = (l + r) >> 1
        self.v = 0
        self.add = 0

class SegmentTree:
    def __init__(self):
        self.root = Node(1, 10**9 + 1)

    def modify(self, l: int, r: int, v: int, node: Node = None):
        if l > r:
            return
        if node is None:
            node = self.root
        if node.l >= l and node.r <= r:
            node.v += v
            node.add += v
            return
        self.pushdown(node)
        if l <= node.mid:
            self.modify(l, r, v, node.left)
        if r > node.mid:
            self.modify(l, r, v, node.right)
        self.pushup(node)

    def query(self, l: int, r: int, node: Node = None) -> int:
        if l > r:
            return 0
        if node is None:
            node = self.root
        if node.l >= l and node.r <= r:
            return node.v
        self.pushdown(node)
        v = 0
        if l <= node.mid:
            v = max(v, self.query(l, r, node.left))
        if r > node.mid:
            v = max(v, self.query(l, r, node.right))
        return v

    def pushup(self, node: Node):
        node.v = max(node.left.v, node.right.v)

    def pushdown(self, node: Node):
        if node.left is None:
            node.left = Node(node.l, node.mid)
        if node.right is None:
            node.right = Node(node.mid + 1, node.r)
        if node.add:
            node.left.v += node.add
            node.right.v += node.add
            node.left.add += node.add
            node.right.add += node.add
            node.add = 0
```

```
class MyCalendarTwo:
    def __init__(self):
        self.tree = SegmentTree()
```

```
    def book(self, startTime: int, endTime: int) -> bool:
        if self.tree.query(startTime + 1, endTime) >= 2:
            return False
        self.tree.modify(startTime + 1, endTime, 1)
        return True

# Your MyCalendarTwo object will be instantiated and called as such:
# obj = MyCalendarTwo()

1094. Car Pooling

Medium · Array, Prefix Sum, Sorting, Simulation, Heap (Priority Queue)

leetcode.com/problems/car-pooling

★ **TOP 10 PROBLEM** in Intervals (Merge / Insert / Overlap): master this one first

PROBLEM

There is a car with `capacity` empty seats. The vehicle only drives east (i.e., it cannot turn around and drive west).

You are given the integer `capacity` and an array `trips` where `trips[i] = [numPassengers`$_i$`, from`$_i$`, to`$_i$`]` indicates that the i^{th} trip has `numPassengers`$_i$ passengers and the locations to pick them up and drop them off are `from`$_i$ and `to`$_i$ respectively. The locations are given as the number of kilometers due east from the car's initial location.

Passengers are dropped off before new passengers are picked up at the same location. At every point along the route, the total number of passengers in the car must not exceed `capacity`.

Return `true` if it is possible to pick up and drop off all passengers for all the given trips, or `false` otherwise.

Example 1:

```
Input: trips = [[2,1,5],[3,3,7]], capacity = 4
Output: false
Explanation:
At kilometer 1, 2 passengers are picked up, so the car holds 2.
At kilometer 3, 3 more are picked up, so the car holds 5.
Since 5 > capacity = 4, the trips cannot all be completed.
```

Example 2:

```
Input: trips = [[2,1,5],[3,3,7]], capacity = 5
Output: true
Explanation:
At kilometer 1, the car holds 2 passengers.
At kilometer 3, the car holds 5 passengers.
At kilometer 5, the first 2 are dropped off, so the car holds 3.
At kilometer 7, the last 3 are dropped off, so the car holds 0.
The maximum occupancy is 5, which never exceeds capacity = 5.
```

Constraints:

- `1 <= trips.length <= 1000`
- `trips[i].length == 3`
- `1 <= numPassengers`$_i$ `<= 100`
- `0 <= from`$_i$ `< to`$_i$ `<= 1000`
- `1 <= capacity <= 10`^{5}

SOLUTION (PYTHON 3)

Solution 1: Difference Array

How to think about it

Each trip adds passengers on [from,to). We need the load never to exceed capacity. Locations are at most 1000, so a difference array is enough. Add at the start, subtract at the end, then prefix-sum and test every position against capacity. The array runs to the latest drop-off; empty stops keep the previous load.

We can use the idea of a difference array, adding the number of passengers to the starting point of each trip and subtracting from the end point. Finally, we just need to check whether the prefix sum of the difference array does not exceed the maximum passenger capacity of the car.

The time complexity is O(n), and the space complexity is O(M). Here, n is the number of trips, and M is the maximum end point in the trips. In this problem, M ≤ 1000.

Python 3

```
class Solution:
    def carPooling(self, trips: List[List[int]], capacity: int) -> bool:
        mx = max(e[2] for e in trips)
        d = [0] * (mx + 1)
        for x, f, t in trips:
            d[f] += x
            d[t] -= x
        return all(s <= capacity for s in accumulate(d))
```

```

1353. Maximum Number of Events That Can Be Attended

Medium · Greedy, Array, Sorting, Heap (Priority Queue)

leetcode.com/problems/maximum-number-of-events-that-can-be-attended

Also appears in pattern 21 Greedy

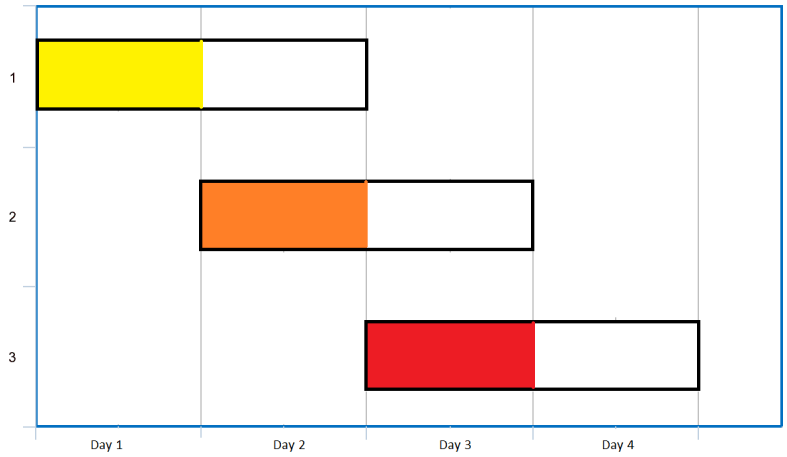
PROBLEM

You are given an array of `events` where `events[i] = [startDay`$_i$`, endDay`$_i$`]`. Every event `i` starts at `startDay`$_i$ and ends at `endDay`$_i$.

You can attend an event `i` at any day `d` where `startDay`$_i$ `<= d <=` `endDay`$_i$. You can only attend one event at any time `d`.

Return *the maximum number of events you can attend*.

Example 1:



```
Input: events = [[1,2],[2,3],[3,4]]
Output: 3
Explanation: You can attend all the three events.
One way to attend them all is as shown.
Attend the first event on day 1.
Attend the second event on day 2.
Attend the third event on day 3.
```

Example 2:

```
Input: events= [[1,2],[2,3],[3,4],[1,2]]
Output: 4
```

Constraints:

- `1 <= events.length <=` 10^5
- `events[i].length == 2`
- `1 <= startDay`$_i$ `<= endDay`$_i$ `<=` 10^5

SOLUTION (PYTHON 3)

Solution 1: Hash Table + Greedy + Priority Queue

How to think about it

One event per day, each event occupying any day in [s,e]. n and the day range reach 10^5, so sorting by end and scanning days naively is tight. Sweep by day: push endings that start today into a min-heap, drop expired ones, and attend the earliest-ending event. Each day is given to the most urgent remaining event.

We use a hash table g to record the start and end times of each event. The key is the start time of the event, and the value is a list containing the end times of all events that start at that time. Two variables, l and r, are used to record the minimum start time and the maximum end time among all events.

For each time point s from l to r in increasing order, we perform the following steps:

1. Remove from the priority queue all events whose end time is less than the current time s.
2. Add the end times of all events that start at the current time s to the priority queue.
3. If the priority queue is not empty, take out the event with the earliest end time, increment the answer count, and remove this event from the priority queue.

In this way, we ensure that at each time point s, we always attend the event that ends the earliest, thus maximizing the number of events attended.

The time complexity is O(M × log n), and the space complexity is O(n), where M is the maximum end time and n is the number of events.

Python 3

```python
class Solution:
    def maxEvents(self, events: List[List[int]]) -> int:
        g = defaultdict(list)
        l, r = inf, 0
        for s, e in events:
            g[s].append(e)
            l = min(l, s)
            r = max(r, e)
        pq = []
        ans = 0
        for s in range(l, r + 1):
            while pq and pq[0] < s:
                heappop(pq)
            for e in g[s]:
                heappush(pq, e)
            if pq:
                heappop(pq)
                ans += 1
        return ans
```

            end, i = heapq.heappop(heap)
            schedule[day] = i
            day += 1
    return schedule
```

1024. Video Stitching

Medium · Greedy, Array, Dynamic Programming

leetcode.com/problems/video-stitching

PROBLEM

You are given a series of video clips from a sporting event that lasted `time` seconds. These video clips can be overlapping with each other and have varying lengths.

Each video clip is described by an array `clips` where `clips[i] = [start_i, end_i]` indicates that the ith clip started at `start_i` and ended at `end_i`.

We can cut these clips into segments freely.

- For example, a clip `[0, 7]` can be cut into segments `[0, 1] + [1, 3] + [3, 7]`.

Return *the minimum number of clips needed so that we can cut the clips into segments that cover the entire sporting event* `[0, time]`. If the task is impossible, return `-1`.

Example 1:

```
Input: clips = [[0,2],[4,6],[8,10],[1,9],[1,5],[5,9]], time = 10
Output: 3
Explanation: We take the clips [0,2], [8,10], [1,9]; a total of 3 clips.
Then, we can reconstruct the sporting event as follows:
We cut [1,9] into segments [1,2] + [2,8] + [8,9].
Now we have segments [0,2] + [2,8] + [8,10] which cover the sporting event [0, 10].
```

Example 2:

```
Input: clips = [[0,1],[1,2]], time = 5
Output: -1
Explanation: We cannot cover [0,5] with only [0,1] and [1,2].
```

Example 3:

```
Input: clips =
[[0,1],[6,8],[0,2],[5,6],[0,4],[0,3],[6,7],[1,3],[4,7],[1,4],[2,5],[2,6],[3,4],[4,5],[5,7],[6,9]],
time = 9
Output: 3
Explanation: We can take clips [0,4], [4,7], and [6,9].
```

Constraints:

- `1 <= clips.length <= 100`
- `0 <= start_i <= end_i <= 100`
- `1 <= time <= 100`

SOLUTION (PYTHON 3)

Solution 1: Greedy

How to think about it

Both the number of clips and the time bound are at most 100, so a subset search could cover [0,time], but there are exponentially many subsets. For a fixed start we only need the clip with the farthest end, which is the jump-game setting. Store the farthest end last[i] of clips starting at i. A left-to-right scan keeps the reachable mx; if mx stalls at i, coverage is impossible. Crossing the previous segment end pre costs one extra clip. The scan yields the minimum number of clips or -1.

Note that if there are multiple sub-intervals with the same starting point, it is optimal to choose the one with the largest right endpoint.

Therefore, we can preprocess all sub-intervals. For each position i, calculate the largest right endpoint among all sub-intervals starting at i, and record it in the array last[i].

We define a variable `mx` to represent the farthest position that can currently be reached, a variable `ans` to represent the current minimum number of sub-intervals needed, and a variable `pre` to represent the right endpoint of the last used sub-interval.

Next, we start enumerating all positions i from 0, using last[i] to update `mx`. If after updating, mx = i, it means that the next position cannot be covered, so the task cannot be completed, return -1.

At the same time, we record the right endpoint `pre` of the last used sub-interval. If pre = i, it means that a new sub-interval needs to be used, so we add 1 to `ans` and update `pre` to `mx`.

After the traversal is over, return `ans`.

The time complexity is O(n+m), and the space complexity is O(m). Where n and m are the lengths of the `clips` array and the value of `time`, respectively.

    def videoStitching(self, clips: List[List[int]], time: int) -> int:
        last = [0] * time
        for a, b in clips:
            if a < time:
                last[a] = max(last[a], b)
        ans = mx = pre = 0
        for i, v in enumerate(last):
            mx = max(mx, v)
            if mx <= i:
                return -1
            if pre == i:
                ans += 1
                pre = mx
        return ans

PATTERN 20 · INTERVALS (MERGE / INSERT / OVERLAP) · PROBLEM 11 OF 20

1288. Remove Covered Intervals

Medium · Array, Sorting

leetcode.com/problems/remove-covered-intervals

★ **TOP 10 PROBLEM** in Intervals (Merge / Insert / Overlap): master this one first

PROBLEM

Given an array `intervals` where `intervals[i] = [l_i, r_i]` represent the interval `[l_i, r_i)`, remove all intervals that are covered by another interval in the list.

The interval `[a, b)` is covered by the interval `[c, d)` if and only if `c <= a` and `b <= d`.

Return *the number of remaining intervals*.

Example 1:

```
Input: intervals = [[1,4],[3,6],[2,8]]
Output: 2
Explanation: Interval [3,6] is covered by [2,8], therefore it is removed.
```

Example 2:

```
Input: intervals = [[1,4],[2,3]]
Output: 1
```

Constraints:

- `1 <= intervals.length <= 1000`
- `intervals[i].length == 2`
- `0 <= l_i < r_i <= 10^5`
- All the given intervals are **unique**.

SOLUTION (PYTHON 3)

Solution 1: Sorting

How to think about it

We drop intervals covered by another. Sorting by rising left end and, on ties, falling right end, an earlier interval cannot be covered by a later narrower one. We keep the largest right end seen: a strictly larger current right end is not covered. Sorting reduces 2-D containment to a 1-D right-end test.

We can sort the intervals in ascending order by their left endpoints, and if the left endpoints are the same, sort them in descending order by their right endpoints.

After sorting, we can traverse the intervals. If the right endpoint of the current interval is greater than the previous right endpoint, it means the current interval is not covered, and we increment the answer by one.

The time complexity is O(n × log n), and the space complexity is O(log n). Here, n is the number of intervals.

Python 3

```
class Solution:
    def removeCoveredIntervals(self, intervals: List[List[int]]) -> int:
        intervals.sort(key=lambda x: (x[0], -x[1]))
        ans = 0
        pre = -inf
        for _, cur in intervals:
            if cur > pre:
                ans += 1
                pre = cur
        return ans
```

PATTERN 20 · INTERVALS (MERGE / INSERT / OVERLAP) · PROBLEM 13 OF 20

436. Find Right Interval

Medium · Array, Binary Search, Sorting

leetcode.com/problems/find-right-interval

Also appears in pattern 37 Two Heaps

PROBLEM

You are given an array of `intervals`, where `intervals[i] = [start_i, end_i]` and each `start_i` is **unique**.

The **right interval** for an interval `i` is an interval `j` such that `start_j >= end_i` and `start_j` is **minimized**. Note that `i` may equal `j`.

Return *an array of **right interval** indices for each interval* `i`. If no **right interval** exists for interval `i`, then put `-1` at index `i`.

Example 1:

```
Input: intervals = [[1,2]]
Output: [-1]
Explanation: There is only one interval in the collection, so it outputs -1.
```

Example 2:

```
Input: intervals = [[3,4],[2,3],[1,2]]
Output: [-1,0,1]
Explanation: There is no right interval for [3,4].
The right interval for [2,3] is [3,4] since start0 = 3 is the smallest start that is >= end1 = 3.
The right interval for [1,2] is [2,3] since start1 = 2 is the smallest start that is >= end2 = 2.
```

Example 3:

```
Input: intervals = [[1,4],[2,3],[3,4]]
Output: [-1,2,-1]
Explanation: There is no right interval for [1,4] and [3,4].
The right interval for [2,3] is [3,4] since start2 = 3 is the smallest start that is >= end1 = 3.
```

Constraints:

- `1 <= intervals.length <= 2 * 10^4`
- `intervals[i].length == 2`
- `-10^6 <= start_i <= end_i <= 10^6`
- The start point of each interval is **unique**.

SOLUTION (PYTHON 3)

Solution 1: Sorting + Binary Search

> **How to think about it**
>
> Each interval wants the leftmost start that is at least its end. A linear scan per end is O(n^2). Sort (start,index) by start and, for every end, binary-search the first start ≥ that end. Sorted starts are monotone, so the first feasible start is the closest one. Storing the original index survives the sort.

We can store the start point and index of each interval into an array `arr`, and sort it by the start point. Then we iterate through the interval array, for each interval `[_, ed]`, we can use binary search to find the first interval whose start point is greater than or equal to `ed`, which is its right-side interval. If found, we store its index into the answer array, otherwise, we store `-1`.

The time complexity is O(n × log n), and the space complexity is O(n). Where n is the length of the intervals.

Python 3

```python
class Solution:
    def findRightInterval(self, intervals: List[List[int]]) -> List[int]:
        n = len(intervals)
        ans = [-1] * n
        arr = sorted((st, i) for i, (st, _) in enumerate(intervals))
        for i, (_, ed) in enumerate(intervals):
            j = bisect_left(arr, (ed, -inf))
            if j < n:
                ans[i] = arr[j][1]
        return ans
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

# 1. Find the LEFT interval: the interval with the largest
# end that is at most my start

# ============================================================
# FOLLOW-UP 1: Find the LEFT interval: the interval with
# the largest end that is at most my start
# ============================================================

# ---- follow-up 1: function ----
# Answer: Sort the intervals by end and binary search the
# last end that is at most the start.
# Time: O(n log n).  Space: O(n).
import bisect

def find_left_intervals(intervals):
    by_end = sorted((end, i) for i, (start, end) in enumerate(intervals))
    ends = [end for end, i in by_end]
    result = []
    for start, end in intervals:
        position = bisect.bisect_right(ends, start) - 1
        result.append(by_end[position][1] if position >= 0 else -1)
    return result
```

759. Employee Free Time

Hard · Array, Sorting, Sweep Line, Heap (Priority Queue)

leetcode.com/problems/employee-free-time

★ **TOP 10 PROBLEM** in Intervals (Merge / Insert / Overlap): master this one first

PROBLEM

We are given a list `schedule` of employees, which represents the working time for each employee.

Each employee has a list of non-overlapping `Intervals`, and these intervals are in sorted order.

Return the list of finite intervals representing **common, positive-length free time** for *all* employees, also in sorted order.

(Even though we are representing `Intervals` in the form `[x, y]`, the objects inside are `Intervals`, not lists or arrays. For example, `schedule[0][0].start = 1`, `schedule[0][0].end = 2`, and `schedule[0][0][0]` is not defined). Also, we wouldn't include intervals like [5, 5] in our answer, as they have zero length.

Example 1:

```
Input: schedule = [[[1,2],[5,6]],[[1,3]],[[4,10]]]
Output: [[3,4]]
Explanation: There are a total of three employees, and all common
free time intervals would be [-inf, 1], [3, 4], [10, inf].
We discard any intervals that contain inf as they aren't finite.
```

Example 2:

```
Input: schedule = [[[1,3],[6,7]],[[2,4]],[[2,5],[9,12]]]
Output: [[5,6],[7,9]]
```

Constraints:

- `1 <= schedule.length , schedule[i].length <= 50`
- `0 <= schedule[i].start < schedule[i].end <= 10^8`

SOLUTION (PYTHON 3)

Solution 1: Interval Merging

How to think about it

Find gaps when every employee is free. Each person's intervals are sorted, but the global list is not. The times when someone is busy are the union of all intervals; gaps of that union are common free time. Sort by start, merge overlaps, and emit [a.end, b.start) between consecutive merged intervals.

We can merge all employees' working time intervals into a single list, then sort and merge the overlapping intervals. Finally, we traverse the merged interval list to find the free time periods between adjacent intervals.

The time complexity is O(mn log(mn)) and the space complexity is O(mn), where m is the number of employees and n is the number of working intervals per employee.

Python 3

```
"""
# Definition for an Interval.
class Interval:
    def __init__(self, start: int = None, end: int = None):
        self.start = start
        self.end = end
"""

class Solution:
    def employeeFreeTime(self, schedule: "[[Interval]]") -> "[Interval]":
        intervals = []
        for e in schedule:
            intervals.extend(e)
        intervals.sort(key=lambda x: (x.start, x.end))
        merged = [intervals[0]]
        for x in intervals[1:]:
            if merged[-1].end < x.start:
                merged.append(x)
            else:
                merged[-1].end = max(merged[-1].end, x.end)
        ans = []
        for a, b in pairwise(merged):
            ans.append(Interval(a.end, b.start))
        return ans
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

Built on the solutions above: helper functions, then the function for each follow-up. No tests and no restating of the question.

```
# FOLLOW-UPS (answered below, in this order):
# 1. The LONGEST common free time

# ============================================================
# FOLLOW-UP 1: The LONGEST common free time
# ============================================================

# ---- follow-up 1: function ----
# Answer: Merge all the working intervals and look at the
# gaps between them; keep the longest gap.
# Time: O(N log N), N = total intervals.  Space: O(N).
def longest_free_gap(schedules):
    intervals = []
    for employee in schedules:

            covered_until = end
    return best
```

PATTERN 20 · INTERVALS (MERGE / INSERT / OVERLAP) · PROBLEM 15 OF 20

732. My Calendar III

Hard · Design, Segment Tree, Binary Search, Ordered Set, Prefix Sum

leetcode.com/problems/my-calendar-iii

★ **TOP 10 PROBLEM** in Intervals (Merge / Insert / Overlap), Segment Tree: master this one first

Also appears in pattern 40 Segment Tree

PROBLEM

A `k`-booking happens when `k` events have some non-empty intersection (i.e., there is some time that is common to all `k` events.)

You are given some events `[startTime, endTime)`, after each given event, return an integer `k` representing the maximum `k`-booking between all the previous events.

Implement the `MyCalendarThree` class:

- `MyCalendarThree()` Initializes the object.
- `int book(int startTime, int endTime)` Returns an integer `k` representing the largest integer such that there exists a `k`-booking in the calendar.

Example 1:

```
Input
["MyCalendarThree", "book", "book", "book", "book", "book", "book"]
[[], [10, 20], [50, 60], [10, 40], [5, 15], [5, 10], [25, 55]]
Output
[null, 1, 1, 2, 3, 3, 3]

Explanation
MyCalendarThree myCalendarThree = new MyCalendarThree();
myCalendarThree.book(10, 20); // return 1
myCalendarThree.book(50, 60); // return 1
myCalendarThree.book(10, 40); // return 2
myCalendarThree.book(5, 15); // return 3
myCalendarThree.book(5, 10); // return 3
myCalendarThree.book(25, 55); // return 3
```

Constraints:

- `0 <= startTime < endTime <= 10^9`
- At most `400` calls will be made to `book`.

SOLUTION (PYTHON 3)

Solution 1: Segment Tree

How to think about it

After each booking we must report the current maximum overlap; at most 400 calls. A difference scan works but still walks every key. This is the same range-add / range-max problem as Calendar II, without the cap at 2. A dynamic segment tree updates the interval and queries the whole line. Nodes store the max and a lazy add. O(log n) per book.

A segment tree divides the entire interval into multiple non-contiguous subintervals, with the number of subintervals not exceeding log(width). To update the value of an element, we only need to update log(width) intervals, and these intervals are all contained within a larger interval that includes the element. When modifying intervals, we use **lazy propagation** to ensure efficiency.

- Each node of the segment tree represents an interval.

- The segment tree has a unique root node representing the entire range, such as [1, N].
