- Each leaf node of the segment tree represents a unit interval of length 1, [x, x].
- For each internal node [l, r], its left child is [l, mid] and its right child is [mid + 1, r], where mid = floor((l + r) / 2) (i.e., floor division).

For this problem, the segment tree nodes maintain the following information:

1. The maximum number of times the interval has been booked, v.
2. Lazy propagation marker, add.

Since the time range is 10^9, which is very large, we use dynamic node creation.

The time complexity is O(n × log n), and the space complexity is O(n), where n is the number of bookings.

1851. Minimum Interval to Include Each Query

Hard · Array, Binary Search, Sorting, Sweep Line, Heap (Priority Queue)

leetcode.com/problems/minimum-interval-to-include-each-query

PROBLEM

You are given a 2D integer array `intervals`, where `intervals[i] = [left_i, right_i]` describes the i^{th} interval starting at `left_i` and ending at `right_i` **(inclusive)**. The **size** of an interval is defined as the number of integers it contains, or more formally `right_i - left_i + 1`.

You are also given an integer array `queries`. The answer to the j^{th} query is the **size of the smallest interval** `i` such that `left_i <= queries[j] <= right_i`. If no such interval exists, the answer is `-1`.

Return *an array containing the answers to the queries*.

Example 1:

```
Input: intervals = [[1,4],[2,4],[3,6],[4,4]], queries = [2,3,4,5]
Output: [3,3,1,4]
Explanation: The queries are processed as follows:
- Query = 2: The interval [2,4] is the smallest interval containing 2. The answer is 4 - 2 + 1 = 3.
- Query = 3: The interval [2,4] is the smallest interval containing 3. The answer is 4 - 2 + 1 = 3.
- Query = 4: The interval [4,4] is the smallest interval containing 4. The answer is 4 - 4 + 1 = 1.
- Query = 5: The interval [3,6] is the smallest interval containing 5. The answer is 6 - 3 + 1 = 4.
```

Example 2:

```
Input: intervals = [[2,3],[2,5],[1,8],[20,25]], queries = [2,19,5,22]
Output: [2,-1,4,6]
Explanation: The queries are processed as follows:
- Query = 2: The interval [2,3] is the smallest interval containing 2. The answer is 3 - 2 + 1 = 2.
- Query = 19: None of the intervals contain 19. The answer is -1.
- Query = 5: The interval [2,5] is the smallest interval containing 5. The answer is 5 - 2 + 1 = 4.
- Query = 22: The interval [20,25] is the smallest interval containing 22. The answer is 25 - 20 + 1 =
6.
```

Constraints:

- `1 <= intervals.length <= 10^5`
- `1 <= queries.length <= 10^5`
- `intervals[i].length == 2`
- `1 <= left_i <= right_i <= 10^7`
- `1 <= queries[j] <= 10^7`

SOLUTION (PYTHON 3)

Solution 1: Sorting + Offline Query + Priority Queue (Min Heap)

> **How to think about it**
>
> Each query wants the shortest interval covering that point. Both arrays can have size 10^5, so scanning all intervals per query is impossible. Sort queries offline by coordinate and intervals by left endpoint. A min-heap stores (length,right) of intervals that already started: push those whose left is at most the query, pop those whose right is too small. The heap top is the shortest cover of the current point.

We notice that the order of queries does not affect the answer, and the intervals involved do not change. Therefore, we consider sorting all queries in ascending order, and sorting all intervals in ascending order of the left endpoint.

We use a priority queue (min heap) pq to maintain all current intervals. Each element in the queue is a pair (v, r), representing an interval with length v and right endpoint r. Initially, the priority queue is empty. In addition, we define a pointer i that points to the current interval being traversed, and initially i=0.

We traverse each query (x, j) in ascending order and perform the following operations:

- If the pointer i has not traversed all intervals, and the left endpoint of the current interval [a, b] is less than or equal to x, then we add this interval to the priority queue and move the pointer i one step forward. Repeat this process.
- If the priority queue is not empty, and the right endpoint of the heap top element is less than x, then we pop the heap top element. Repeat this process.
- At this point, if the priority queue is not empty, then the heap top element is the smallest interval containing x. We add its length v to the answer array ans.

After the above process is over, we return the answer array ans.

The time complexity is O(n × log n + m × log m), and the space complexity is O(n + m). Where n and m are the lengths of the arrays `intervals` and `queries` respectively.

Python 3

```python
class Solution:
    def minInterval(self, intervals: List[List[int]], queries: List[int]) -> List[int]:
        n, m = len(intervals), len(queries)
        intervals.sort()
        queries = sorted((x, i) for i, x in enumerate(queries))
        ans = [-1] * m
        pq = []
        i = 0
        for x, j in queries:
            while i < n and intervals[i][0] <= x:
                a, b = intervals[i]
                heappush(pq, (b - a + 1, b))
                i += 1
            while pq and pq[0][1] < x:
                heappop(pq)
            if pq:
                ans[j] = pq[0][0]
        return ans
```

    return answer
```

715. Range Module

Hard · Design, Segment Tree, Ordered Set

leetcode.com/problems/range-module

★ **TOP 10 PROBLEM** in Segment Tree: master this one first

Also appears in pattern 40 Segment Tree

PROBLEM

A Range Module is a module that tracks ranges of numbers. Design a data structure to track the ranges represented as **half-open intervals** and query about them.

A **half-open interval** `[left, right)` denotes all the real numbers `x` where `left <= x < right`.

Implement the `RangeModule` class:

- `RangeModule()` Initializes the object of the data structure.
- `void addRange(int left, int right)` Adds the **half-open interval** `[left, right)`, tracking every real number in that interval. Adding an interval that partially overlaps with currently tracked numbers should add any numbers in the interval `[left, right)` that are not already tracked.
- `boolean queryRange(int left, int right)` Returns `true` if every real number in the interval `[left, right)` is currently being tracked, and `false` otherwise.
- `void removeRange(int left, int right)` Stops tracking every real number currently being tracked in the **half-open interval** `[left, right)`.

Example 1:

```
Input
["RangeModule", "addRange", "removeRange", "queryRange", "queryRange", "queryRange"]
[[], [10, 20], [14, 16], [10, 14], [13, 15], [16, 17]]
Output
[null, null, null, true, false, true]

Explanation
RangeModule rangeModule = new RangeModule();
rangeModule.addRange(10, 20);
rangeModule.removeRange(14, 16);
rangeModule.queryRange(10, 14); // return True,(Every number in [10, 14) is being tracked)
rangeModule.queryRange(13, 15); // return False,(Numbers like 14, 14.03, 14.17 in [13, 15) are not
being tracked)
rangeModule.queryRange(16, 17); // return True, (The number 16 in [16, 17) is still being tracked,
despite the remove operation)
```

Constraints:

- $1 <= left < right <= 10^9$
- At most 10^4 calls will be made to `addRange`, `queryRange`, and `removeRange`.

SOLUTION (PYTHON 3)

Solution 1: Segment Tree

How to think about it

Maintain add, remove, and covered-query on half-open ranges with endpoints up to 10^9 and about 10^4 operations. Merging an explicit interval list can scan many fragments per update. These are range assign / range query operations. A segment tree handles them in logarithmic time; the universe is too large to allocate fully, so we create nodes on demand and push lazy assign marks. Each node stores whether its segment is fully covered. A fully contained update writes the mark; a query returns v on a covered node, otherwise pushes down and ands the two children. Each call is O(log n).

According to the problem description, we need to maintain a set of intervals, supporting operations of interval addition, deletion, and query. For the addition and deletion of intervals, we can use a segment tree to maintain the set of intervals.

The segment tree divides the entire interval into multiple non-continuous sub-intervals, the number of which does not exceed log(width). To update the value of an element, only log(width) intervals need to be updated, and these intervals are all included in a large interval containing the element. When modifying the interval, we need to use **lazy propagation** to ensure efficiency.

- Each node of the segment tree represents an interval;
- The segment tree has a unique root node, representing the entire statistical range, such as [1,N];
- Each leaf node of the segment tree represents an elementary interval of length 1, [x,x];
- For each internal node [l,r], its left child is [l,mid], and the right child is [mid+1,r], where mid=$\lfloor (l+r)/2 \rfloor$ (rounded down).

Due to the large data range of the problem, we can implement it with a dynamically allocated segment tree. A dynamically allocated segment tree means that we only allocate nodes when needed, instead of allocating all nodes at the beginning. This can save space, but it requires **lazy propagation** to maintain interval modification.

In terms of time complexity, the time complexity of each operation is O(log n). The space complexity is O(m × log n). Here, m is the number of operations, and n is the data range.

Python 3

```
class Node:
    __slots__ = ['left', 'right', 'add', 'v']

    def __init__(self):
        self.left = None
        self.right = None
        self.add = 0
        self.v = False

1326. Minimum Number of Taps to Open to Water a Garden

Hard · Greedy, Array, Dynamic Programming

leetcode.com/problems/minimum-number-of-taps-to-open-to-water-a-garden

Also appears in pattern 21 Greedy

PROBLEM

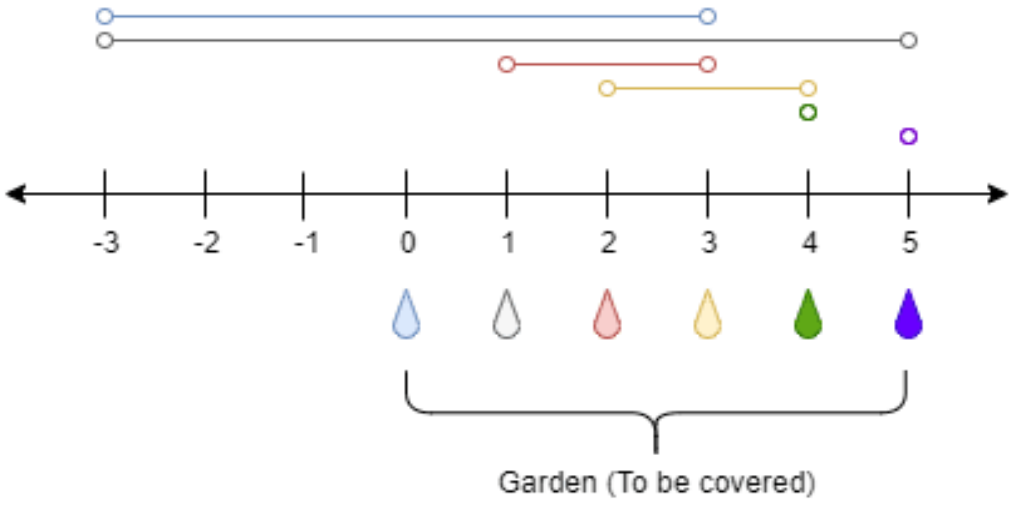
There is a one-dimensional garden on the x-axis. The garden starts at the point `0` and ends at the point `n`. (i.e., the length of the garden is `n`).

There are `n + 1` taps located at points `[0, 1, ..., n]` in the garden.

Given an integer `n` and an integer array `ranges` of length `n + 1` where `ranges[i]` (0-indexed) means the `i-th` tap can water the area `[i - ranges[i], i + ranges[i]]` if it was open.

Return *the minimum number of taps* that should be open to water the whole garden, If the garden cannot be watered return **-1**.

Example 1:



```
Input: n = 5, ranges = [3,4,1,1,0,0]
Output: 1
Explanation: The tap at point 0 can cover the interval [-3,3]
The tap at point 1 can cover the interval [-3,5]
The tap at point 2 can cover the interval [1,3]
The tap at point 3 can cover the interval [2,4]
The tap at point 4 can cover the interval [4,4]
The tap at point 5 can cover the interval [5,5]
Opening Only the second tap will water the whole garden [0,5]
```

Example 2:

```
Input: n = 3, ranges = [0,0,0,0]
Output: -1
Explanation: Even if you activate all the four taps you cannot water the whole garden.
```

Constraints:

- `1 <= n <= 10^4`
- `ranges.length == n + 1`
- `0 <= ranges[i] <= 100`

SOLUTION (PYTHON 3)

Solution 1: Greedy

> **How to think about it**
>
> Each tap covers $[i-r_i, i+r_i]$; we want the fewest taps that cover [0,n]. Subset search is impossible for $n \le 10^4$. Among taps that cover the same left end, the one that reaches farthest right is best, which is the jump-game setting: store in last[l] the farthest right reachable from l. Scanning positions, we keep the current reach mx and the previous segment end pre; hitting pre opens one more tap. If $mx \le i$ at any point, coverage fails.

We note that for all taps that can cover a certain left endpoint, choosing the tap that can cover the farthest right endpoint is optimal.

Therefore, we can preprocess the array ranges. For the i-th tap, it can cover the left endpoint l = max(0, i - ranges[i]) and the right endpoint r = i + ranges[i]. We calculate the position of the tap that can cover the left endpoint l with the farthest right endpoint and record it in the array last[i].

Then we define the following three variables:

- Variable ans represents the final answer, i.e., the minimum number of taps;
- Variable mx represents the farthest right endpoint that can currently be covered;
- Variable pre represents the farthest right endpoint covered by the previous tap.

We traverse all positions in the range [0, …, n-1]. For the current position i, we use last[i] to update mx, i.e., mx = max(mx, last[i]).

- If $mx \le i$, it means the next position cannot be covered, so we return -1.
- If pre = i, it means a new subinterval needs to be used, so we increment ans by 1 and update pre = mx.

After the traversal, we return ans.

The time complexity is O(n), and the space complexity is O(n). Here, n is the length of the garden.

352. Data Stream as Disjoint Intervals

Hard · Union Find, Design, Hash Table, Binary Search, Data Stream, Ordered Set

leetcode.com/problems/data-stream-as-disjoint-intervals

PROBLEM

Given a data stream input of non-negative integers $a_1, a_2, \ldots, a_n$, summarize the numbers seen so far as a list of disjoint intervals.

Implement the `SummaryRanges` class:

- `SummaryRanges()` Initializes the object with an empty stream.
- `void addNum(int value)` Adds the integer `value` to the stream.
- `int[][] getIntervals()` Returns a summary of the integers in the stream currently as a list of disjoint intervals $[start_i, end_i]$. The answer should be sorted by $start_i$.

Example 1:

```
Input
["SummaryRanges", "addNum", "getIntervals", "addNum", "getIntervals", "addNum", "getIntervals",
"addNum", "getIntervals", "addNum", "getIntervals"]
[[], [1], [], [3], [], [7], [], [2], [], [6], []]
Output
[null, null, [[1, 1]], null, [[1, 1], [3, 3]], null, [[1, 1], [3, 3], [7, 7]], null, [[1, 3], [7, 7]],
null, [[1, 3], [6, 7]]]

Explanation
SummaryRanges summaryRanges = new SummaryRanges();
summaryRanges.addNum(1); // arr = [1]
summaryRanges.getIntervals(); // return [[1, 1]]
summaryRanges.addNum(3); // arr = [1, 3]
summaryRanges.getIntervals(); // return [[1, 1], [3, 3]]
summaryRanges.addNum(7); // arr = [1, 3, 7]
summaryRanges.getIntervals(); // return [[1, 1], [3, 3], [7, 7]]
summaryRanges.addNum(2); // arr = [1, 2, 3, 7]
summaryRanges.getIntervals(); // return [[1, 3], [7, 7]]
summaryRanges.addNum(6); // arr = [1, 2, 3, 6, 7]
summaryRanges.getIntervals(); // return [[1, 3], [6, 7]]
```

Constraints:

- $0 <= value <= 10^4$
- At most $3 * 10^4$ calls will be made to `addNum` and `getIntervals`.
- At most 10^2 calls will be made to `getIntervals`.

Follow up: What if there are lots of merges and the number of disjoint intervals is small compared to the size of the data stream?

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Integers from a stream must merge into disjoint intervals. Sorting everything on each insert is heavy. An ordered map keyed by left endpoints lets an insert touch only neighbors. Bisect to the successor and predecessor: fill a two-sided gap by joining three intervals, extend one side if adjacent, otherwise insert a singleton. `getIntervals` lists the sorted values.

Python 3

```python
class SummaryRanges:
    def __init__(self):
        self.mp = SortedDict()

    def addNum(self, val: int) -> None:
        n = len(self.mp)
        ridx = self.mp.bisect_right(val)
        lidx = n if ridx == 0 else ridx - 1
        keys = self.mp.keys()
        values = self.mp.values()
        if (
            lidx != n
            and ridx != n
            and values[lidx][1] + 1 == val
            and values[ridx][0] - 1 == val
        ):
            self.mp[keys[lidx]][1] = self.mp[keys[ridx]][1]
            self.mp.pop(keys[ridx])
        elif lidx != n and val <= values[lidx][1] + 1:
            self.mp[keys[lidx]][1] = max(val, self.mp[keys[lidx]][1])
        elif ridx != n and val >= values[ridx][0] - 1:
            self.mp[keys[ridx]][0] = min(val, self.mp[keys[ridx]][0])
        else:
            self.mp[val] = [val, val]

    def getIntervals(self) -> List[List[int]]:
        return list(self.mp.values())

# # Your SummaryRanges object will be instantiated and called as such:
# # obj = SummaryRanges()
# # obj.addNum(val)
# # param_2 = obj.getIntervals()
```

Complexity. Time: addNum O(log n), getIntervals O(n). Space: O(n).

699. Falling Squares

Hard · Segment Tree, Array, Ordered Set

leetcode.com/problems/falling-squares

★ **TOP 10 PROBLEM** in Segment Tree: master this one first

Also appears in pattern 40 Segment Tree

PROBLEM

There are several squares being dropped onto the X-axis of a 2D plane.

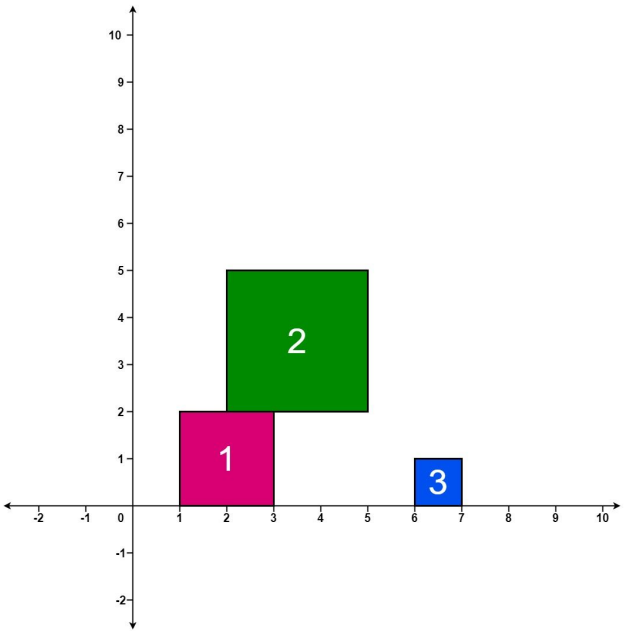
You are given a 2D integer array `positions` where `positions[i] = [left`$_i$`, sideLength`$_i$`]` represents the i^{th} square with a side length of `sideLength`$_i$ that is dropped with its left edge aligned with X-coordinate `left`$_i$.

Each square is dropped one at a time from a height above any landed squares. It then falls downward (negative Y direction) until it either lands **on the top side of another square** or **on the X-axis**. A square brushing the left/right side of another square does not count as landing on it. Once it lands, it freezes in place and cannot be moved.

After each square is dropped, you must record the **height of the current tallest stack of squares**.

Return *an integer array* `ans` *where* `ans[i]` *represents the height described above after dropping the* i^{th} *square*.

Example 1:



```
Input: positions = [[1,2],[2,3],[6,1]]
Output: [2,5,5]
Explanation:
After the first drop, the tallest stack is square 1 with a height of 2.
After the second drop, the tallest stack is squares 1 and 2 with a height of 5.
After the third drop, the tallest stack is still squares 1 and 2 with a height of 5.
Thus, we return an answer of [2, 5, 5].
```

Example 2:

```
Input: positions = [[100,100],[200,100]]
Output: [100,100]
Explanation:
After the first drop, the tallest stack is square 1 with a height of 100.
After the second drop, the tallest stack is either square 1 or square 2, both with heights of 100.
Thus, we return an answer of [100, 100].
Note that square 2 only brushes the right side of square 1, which does not count as landing on it.
```

Constraints:

- `1 <= positions.length <= 1000`
- `1 <= left_i <= 10^8`
- `1 <= sideLength_i <= 10^6`

SOLUTION (PYTHON 3)

Solution 1: Segment Tree

> **How to think about it**
>
> Squares drop onto the current skyline; after each drop we need the global max height. Coordinates reach 10^9, so an array is impossible. A dynamic segment tree stores range maxima: query [l,r] for the landing height, add the side length, and assign that height back with a lazy tag. Track the running maximum.

According to the problem description, we need to maintain a set of intervals that support modification and query operations. In this case, we can use a segment tree to solve the problem.

A segment tree divides the entire interval into multiple non-contiguous sub-intervals, with the number of sub-intervals not exceeding log(width), where width is the length of the interval. To update the value of an element, we only need to update log(width) intervals, and these intervals are all contained within a larger interval that includes the element. When modifying intervals, we need to use **lazy propagation** to ensure efficiency.

- Each node of the segment tree represents an interval;
- The segment tree has a unique root node representing the entire statistical range, such as [1, n];
- Each leaf node of the segment tree represents a primitive interval of length 1, [x, x];
- For each internal node [l, r], its left child is [l, mid], and its right child is [mid + 1, r], where mid = (l + r)/2;

For this problem, the information maintained by the segment tree nodes includes:

1. The maximum height v of the blocks in the interval
2. Lazy propagation marker add

Additionally, since the range of the number line is very large, up to 10^8, we use dynamic node creation.

In terms of time complexity, each query and modification has a time complexity of O(log n), and the total time complexity is O(n log n). The space complexity is O(n).

Python 3

```
class Node:
    def __init__(self, l, r):
        self.left = None
        self.right = None
        self.l = l
        self.r = r
        self.mid = (l + r) >> 1
        self.v = 0
        self.add = 0

class SegmentTree:
    def __init__(self):
        self.root = Node(1, int(1e9))

    def modify(self, l, r, v, node=None):
        if l > r:
            return
        if node is None:

PATTERN 21 · GREEDY · PROBLEM 1 OF 20

860. Lemonade Change

Easy · Greedy, Array

leetcode.com/problems/lemonade-change

★ **TOP 10 PROBLEM** in Greedy: master this one first

PROBLEM

At a lemonade stand, each lemonade costs `$5`. Customers are standing in a queue to buy from you and order one at a time (in the order specified by bills). Each customer will only buy one lemonade and pay with either a `$5`, `$10`, or `$20` bill. You must provide the correct change to each customer so that the net transaction is that the customer pays `$5`.

Note that you do not have any change in hand at first.

Given an integer array `bills` where `bills[i]` is the bill the `i`th customer pays, return `true` *if you can provide every customer with the correct change, or* `false` *otherwise*.

Example 1:

```
Input: bills = [5,5,5,10,20]
Output: true
Explanation:
From the first 3 customers, we collect three $5 bills in order.
From the fourth customer, we collect a $10 bill and give back a $5.
From the fifth customer, we give a $10 bill and a $5 bill.
Since all customers got correct change, we output true.
```

Example 2:

```
Input: bills = [5,5,10,10,20]
Output: false
Explanation:
From the first two customers in order, we collect two $5 bills.
For the next two customers in order, we collect a $10 bill and give back a $5 bill.
For the last customer, we can not give the change of $15 back because we only have two $10 bills.
Since not every customer received the correct change, the answer is false.
```

Constraints:

- `1 <= bills.length <= 10`^{5}
- `bills[i]` is either `5`, `10`, or `20`.

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

Bills are only 5, 10, and 20, and change must come from cash already taken. n≤ 10^5, so greedy: a 20 prefers one 10 plus one 5, otherwise three 5s. Track counts of 5s and 10s; a negative 5 count fails. The full history is unnecessary.

Python 3

```python
class Solution:
    def lemonadeChange(self, bills: List[int]) -> bool:
        five = ten = 0
        for v in bills:
            if v == 5:
                five += 1
            elif v == 10:
                ten += 1
                five -= 1
            else:
                if ten:
                    ten -= 1
                    five -= 1
                else:
                    five -= 3
            if five < 0:
                return False
        return True
```

Complexity. Time: O(n). Space: O(1).

Solution 2: One-liner

> **How to think about it**
>
> Method 1 already covers every change rule. Method 2 folds the same two counters into one every scan, branching on denomination with xor tests. The meaning is unchanged; only the implementation is a one-liner, still failing when the 5 count goes negative.

Python 3 (written for this guide: the doocs page has no Python 3 version of this solution)

```python
class Solution:
    def lemonadeChange(self, bills: List[int]) -> bool:
        five = ten = 0
        for bill in bills:
            if bill == 5:
                five += 1
            elif bill == 10:
                five -= 1
                ten += 1
            elif ten:
                ten -= 1
                five -= 1
            else:
                five -= 3
            if five < 0:
                return False
        return True
```

Complexity. Time: O(n). Space: O(1).

PATTERN 21 · GREEDY · PROBLEM 2 OF 20

1710. Maximum Units on a Truck

Easy · Greedy, Array, Sorting

leetcode.com/problems/maximum-units-on-a-truck

★ **TOP 10 PROBLEM** in Greedy: master this one first

PROBLEM

You are assigned to put some amount of boxes onto **one truck**. You are given a 2D array `boxTypes`, where `boxTypes[i] = [numberOfBoxes`$_i$`, numberOfUnitsPerBox`$_i$`]`:

- `numberOfBoxes`$_i$ is the number of boxes of type `i`.
- `numberOfUnitsPerBox`$_i$ is the number of units in each box of the type `i`.

You are also given an integer `truckSize`, which is the **maximum** number of **boxes** that can be put on the truck. You can choose any boxes to put on the truck as long as the number of boxes does not exceed `truckSize`.

Return *the **maximum** total number of **units** that can be put on the truck.*

Example 1:

```
Input: boxTypes = [[1,3],[2,2],[3,1]], truckSize = 4
Output: 8
Explanation: There are:
- 1 box of the first type that contains 3 units.
- 2 boxes of the second type that contain 2 units each.
- 3 boxes of the third type that contain 1 unit each.
You can take all the boxes of the first and second types, and one box of the third type.
The total number of units will be = (1 * 3) + (2 * 2) + (1 * 1) = 8.
```

Example 2:

```
Input: boxTypes = [[5,10],[2,5],[4,7],[3,9]], truckSize = 10
Output: 91
```

Constraints:

- `1 <= boxTypes.length <= 1000`
- `1 <= numberOfBoxes`$_i$`, numberOfUnitsPerBox`$_i$` <= 1000`
- `1 <= truckSize <=` 10^6

SOLUTIONS (PYTHON 3)

Solution 1: Greedy + Sorting

How to think about it

Capacity is measured in boxes, but the objective is units. Boxes of one type share the same unit count, so denser types should be taken first. Sort by units per box descending and load min(truckSize,count) of each type, decreasing remaining capacity until it is gone.

According to the problem, we should choose as many units as possible. Therefore, we first sort `boxTypes` in descending order of the number of units.

Then we traverse `boxTypes` from front to back, choose up to `truckSize` boxes, and accumulate the number of units.

The time complexity is O(n × log n), where n is the length of the two-dimensional array `boxTypes`.

Python 3

```python
class Solution:
    def maximumUnits(self, boxTypes: List[List[int]], truckSize: int) -> int:
        ans = 0
        for a, b in sorted(boxTypes, key=lambda x: -x[1]):
            ans += b * min(truckSize, a)
            truckSize -= a
            if truckSize <= 0:
                break
        return ans
```

Solution 2: Counting Sort

> **How to think about it**
>
> Solution 1 spends O(nlog n) on sorting. Units per box are at most 1000, so a counting array can store box counts by that value. Scan from 1000 down to 1 and load in the same greedy order, now in linear time.

We can also use the idea of counting sort, create an array cnt of length 1001, where cnt[b] represents the number of boxes with b units.

Then starting from the box with the maximum number of units, choose up to `truckSize` boxes, and accumulate the number of units.

The time complexity is O(M), where M is the maximum number of units. In this problem, M=1000.

Python 3

```python
class Solution:
    def maximumUnits(self, boxTypes: List[List[int]], truckSize: int) -> int:
        cnt = [0] * 1001
        for a, b in boxTypes:
            cnt[b] += a
        ans = 0
        for b in range(1000, 0, -1):
            a = cnt[b]
            if a:
                ans += b * min(truckSize, a)
                truckSize -= a
                if truckSize <= 0:
                    break
        return ans
```

PATTERN 21 · GREEDY · PROBLEM 4 OF 20

45. Jump Game II

Medium · Greedy, Array, Dynamic Programming

leetcode.com/problems/jump-game-ii

★ **TOP 10 PROBLEM** in Greedy: master this one first

PROBLEM

You are given a **0-indexed** array of integers `nums` of length `n`. You are initially positioned at index 0.

Each element `nums[i]` represents the maximum length of a forward jump from index `i`. In other words, if you are at index `i`, you can jump to any index `(i + j)` where:

- `0 <= j <= nums[i]` and
- `i + j < n`

Return *the minimum number of jumps to reach index* `n - 1`. The test cases are generated such that you can reach index `n - 1`.

Example 1:

```
Input: nums = [2,3,1,1,4]
Output: 2
Explanation: The minimum number of jumps to reach the last index is 2. Jump 1 step from index 0 to 1, then 3 steps to the last index.
```

Example 2:

```
Input: nums = [2,3,0,1,4]
Output: 2
```

Constraints:

- `1 <= nums.length <= 10^4`
- `0 <= nums[i] <= 1000`
- It's guaranteed that you can reach `nums[n - 1]`.

SOLUTION (PYTHON 3)

Solution 1: Greedy Algorithm

How to think about it

The first idea is DP: f[i] is the fewest jumps to i, and from i we relax i+1..i+nums[i]. Correct, worst-case $O(n^2)$. $n \le 10^4$ may pass, but we only need the end, not a value at every index. The bottleneck is maintaining exact min jumps per position. Jump k covers a contiguous range; the farthest we can see inside it is the right end of jump k+1. Scan once, tracking this jump's boundary and the farthest the next jump can reach. Hitting the boundary forces a jump. That is BFS by layers without a queue.

We can use a variable mx to record the farthest position that can be reached from the current position, a variable last to record the position of the last jump, and a variable ans to record the number of jumps.

Next, we traverse each position i in [0,..n - 2]. For each position i, we can calculate the farthest position that can be reached from the current position through i + nums[i]. We use mx to record this farthest position, that is, mx = max(mx, i + nums[i]). Then, we check whether the current position has reached the boundary of the last jump, that is, i = last. If it has reached, then we need to make a jump, update last to mx, and increase the number of jumps ans by 1.

Finally, we return the number of jumps ans.

The time complexity is O(n), where n is the length of the array. The space complexity is O(1).

```

PATTERN 21 · GREEDY · PROBLEM 5 OF 20

134. Gas Station

Medium · Greedy, Array

leetcode.com/problems/gas-station

★ **TOP 10 PROBLEM** in Greedy: master this one first

PROBLEM

There are `n` gas stations along a circular route, where the amount of gas at the i^{th} station is `gas[i]`.

You have a car with an unlimited gas tank and it costs `cost[i]` of gas to travel from the i^{th} station to its next `(i + 1)`th station. You begin the journey with an empty tank at one of the gas stations.

Given two integer arrays `gas` and `cost`, return *the starting gas station's index if you can travel around the circuit once in the clockwise direction, otherwise return* `-1`. If there exists a solution, it is **guaranteed** to be **unique**.

Example 1:

```
Input: gas = [1,2,3,4,5], cost = [3,4,5,1,2]
Output: 3
Explanation:
Start at station 3 (index 3) and fill up with 4 unit of gas. Your tank = 0 + 4 = 4
Travel to station 4. Your tank = 4 - 1 + 5 = 8
Travel to station 0. Your tank = 8 - 2 + 1 = 7
Travel to station 1. Your tank = 7 - 3 + 2 = 6
Travel to station 2. Your tank = 6 - 4 + 3 = 5
Travel to station 3. The cost is 5. Your gas is just enough to travel back to station 3.
Therefore, return 3 as the starting index.
```

Example 2:

```
Input: gas = [2,3,4], cost = [3,4,3]
Output: -1
Explanation:
You can't start at station 0 or 1, as there is not enough gas to travel to the next station.
Let's start at station 2 and fill up with 4 unit of gas. Your tank = 0 + 4 = 4
Travel to station 0. Your tank = 4 - 3 + 2 = 3
Travel to station 1. Your tank = 3 - 3 + 3 = 3
You cannot travel back to station 2, as it requires 4 unit of gas but you only have 3.
Therefore, you can't travel around the circuit once no matter where you start.
```

Constraints:

- `n == gas.length == cost.length`
- `1 <= n <=` 10^5
- `0 <= gas[i], cost[i] <=` 10^4
- The input is generated such that the answer is unique.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

We need a starting station that completes the loop, if any. n≤ 10^5, so simulating from every start is O(n^2). If total gas is less than total cost there is no answer. A negative tank means the start must move earlier to cover that deficit. The code grows the end forward and the start backward from the last station, shifting i left whenever the tank drops below zero. Each station is used once; a non-negative tank at the end is the start.

Python 3

```python
class Solution:
    def canCompleteCircuit(self, gas: List[int], cost: List[int]) -> int:
        n = len(gas)
        i = j = n - 1
        cnt = s = 0
        while cnt < n:
            s += gas[j] - cost[j]
            cnt += 1
            j = (j + 1) % n
            while s < 0 and cnt < n:
                i -= 1
                s += gas[i] - cost[i]
                cnt += 1
        return -1 if s < 0 else i
```

    return -lowest
```

PATTERN 21 · GREEDY · PROBLEM 10 OF 20

122. Best Time to Buy and Sell Stock II

Medium · Greedy, Array, Dynamic Programming

leetcode.com/problems/best-time-to-buy-and-sell-stock-ii

★ **TOP 10 PROBLEM** in Greedy: master this one first

PROBLEM

You are given an integer array `prices` where `prices[i]` is the price of a given stock on the i^{th} day.

On each day, you may decide to buy and/or sell the stock. You can only hold **at most one** share of the stock at any time. However, you can sell and buy the stock multiple times on the **same day**, ensuring you never hold more than one share of the stock.

Find and return *the **maximum** profit you can achieve*.

Example 1:

```
Input: prices = [7,1,5,3,6,4]
Output: 7
Explanation: Buy on day 2 (price = 1) and sell on day 3 (price = 5), profit = 5-1 = 4.
Then buy on day 4 (price = 3) and sell on day 5 (price = 6), profit = 6-3 = 3.
Total profit is 4 + 3 = 7.
```

Example 2:

```
Input: prices = [1,2,3,4,5]
Output: 4
Explanation: Buy on day 1 (price = 1) and sell on day 5 (price = 5), profit = 5-1 = 4.
Total profit is 4.
```

Example 3:

```
Input: prices = [7,6,4,3,1]
Output: 0
Explanation: There is no way to make a positive profit, so we never buy the stock to achieve the
maximum profit of 0.
```

Constraints:

- `1 <= prices.length <= 3 * 10^4`
- `0 <= prices[i] <= 10^4`

SOLUTIONS (PYTHON 3)

Solution 1: Greedy Algorithm

How to think about it

We may trade as often as we like, but cannot hold two shares. Summing every adjacent uptick equals buying each valley and selling the next peak. n ≤ 3× 10^4. Walk consecutive days and add positive differences only.

Starting from the second day, if the stock price is higher than the previous day, buy on the previous day and sell on the current day to make a profit. If the stock price is lower than the previous day, do not buy or sell. In other words, buy and sell on all rising trading days, and do not trade on all falling trading days. The final profit will be the maximum.

The time complexity is O(n), where n is the length of the `prices` array. The space complexity is O(1).

Python 3

```
class Solution:
    def maxProfit(self, prices: List[int]) -> int:
        return sum(max(0, b - a) for a, b in pairwise(prices))
```

Solution 2: Dynamic Programming

> **How to think about it**
>
> The greedy form has no explicit state, so it does not extend cleanly to limited transactions or a cooldown. f[i][0/1] is the best profit on day i holding or not; transitions are keep, buy today, stay flat, or sell today. Same answer as Solution 1, more general state.

We define f[i][j] as the maximum profit after trading on the ith day, where j indicates whether we currently hold the stock. When holding the stock, j=0, and when not holding the stock, j=1. The initial state is f[0][0]=-prices[0], and all other states are 0.

If we currently hold the stock, it may be that we held the stock the day before and do nothing today, i.e., f[i][0]=f[i-1][0]. Or it may be that we did not hold the stock the day before and bought the stock today, i.e., f[i][0]=f[i-1][1]-prices[i].

If we currently do not hold the stock, it may be that we did not hold the stock the day before and do nothing today, i.e., f[i][1]=f[i-1][1]. Or it may be that we held the stock the day before and sold the stock today, i.e., f[i][1]=f[i-1][0]+prices[i].

Therefore, we can write the state transition equation as:

$$\text{cases } f[i][0]=\max(f[i-1][0],f[i-1][1]-prices[i])\backslash\ f[i][1]=\max(f[i-1][1],f[i-1][0]+prices[i]) \text{ cases}$$

The final answer is f[n-1][1], where n is the length of the `prices` array.

The time complexity is O(n), and the space complexity is O(n). Here, n is the length of the `prices` array.

Python 3

```
class Solution:
    def maxProfit(self, prices: List[int]) -> int:
        n = len(prices)
        f = [[0] * 2 for _ in range(n)]
        f[0][0] = -prices[0]
        for i in range(1, n):
            f[i][0] = max(f[i - 1][0], f[i - 1][1] - prices[i])
            f[i][1] = max(f[i - 1][1], f[i - 1][0] + prices[i])
        return f[n - 1][1]
```

Solution 3: Dynamic Programming (Space Optimization)

> **How to think about it**
>
> Day i in Solution 2 depends only on day i-1's two states, so two rolling variables cut space to O(1).

We can find that in Solution 2, the state of the ith day is only related to the state of the i-1th day. Therefore, we can use only two variables to maintain the state of the i-1th day, thereby optimizing the space complexity to O(1).

The time complexity is O(n), where n is the length of the `prices` array. The space complexity is O(1).

Python 3

```
class Solution:
    def maxProfit(self, prices: List[int]) -> int:
        n = len(prices)
        f = [-prices[0], 0]
        for i in range(1, n):
            g = [0] * 2
            g[0] = max(f[0], f[1] - prices[i])
            g[1] = max(f[1], f[0] + prices[i])
            f = g
        return f[1]
```

PATTERN 21 · GREEDY · PROBLEM 11 OF 20

1029. Two City Scheduling

Medium · Greedy, Array, Hungarian Algorithm, Sorting, SSP

leetcode.com/problems/two-city-scheduling

PROBLEM

A company is planning to interview `2n` people. Given the array `costs` where `costs[i] = [aCost`$_i$`, bCost`$_i$`]`, the cost of flying the `i`th person to city `a` is `aCost`$_i$, and the cost of flying the `i`th person to city `b` is `bCost`$_i$.

Return *the minimum cost to fly every person to a city* such that exactly `n` people arrive in each city.

Example 1:

```
Input: costs = [[10,20],[30,200],[400,50],[30,20]]
Output: 110
Explanation:
The first person goes to city A for a cost of 10.
The second person goes to city A for a cost of 30.
The third person goes to city B for a cost of 50.
The fourth person goes to city B for a cost of 20.

The total minimum cost is 10 + 30 + 50 + 20 = 110 to have half the people interviewing in each city.
```

Example 2:

```
Input: costs = [[259,770],[448,54],[926,667],[184,139],[840,118],[577,469]]
Output: 1859
```

Example 3:

```
Input: costs = [[515,563],[451,713],[537,709],[343,819],[855,779],[457,60],[650,359],[631,42]]
Output: 3086
```

Constraints:

- `2 * n == costs.length`
- `2 <= costs.length <= 100`
- `costs.length` is even.
- `1 <= aCost`$_i$`, bCost`$_i$` <= 1000`

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Choosing which n of 2n people fly to A is exponential if done by subsets. Sending everyone to B and then switching n people to A changes the cost by aCost-bCost. The people with the smallest (most negative) differences save the most when switched. Sorting by aCost-bCost and sending the first half to A and the rest to B is optimal. The answer is the corresponding half-and-half sum.

Python 3

```python
class Solution:
    def twoCitySchedCost(self, costs: List[List[int]]) -> int:
        costs.sort(key=lambda x: x[0] - x[1])
        n = len(costs) >> 1
        return sum(costs[i][0] + costs[i + n][1] for i in range(n))
```

Complexity. Time: O(n log n). Space: O(log n) for the sort.

```

PATTERN 21 · GREEDY · PROBLEM 16 OF 20

406. Queue Reconstruction by Height

Medium · Binary Indexed Tree, Segment Tree, Array, Sorting

leetcode.com/problems/queue-reconstruction-by-height

★ **TOP 10 PROBLEM** in Greedy, Sorting: master this one first

Also appears in pattern 23 Sorting, 41 Binary Indexed Tree (Fenwick Tree)

PROBLEM

You are given an array of people, `people`, which are the attributes of some people in a queue (not necessarily in order). Each `people[i] = [h_i, k_i]` represents the i^{th} person of height h_i with **exactly** k_i other people in front who have a height greater than or equal to h_i.

Reconstruct and return *the queue that is represented by the input array* `people`. The returned queue should be formatted as an array `queue`, where `queue[j] = [h_j, k_j]` is the attributes of the j^{th} person in the queue (`queue[0]` is the person at the front of the queue).

Example 1:

```
Input: people = [[7,0],[4,4],[7,1],[5,0],[6,1],[5,2]]
Output: [[5,0],[7,0],[5,2],[6,1],[4,4],[7,1]]
Explanation:
Person 0 has height 5 with no other people taller or the same height in front.
Person 1 has height 7 with no other people taller or the same height in front.
Person 2 has height 5 with two persons taller or the same height in front, which is person 0 and 1.
Person 3 has height 6 with one person taller or the same height in front, which is person 1.
Person 4 has height 4 with four people taller or the same height in front, which are people 0, 1, 2, and 3.
Person 5 has height 7 with one person taller or the same height in front, which is person 1.
Hence [[5,0],[7,0],[5,2],[6,1],[4,4],[7,1]] is the reconstructed queue.
```

Example 2:

```
Input: people = [[6,0],[5,0],[4,0],[3,2],[2,2],[1,4]]
Output: [[4,0],[5,0],[2,2],[3,2],[1,4],[6,0]]
```

Constraints:

- `1 <= people.length <= 2000`
- $0 \le h_i \le 10^6$
- $0 \le k_i <$ `people.length`
- It is guaranteed that the queue can be reconstructed.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Each person [h,k] must have exactly k people of height at least h in front. Inserting shorter people first lets later taller people change those k counts. Sort by height descending, then k ascending, and insert each person at index k. Everyone already in the queue is taller or equal, so that index is exactly the required count, and earlier people are unaffected. Taller people occupy their slots first; a shorter insertion is invisible to them.

Python 3

```
class Solution:
    def reconstructQueue(self, people: List[List[int]]) -> List[List[int]]:
        people.sort(key=lambda x: (-x[0], x[1]))
        ans = []
        for p in people:
            ans.insert(p[1], p)
        return ans
```

Complexity. Time: O(n^2) (each insert into a list is O(n)). Space: O(n).

                    break
                free += 1
    return slots
```

PATTERN 21 · GREEDY · PROBLEM 18 OF 20

135. Candy

Hard · Greedy, Array

leetcode.com/problems/candy

★ **TOP 10 PROBLEM** in Greedy: master this one first

PROBLEM

There are `n` children standing in a line.

Each child is assigned a rating value given in the integer array `ratings`.

You are giving candies to these children subjected to the following requirements:

- Each child must have **at least** one candy.
- Children with a **higher** rating get more candies than their neighbors.

Return the **minimum** number of candies you need to have to distribute the candies to the children.

Example 1:

```
Input: ratings = [1,0,2]
Output: 5
Explanation: You can allocate to the first, second and third child with 2, 1, 2 candies respectively.
```

Example 2:

```
Input: ratings = [1,2,2]
Output: 4
Explanation: You can allocate to the first, second and third child with 1, 2, 1 candies respectively.
The third child gets 1 candy because it satisfies the above two conditions.
```

Constraints:

- `1 <= n == ratings.length <= 5 * 10^4`
- `0 <= ratings[i] <= 5 * 10^4`

SOLUTION (PYTHON 3)

Solution 1: Two traversals

How to think about it

A higher-rated child must get more candy than a neighbor; minimize the total. n≤ 5× 10^4. Sorting by rating can work but equal ratings are fiddly. The left and right constraints are independent: a left-to-right pass enforces “more than the left neighbor”, a right-to-left pass enforces the right, and each child takes the max. Both increasing chains survive.

We initialize two arrays left and right, where left[i] represents the minimum number of candies the current child should get when the current child's score is higher than the left child's score, and right[i] represents the minimum number of candies the current child should get when the current child's score is higher than the right child's score. Initially, left[i]=1, right[i]=1.

We traverse the array from left to right once, and if the current child's score is higher than the left child's score, then left[i]=left[i-1]+1; similarly, we traverse the array from right to left once, and if the current child's score is higher than the right child's score, then right[i]=right[i+1]+1.

Finally, we traverse the array of scores once, and the minimum number of candies each child should get is the maximum of left[i] and right[i], and we add them up to get the answer.

Time complexity O(n), space complexity O(n). Where n is the length of the array of scores.

Python 3

```
class Solution:
    def candy(self, ratings: List[int]) -> int:
        n = len(ratings)
        left = [1] * n
        right = [1] * n
        for i in range(1, n):
            if ratings[i] > ratings[i - 1]:
                left[i] = left[i - 1] + 1
        for i in range(n - 2, -1, -1):
            if ratings[i] > ratings[i + 1]:
                right[i] = right[i + 1] + 1
        return sum(max(a, b) for a, b in zip(left, right))
```

    return total
```

PATTERN 21 · GREEDY · PROBLEM 20 OF 20

630. Course Schedule III

Hard · Greedy, Array, Sorting, Heap (Priority Queue)

leetcode.com/problems/course-schedule-iii

PROBLEM

There are `n` different online courses numbered from `1` to `n`. You are given an array `courses` where `courses[i] = [duration_i, lastDay_i]` indicate that the i^{th} course should be taken **continuously** for `duration_i` days and must be finished before or on `lastDay_i`.

You will start on the 1^{st} day and you cannot take two or more courses simultaneously.

Return *the maximum number of courses that you can take*.

Example 1:

```
Input: courses = [[100,200],[200,1300],[1000,1250],[2000,3200]]
Output: 3
Explanation:
There are totally 4 courses, but you can take 3 courses at most:
First, take the 1st course, it costs 100 days so you will finish it on the 100th day, and ready to take the next course on the 101st day.
Second, take the 3rd course, it costs 1000 days so you will finish it on the 1100th day, and ready to take the next course on the 1101st day.
Third, take the 2nd course, it costs 200 days so you will finish it on the 1300th day.
The 4th course cannot be taken now, since you will finish it on the 3300th day, which exceeds the closed date.
```

Example 2:

```
Input: courses = [[1,2]]
Output: 1
```

Example 3:

```
Input: courses = [[3,2],[4,3]]
Output: 0
```

Constraints:

- `1 <= courses.length <= 10^4`
- `1 <= duration_i, lastDay_i <= 10^4`

SOLUTION (PYTHON 3)

Solution 1: Greedy + Priority Queue (Max-Heap)

> **How to think about it**
>
> Each course has a duration and a deadline; searching subsets is impossible for n≤ 10^4. Sort by deadline and take every course. If the running time exceeds the deadline, drop the longest taken course (max-heap) to free room for later tighter ones. The heap size is the answer.

We can sort the courses in ascending order by their end time, and each time select the course with the earliest deadline to take.

If the total time s of the selected courses exceeds the end time last of the current course, we remove the course with the longest duration from the previously selected courses, until the constraint of the current course's end time is satisfied. Here we use a priority queue (max-heap) pq to maintain the durations of the currently selected courses, and each time we pop the course with the longest duration from the priority queue to remove it.

Finally, the number of elements in the priority queue is the maximum number of courses we can take.

The time complexity is O(n × log n) and the space complexity is O(n), where n is the number of courses.

Python 3

```
class Solution:
    def scheduleCourse(self, courses: List[List[int]]) -> int:
        courses.sort(key=lambda x: x[1])
        pq = []
        s = 0
        for duration, last in courses:
            heappush(pq, -duration)
            s += duration
            while s > last:
                s += heappop(pq)
        return len(pq)
```

THE IDEA

A table where each cell is built from its neighbours above and to the left (or from two indexes). Often the table can shrink to one row.

Signals: unique paths, minimum path sum, edit distance, longest common subsequence, maximal square, interleaving strings.

A TEMPLATE TO KEEP IN YOUR HANDS (PYTHON)

```
dp = [[0] * (m + 1) for _ in range(n + 1)]
for i in range(1, n + 1):
    for j in range(1, m + 1):
        if a[i - 1] == b[j - 1]:
            dp[i][j] = dp[i - 1][j - 1] + 1
        else:
            dp[i][j] = max(dp[i - 1][j], dp[i][j - 1])
```

PATTERN 22 · DYNAMIC PROGRAMMING - 2D / GRID · PROBLEM 1 OF 20

62. Unique Paths

Medium · Math, Dynamic Programming, Combinatorics

leetcode.com/problems/unique-paths

★ **TOP 10 PROBLEM** in Dynamic Programming - 2D / Grid: master this one first

PROBLEM

There is a robot on an `m x n` grid. The robot is initially located at the **top-left corner** (i.e., `grid[0][0]`). The robot tries to move to the **bottom-right corner** (i.e., `grid[m - 1][n - 1]`). The robot can only move either down or right at any point in time.

Given the two integers `m` and `n`, return *the number of possible unique paths that the robot can take to reach the bottom-right corner*.

The test cases are generated so that the answer will be less than or equal to `2 * 10^9`.

Example 1:

```
Input: m = 3, n = 7
Output: 28
```

Example 2:

```
Input: m = 3, n = 2
Output: 3
Explanation: From the top-left corner, there are a total of 3 ways to reach the bottom-right corner:
1. Right -> Down -> Down
2. Down -> Down -> Right
3. Down -> Right -> Down
```

Constraints:

- `1 <= m, n <= 100`

SOLUTIONS (PYTHON 3)

Solution 1: Dynamic Programming

How to think about it

The first idea is to search: only right or down, enumerate every path. With m, n ≤ 100, the path count is combinatorial, so a raw search explodes. The bottleneck is revisiting the same cell. Paths into (i, j) come only from above or the left and do not overlap, so the subproblems add. Store that count in f[i][j] and fill in row-major order so the dependencies already exist. Start at 1; the bottom-right cell is the answer.

We define f[i][j] to represent the number of paths from the top left corner to (i, j), initially f[0][0] = 1, and the answer is f[m - 1][n - 1].

Consider f[i][j]:

- If i > 0, then f[i][j] can be reached by taking one step from f[i - 1][j], so f[i][j] = f[i][j] + f[i - 1][j];
- If j > 0, then f[i][j] can be reached by taking one step from f[i][j - 1], so f[i][j] = f[i][j] + f[i][j - 1].

Therefore, we have the following state transition equation:

$$f[i][j] = \begin{cases} 1 & i = 0, j = 0 \\ f[i - 1][j] + f[i][j - 1] & \text{otherwise} \end{cases}$$

The final answer is f[m - 1][n - 1].

The time complexity is O(m × n), and the space complexity is O(m × n). Here, m and n are the number of rows and columns of the grid, respectively.

Python 3

```python
class Solution:
    def uniquePaths(self, m: int, n: int) -> int:
        f = [[0] * n for _ in range(m)]
        f[0][0] = 1
        for i in range(m):
            for j in range(n):
                if i:
                    f[i][j] += f[i - 1][j]
                if j:
                    f[i][j] += f[i][j - 1]
        return f[-1][-1]
```

Solution 2: Dynamic Programming (Prefilled Borders)

> **How to think about it**
>
> Solution 1 tests “has an above / has a left” on every cell, so the border keeps taking extra branches. The first row can arrive only from the left, the first column only from above, and both are all 1. Prefill those borders and the interior adds unconditionally. Same complexity, cleaner code.

Fill the first row and first column with 1, then only compute interior cells f[i][j] = f[i-1][j] + f[i][j-1]. Time and space stay O(m × n).

Python 3

```python
class Solution:
    def uniquePaths(self, m: int, n: int) -> int:
        f = [[1] * n for _ in range(m)]
        for i in range(1, m):
            for j in range(1, n):
                f[i][j] = f[i - 1][j] + f[i][j - 1]
        return f[-1][-1]
```

Solution 3: Dynamic Programming (Rolling Array)

> **How to think about it**
>
> The first two solutions keep a full m × n table. f[i][j] only needs the previous row f[i-1][j] and the left cell f[i][j-1], so the first dimension can go. After compressing to 1D, f[j] is still the previous row until we update it; add f[j-1] to get the current row. Space drops to O(n), time stays the same.

f[i][j] depends only on the previous row and the left cell, so a 1D array of length n is enough. The time complexity is O(m × n) and the space complexity is O(n).

Python 3

```
class Solution:
    def uniquePaths(self, m: int, n: int) -> int:
        f = [1] * n
        for _ in range(1, m):
            for j in range(1, n):
                f[j] += f[j - 1]
        return f[-1]
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

    return paths(row + 1, col + 1) * paths(m - row, n - col)
```

PATTERN 22 · DYNAMIC PROGRAMMING - 2D / GRID · PROBLEM 2 OF 20

63. Unique Paths II

Medium · Array, Dynamic Programming, Matrix

leetcode.com/problems/unique-paths-ii

PROBLEM

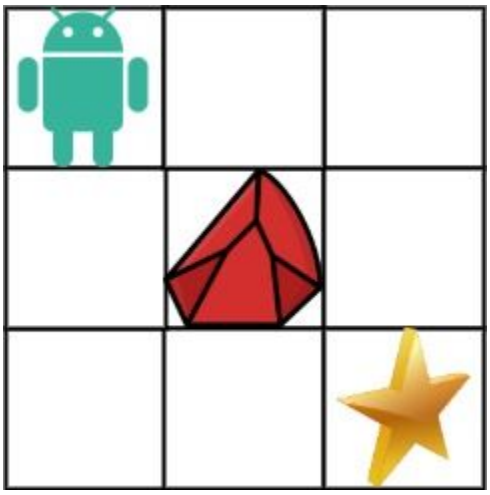
You are given an `m x n` integer array `grid`. There is a robot initially located at the **top-left corner** (i.e., `grid[0][0]`). The robot tries to move to the **bottom-right corner** (i.e., `grid[m - 1][n - 1]`). The robot can only move either down or right at any point in time.

An obstacle and space are marked as `1` or `0` respectively in `grid`. A path that the robot takes cannot include **any** square that is an obstacle.

Return *the number of possible unique paths that the robot can take to reach the bottom-right corner*.

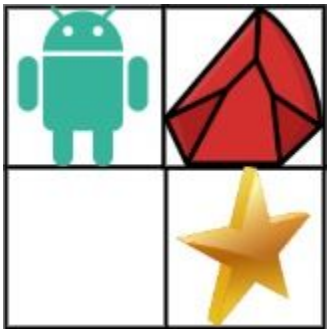
The testcases are generated so that the answer will be less than or equal to $2 * 10^9$.

Example 1:



```
Input: obstacleGrid = [[0,0,0],[0,1,0],[0,0,0]]
Output: 2
Explanation: There is one obstacle in the middle of the 3x3 grid above.
There are two ways to reach the bottom-right corner:
1. Right -> Right -> Down -> Down
2. Down -> Down -> Right -> Right
```

Example 2:



```
Input: obstacleGrid = [[0,1],[0,0]]
Output: 1
```

Constraints:

- `m == obstacleGrid.length`
- `n == obstacleGrid[i].length`
- `1 <= m, n <= 100`
- `obstacleGrid[i][j]` is `0` or `1`.

SOLUTIONS (PYTHON 3)

Solution 1: Memoization Search

> **How to think about it**
>
> As in Unique Paths, a raw search that only moves down or right explodes: m, n ≤ 100. Obstacles also break the "first row and column are all 1" shortcut. The bottleneck is expanding the same cell (i, j) many times. From here, out-of-bounds or an obstacle is 0, the destination is 1, otherwise the two branches add. Memoize dfs(i, j) so each cell is computed once; time and space are both O(mn).

We design a function dfs(i, j) to represent the number of paths from the grid (i, j) to the grid (m - 1, n - 1). Here, m and n are the number of rows and columns of the grid, respectively.

The execution process of the function dfs(i, j) is as follows:

- If i ≥ m or j ≥ n, or obstacleGrid[i][j] = 1, the number of paths is 0;
- If i = m - 1 and j = n - 1, the number of paths is 1;
- Otherwise, the number of paths is dfs(i + 1, j) + dfs(i, j + 1).

To avoid redundant calculations, we can use memoization.

The time complexity is O(m × n), and the space complexity is O(m × n). Here, m and n are the number of rows and columns of the grid, respectively.

Python 3

```python
class Solution:
    def uniquePathsWithObstacles(self, obstacleGrid: List[List[int]]) -> int:
        @cache
        def dfs(i: int, j: int) -> int:
            if i >= m or j >= n or obstacleGrid[i][j]:
                return 0
            if i == m - 1 and j == n - 1:
                return 1
            return dfs(i + 1, j) + dfs(i, j + 1)

        m, n = len(obstacleGrid), len(obstacleGrid[0])
        return dfs(0, 0)
```

Solution 2: Dynamic Programming

> **How to think about it**
>
> Solution 1 is already O(mn) after memoization, but it is still recursive, with a deeper implicit stack and larger constants. Obstacles cut the first row and column, so those borders are no longer all 1; filling a table bottom-up is more direct. f[i][j] is the number of paths from the start: 0 on an obstacle, otherwise from above and the left. Prefill the first row and column up to the first obstacle, then fill the interior—no recursion.

We can use a dynamic programming approach by defining a 2D array f, where f[i][j] represents the number of paths from the grid (0,0) to the grid (i,j).

We first initialize all values in the first column and the first row of f, then traverse the other rows and columns with two cases:

- If obstacleGrid[i][j] = 1, it means the number of paths is 0, so f[i][j] = 0;
- If obstacleGrid[i][j] = 0, then f[i][j] = f[i - 1][j] + f[i][j - 1].

Finally, return f[m - 1][n - 1].

The time complexity is O(m × n), and the space complexity is O(m × n). Here, m and n are the number of rows and columns of the grid, respectively.

Python 3

```python
class Solution:
    def uniquePathsWithObstacles(self, obstacleGrid: List[List[int]]) -> int:
        m, n = len(obstacleGrid), len(obstacleGrid[0])
        f = [[0] * n for _ in range(m)]
        for i in range(m):
            if obstacleGrid[i][0] == 1:
                break
            f[i][0] = 1
        for j in range(n):
            if obstacleGrid[0][j] == 1:
                break
            f[0][j] = 1
        for i in range(1, m):
            for j in range(1, n):
                if obstacleGrid[i][j] == 0:
                    f[i][j] = f[i - 1][j] + f[i][j - 1]
        return f[-1][-1]
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

Built on the solutions above: helper functions, then the function for each follow-up. No tests and no restating of the question.

```

64. Minimum Path Sum

Medium · Array, Dynamic Programming, Matrix

leetcode.com/problems/minimum-path-sum

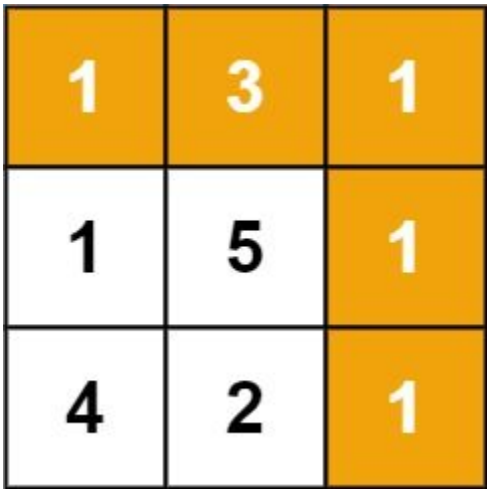
★ **TOP 10 PROBLEM** in Dynamic Programming - 2D / Grid: master this one first

PROBLEM

Given a `m x n grid` filled with non-negative numbers, find a path from top left to bottom right, which minimizes the sum of all numbers along its path.

Note: You can only move either down or right at any point in time.

Example 1:



```
Input: grid = [[1,3,1],[1,5,1],[4,2,1]]
Output: 7
Explanation: Because the path 1 → 3 → 1 → 1 → 1 minimizes the sum.
```

Example 2:

```
Input: grid = [[1,2,3],[4,5,6]]
Output: 12
```

Constraints:

- `m == grid.length`
- `n == grid[i].length`
- `1 <= m, n <= 200`
- `0 <= grid[i][j] <= 200`

SOLUTION (PYTHON 3)

Solution 1: Dynamic Programming

How to think about it

The first idea is to enumerate every path from the top left to the bottom right and take the smallest sum. m, n ≤ 200, so the number of paths is exponential. The bottleneck is recomputing overlapping prefixes. We may only move right or down, so the optimum into (i, j) is the better of the cell above and the cell to the left, plus the current value. Store that minimum in f[i][j]: the borders accumulate along a single edge; the interior takes a min then adds grid[i][j]. Fill by rows; the bottom-right cell is the answer.

We define f[i][j] to represent the minimum path sum from the top left corner to (i, j). Initially, f[0][0] = grid[0][0], and the answer is f[m - 1][n - 1].

Consider f[i][j]:

- If j = 0, then f[i][j] = f[i - 1][j] + grid[i][j];
- If i = 0, then f[i][j] = f[i][j - 1] + grid[i][j];
- If i > 0 and j > 0, then f[i][j] = min(f[i - 1][j], f[i][j - 1]) + grid[i][j].

Finally, return f[m - 1][n - 1].

The time complexity is O(m × n), and the space complexity is O(m × n). Here, m and n are the number of rows and columns of the grid, respectively.

Python 3

```python
class Solution:
    def minPathSum(self, grid: List[List[int]]) -> int:
        m, n = len(grid), len(grid[0])
        f = [[0] * n for _ in range(m)]
        f[0][0] = grid[0][0]
        for i in range(1, m):
            f[i][0] = f[i - 1][0] + grid[i][0]
        for j in range(1, n):
            f[0][j] = f[0][j - 1] + grid[0][j]
        for i in range(1, m):
            for j in range(1, n):
                f[i][j] = min(f[i - 1][j], f[i][j - 1]) + grid[i][j]
        return f[-1][-1]
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

                    best[(nr, nc)] = new_cost
                    heapq.heappush(heap, (new_cost, nr, nc))
    return None
```

1143. Longest Common Subsequence

Medium · String, Dynamic Programming, Longest Common Subsequence

leetcode.com/problems/longest-common-subsequence

★ **TOP 10 PROBLEM** in Dynamic Programming - 2D / Grid: master this one first

PROBLEM

Given two strings `text1` and `text2`, return *the length of their longest* ***common subsequence***. If there is no **common subsequence**, return `0`.

A **subsequence** of a string is a new string generated from the original string with some characters (can be none) deleted without changing the relative order of the remaining characters.

- For example, `"ace"` is a subsequence of `"abcde"`.

A **common subsequence** of two strings is a subsequence that is common to both strings.

Example 1:

```
Input: text1 = "abcde", text2 = "ace"
Output: 3
Explanation: The longest common subsequence is "ace" and its length is 3.
```

Example 2:

```
Input: text1 = "abc", text2 = "abc"
Output: 3
Explanation: The longest common subsequence is "abc" and its length is 3.
```

Example 3:

```
Input: text1 = "abc", text2 = "def"
Output: 0
Explanation: There is no such common subsequence, so the result is 0.
```

Constraints:

- `1 <= text1.length, text2.length <= 1000`
- `text1` and `text2` consist of only lowercase English characters.

SOLUTION (PYTHON 3)

Solution 1: Dynamic Programming

How to think about it

A common subsequence need not be contiguous; enumerating subsequences is too costly. f[i][j] is the LCS of the two prefixes: matching last characters add one to f[i-1][j-1], otherwise take the better of dropping one character. Filling by prefix length uses only shorter prefixes.

We define f[i][j] as the length of the longest common subsequence of the first i characters of text1 and the first j characters of text2. Therefore, the answer is f[m][n], where m and n are the lengths of text1 and text2, respectively.

If the ith character of text1 and the jth character of text2 are the same, then f[i][j] = f[i - 1][j - 1] + 1; if the ith character of text1 and the jth character of text2 are different, then f[i][j] = max(f[i - 1][j], f[i][j - 1]). The state transition equation is:

f[i][j] = cases f[i - 1][j - 1] + 1, & if text1[i - 1] = text2[j - 1] \ max(f[i - 1][j], f[i][j - 1]), & if text1[i - 1] ≠ text2[j - 1] cases

The time complexity is O(m × n), and the space complexity is O(m × n). Here, m and n are the lengths of text1 and text2, respectively.

Python 3

```python
class Solution:
    def longestCommonSubsequence(self, text1: str, text2: str) -> int:
        m, n = len(text1), len(text2)
        f = [[0] * (n + 1) for _ in range(m + 1)]
        for i in range(1, m + 1):
            for j in range(1, n + 1):
                if text1[i - 1] == text2[j - 1]:
                    f[i][j] = f[i - 1][j - 1] + 1
                else:
                    f[i][j] = max(f[i - 1][j], f[i][j - 1])
        return f[m][n]
```

221. Maximal Square

Medium · Array, Dynamic Programming, Matrix

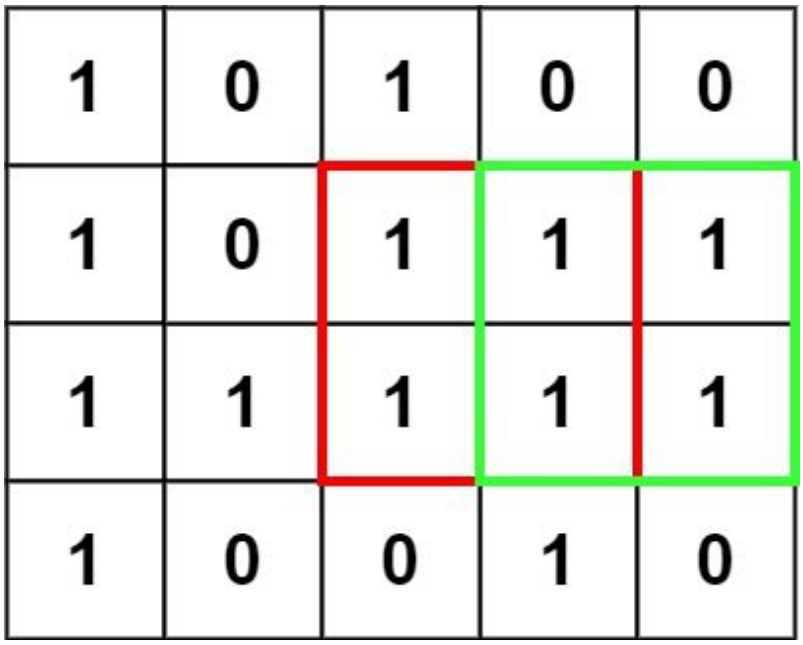
leetcode.com/problems/maximal-square

★ **TOP 10 PROBLEM** in Dynamic Programming - 2D / Grid: master this one first

PROBLEM

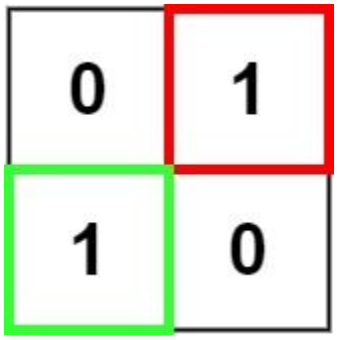
Given an `m x n` binary `matrix` filled with `0`'s and `1`'s, *find the largest square containing only* `1`'s *and return its area*.

Example 1:



```
Input: matrix =
[["1","0","1","0","0"],["1","0","1","1","1"],["1","1","1","1","1"],["1","0","0","1","0"]]
Output: 4
```

Example 2:



```
Input: matrix = [["0","1"],["1","0"]]
Output: 1
```

Example 3:

```
Input: matrix = [["0"]]
Output: 0
```

Constraints:

- `m == matrix.length`
- `n == matrix[i].length`
- `1 <= m, n <= 300`
- `matrix[i][j]` is `'0'` or `'1'`.

SOLUTION (PYTHON 3)

Solution 1: Dynamic Programming

> **How to think about it**
>
> Checking a square above every bottom-right cell revisits many cells. The largest side ending at (i,j) is limited by the three sides ending at its left, upper, and upper-left neighbors. Let dp[i+1][j+1] be that side: 0 on a 0 cell, otherwise one plus the min of those three. The answer is the square of the largest side.

We define dp[i + 1][j + 1] as the maximum square side length with the lower right corner at index (i, j). The answer is the maximum value among all dp[i + 1][j + 1].

The state transition equation is:

$$dp[i + 1][j + 1] = \begin{cases} 0 & \text{if matrix}[i][j] = '0' \\ \min(dp[i][j], dp[i][j + 1], dp[i + 1][j]) + 1 & \text{if matrix}[i][j] = '1' \end{cases}$$

The time complexity is $O(m \times n)$, and the space complexity is $O(m \times n)$. Where m and n are the number of rows and columns of the matrix, respectively.

Python 3

```python
class Solution:
    def maximalSquare(self, matrix: List[List[str]]) -> int:
        m, n = len(matrix), len(matrix[0])
        dp = [[0] * (n + 1) for _ in range(m + 1)]
        mx = 0
        for i in range(m):
            for j in range(n):
                if matrix[i][j] == '1':
                    dp[i + 1][j + 1] = min(dp[i][j + 1], dp[i + 1][j], dp[i][j]) + 1
                    mx = max(mx, dp[i + 1][j + 1])
        return mx * mx
```

    return best * best
```

120. Triangle

Medium · Array, Dynamic Programming

leetcode.com/problems/triangle

★ **TOP 10 PROBLEM** in Dynamic Programming - 2D / Grid: master this one first

PROBLEM

Given a `triangle` array, return *the minimum path sum from top to bottom*.

For each step, you may move to an adjacent number of the row below. More formally, if you are on index `i` on the current row, you may move to either index `i` or index `i + 1` on the next row.

Example 1:

```
Input: triangle = [[2],[3,4],[6,5,7],[4,1,8,3]]
Output: 11
Explanation: The triangle looks like:
   2
  3 4
 6 5 7
4 1 8 3
The minimum path sum from top to bottom is 2 + 3 + 5 + 1 = 11 (underlined above).
```

Example 2:

```
Input: triangle = [[-10]]
Output: -10
```

Constraints:

- `1 <= triangle.length <= 200`
- `triangle[0].length == 1`
- `triangle[i].length == triangle[i - 1].length + 1`
- -10^4 `<= triangle[i][j] <=` 10^4

Follow up:

Could you do this using only

`O(n)`

extra space, where

`n`

is the total number of rows in the triangle?

SOLUTIONS (PYTHON 3)

Solution 1: Dynamic Programming

How to think about it

Each step may only move to an adjacent cell on the next row; enumerating paths grows exponentially with the number of rows. Subproblems overlap: the best path from a cell depends only on the two cells below. Define f[i][j] bottom-up as the min path from that cell to the last row. Each cell takes the min of the two below plus itself; f[0][0] is the answer.

We define f[i][j] as the minimum path sum from the bottom of the triangle to position (i, j). Here, position (i, j) refers to the position in row i and column j of the triangle (both indexed from 0). We have the following state transition equation:

$$f[i][j] = \min(f[i + 1][j], f[i + 1][j + 1]) + triangle[i][j]$$

The answer is f[0][0].

Python 3

```python
class Solution:
    def minimumTotal(self, triangle: List[List[int]]) -> int:
        n = len(triangle)
        f = [[0] * (n + 1) for _ in range(n + 1)]
        for i in range(n - 1, -1, -1):
            for j in range(i + 1):
                f[i][j] = min(f[i + 1][j], f[i + 1][j + 1]) + triangle[i][j]
        return f[0][0]
```

Complexity. Time: O(n^2), n = number of rows. Space: O(n^2).

Solution 2: Dynamic Programming (Space Optimization)

> **How to think about it**
>
> In Solution 1, f[i][j] depends only on the next row. Rolling a one-dimensional array upward cuts space from $O(n^2)$ to O(n), which matches the follow-up.

We notice that the state f[i][j] only depends on states f[i + 1][j] and f[i + 1][j + 1]. Therefore, we can use a one-dimensional array instead of a two-dimensional array, reducing the space complexity from $O(n^2)$ to O(n).

The time complexity is $O(n^2)$, and the space complexity is O(n), where n is the number of rows in the triangle.

Python 3

```python
class Solution:
    def minimumTotal(self, triangle: List[List[int]]) -> int:
        n = len(triangle)
        f = [0] * (n + 1)
        for i in range(n - 1, -1, -1):
            for j in range(i + 1):
                f[j] = min(f[j], f[j + 1]) + triangle[i][j]
        return f[0]
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

            best[c] = triangle[r][c] + bigger
    return best[0]
```

97. Interleaving String

Medium · String, Dynamic Programming

leetcode.com/problems/interleaving-string

★ **TOP 10 PROBLEM** in Dynamic Programming - 2D / Grid: master this one first

PROBLEM

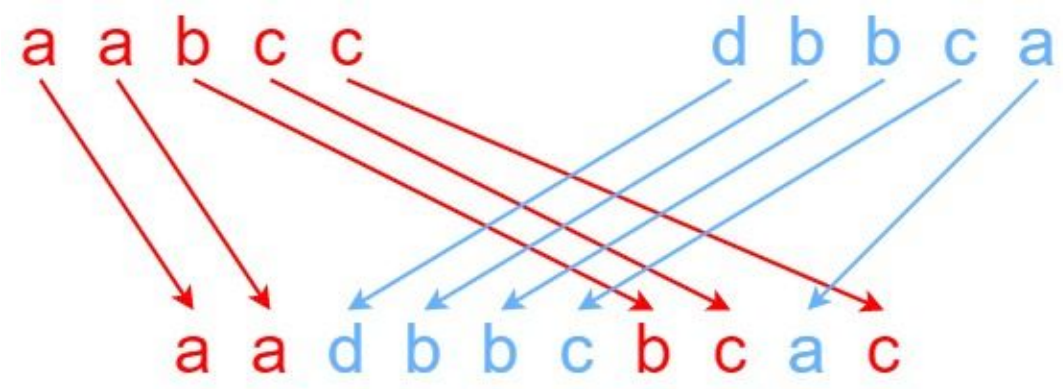
Given strings `s1`, `s2`, and `s3`, find whether `s3` is formed by an **interleaving** of `s1` and `s2`.

An **interleaving** of two strings `s` and `t` is a configuration where `s` and `t` are divided into `n` and `m` substrings respectively, such that:

- $s = s_1 + s_2 + ... + s_n$
- $t = t_1 + t_2 + ... + t_m$
- $|n - m| <= 1$
- The **interleaving** is $s_1 + t_1 + s_2 + t_2 + s_3 + t_3 + ...$ or $t_1 + s_1 + t_2 + s_2 + t_3 + s_3 + ...$

Note: `a + b` is the concatenation of strings `a` and `b`.

Example 1:



```
Input: s1 = "aabcc", s2 = "dbbca", s3 = "aadbbcbcac"
Output: true
Explanation: One way to obtain s3 is:
Split s1 into s1 = "aa" + "bc" + "c", and s2 into s2 = "dbbc" + "a".
Interleaving the two splits, we get "aa" + "dbbc" + "bc" + "a" + "c" = "aadbbcbcac".
Since s3 can be obtained by interleaving s1 and s2, we return true.
```

Example 2:

```
Input: s1 = "aabcc", s2 = "dbbca", s3 = "aadbbbaccc"
Output: false
Explanation: Notice how it is impossible to interleave s2 with any other string to obtain s3.
```

Example 3:

```
Input: s1 = "", s2 = "", s3 = ""
Output: true
```

Constraints:

- `0 <= s1.length, s2.length <= 100`
- `0 <= s3.length <= 200`
- `s1`, `s2`, and `s3` consist of lowercase English letters.

Follow up: Could you solve it using only `O(s2.length)` additional memory space?

SOLUTIONS (PYTHON 3)

Solution 1: Memoization Search

> **How to think about it**
>
> An interleaving keeps the relative order of s_1 and s_2, so lengths must match first. Brute force chooses the next char from s_1 or s_2 at every step and explodes. The state is only "how much of s_1 and s_2 we have used": s_3's index is k=i+j. A choice is legal iff $s_1[i]$ or $s_2[j]$ equals $s_3[k]$. Memoize (i,j) and there are O(mn) subproblems.

Let's denote the length of string s_1 as m and the length of string s_2 as n. If $m + n \neq |s_3|$, then s_3 is definitely not an interleaving string of s_1 and s_2, so we return `false`.

Next, we design a function dfs(i, j), which represents whether the remaining part of s_3 can be interleaved from the ith character of s_1 and the jth character of s_2. The answer is dfs(0, 0).

The calculation process of function dfs(i, j) is as follows:

If $i \geq m$ and $j \geq n$, it means that both s_1 and s_2 have been traversed, so we return `true`.

If $i < m$ and $s_1[i] = s_3[i + j]$, it means that the character $s_1[i]$ is part of $s_3[i + j]$. Therefore, we recursively call dfs(i + 1, j) to check whether the next character of s_1 can match the current character of s_2. If it can match, we return `true`.

Similarly, if $j < n$ and $s_2[j] = s_3[i + j]$, it means that the character $s_2[j]$ is part of $s_3[i + j]$. Therefore, we recursively call dfs(i, j + 1) to check whether the next character of s_2 can match the current character of s_1. If it can match, we return `true`.

Otherwise, we return `false`.

To avoid repeated calculations, we can use memoization search.

The time complexity is $O(m \times n)$, and the space complexity is $O(m \times n)$. Here, m and n are the lengths of strings s_1 and s_2 respectively.

Python 3

```python
class Solution:
    def isInterleave(self, s1: str, s2: str, s3: str) -> bool:
        @cache
        def dfs(i: int, j: int) -> bool:
            if i >= m and j >= n:
                return True
            k = i + j
            if i < m and s1[i] == s3[k] and dfs(i + 1, j):
                return True
            if j < n and s2[j] == s3[k] and dfs(i, j + 1):
                return True
            return False

        m, n = len(s1), len(s2)
        if m + n != len(s3):
            return False
        return dfs(0, 0)
```

Solution 2: Dynamic Programming

> **How to think about it**
>
> Solution 1 already has the transition. Bottom-up: f[i][j] means the first i chars of s_1 and first j of s_2 can form the first i+j of s_3. Empty-empty is true; fill by increasing i,j and drop the recursion stack.

We can convert the memoization search in Solution 1 into dynamic programming.

We define f[i][j] to represent whether the first i characters of string s_1 and the first j characters of string s_2 can interleave to form the first i + j characters of string s_3. When transitioning states, we can consider whether the current character is obtained from the last character of s_1 or the last character of s_2. Therefore, we have the state transition equation:

$$f[i][j] = \text{cases } f[i - 1][j] \ \& \text{ if } s_1[i - 1] = s_3[i + j - 1] \ \backslash \text{ or } f[i][j - 1] \ \& \text{ if } s_2[j - 1] = s_3[i + j - 1] \ \backslash \text{ false } \& \text{ otherwise cases}$$

where f[0][0] = true indicates that an empty string is an interleaving string of two empty strings.

The answer is f[m][n].

The time complexity is O(m × n), and the space complexity is O(m × n). Here, m and n are the lengths of strings s_1 and s_2 respectively.

Python 3

```python
class Solution:
    def isInterleave(self, s1: str, s2: str, s3: str) -> bool:
        m, n = len(s1), len(s2)
        if m + n != len(s3):
            return False
        f = [[False] * (n + 1) for _ in range(m + 1)]
        f[0][0] = True
        for i in range(m + 1):
            for j in range(n + 1):
                k = i + j - 1
                if i and s1[i - 1] == s3[k]:
                    f[i][j] = f[i - 1][j]
                if j and s2[j - 1] == s3[k]:
                    f[i][j] |= f[i][j - 1]
        return f[m][n]
```

Solution 3: Rolling Array Optimization

> **How to think about it**
>
> The follow-up asks for O(|s_2|) extra space. f[i][j] depends only on the previous row and the left cell, so one rolling array is enough — the O(n) bound in the problem.

We notice that f[i][j] is only related to f[i - 1][j] and f[i][j - 1]. Therefore, we can use a rolling array to reduce the space complexity to O(n). The time complexity remains O(m × n).

Python 3

```python
class Solution:
    def isInterleave(self, s1: str, s2: str, s3: str) -> bool:
        m, n = len(s1), len(s2)
        if m + n != len(s3):
            return False
        f = [True] + [False] * n
        for i in range(m + 1):
            for j in range(n + 1):
                k = i + j - 1
                if i:
                    f[j] &= s1[i - 1] == s3[k]
                if j:
                    f[j] |= f[j - 1] and s2[j - 1] == s3[k]
        return f[n]
```

931. Minimum Falling Path Sum

Medium · Array, Dynamic Programming, Matrix

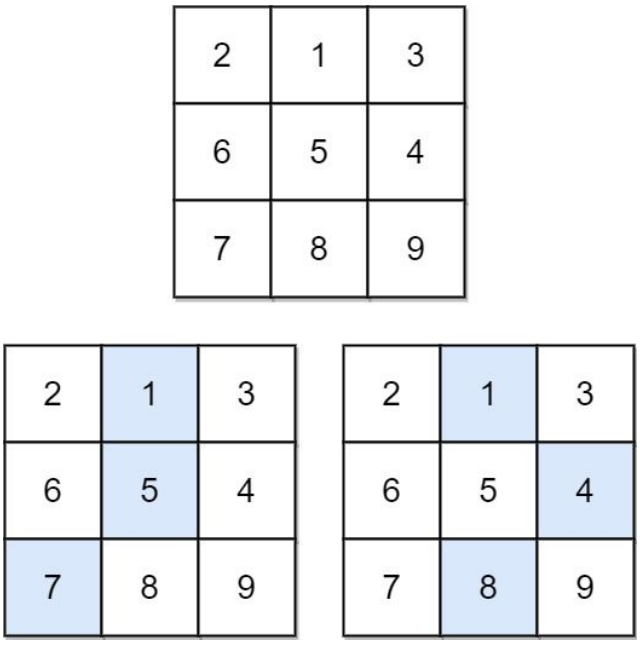
leetcode.com/problems/minimum-falling-path-sum

PROBLEM

Given an `n x n` array of integers `matrix`, return *the **minimum sum** of any **falling path** through* `matrix`.

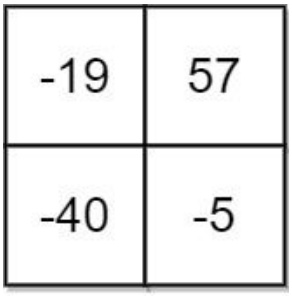
A **falling path** starts at any element in the first row and chooses the element in the next row that is either directly below or diagonally left/right. Specifically, the next element from position `(row, col)` will be `(row + 1, col - 1)`, `(row + 1, col)`, or `(row + 1, col + 1)`.

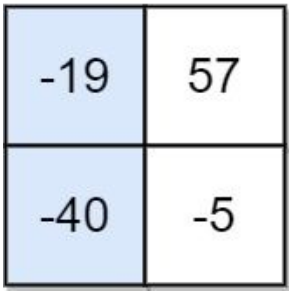
Example 1:



```
Input: matrix = [[2,1,3],[6,5,4],[7,8,9]]
Output: 13
Explanation: There are two falling paths with a minimum sum as shown.
```

Example 2:





```
Input: matrix = [[-19,57],[-40,-5]]
Output: -59
Explanation: The falling path with a minimum sum is shown.
```

Constraints:

- `n == matrix.length == matrix[i].length`
- `1 <= n <= 100`
- `-100 <= matrix[i][j] <= 100`

SOLUTION (PYTHON 3)

Solution 1: Dynamic Programming (Rolling Array)

How to think about it

A falling path may step only to the three adjacent cells in the next row, and n≤ 100. Enumerating paths is impossible. The best way to (i,j) depends only on the previous row at j-1,j,j+1. Compute this row by row and roll a one-dimensional array, using O(n) extra space.

Let f[i][j] be the minimum falling path sum that ends at row i, column j:

f[i][j] = matrix[i][j] + min { aligned & f[i - 1][j - 1], & j > 0 \ & f[i - 1][j], & 0 ≤ j < n \ & f[i - 1][j + 1], & j + 1 < n aligned .

The answer is $\min_{0 \le j < n} f[n - 1][j]$.

f[i][j] depends only on the previous row, so we keep two arrays f and g of length n.

The time complexity is $O(n^2)$ and the space complexity is O(n), where n is the side length of the matrix.

Python 3

```python
class Solution:
    def minFallingPathSum(self, matrix: List[List[int]]) -> int:
        n = len(matrix)
        f = [0] * n
        for row in matrix:
            g = [0] * n
            for j, x in enumerate(row):
                l, r = max(0, j - 1), min(n, j + 2)
                g[j] = min(f[l:r]) + x
            f = g
        return min(f)
```

PATTERN 22 · DYNAMIC PROGRAMMING - 2D / GRID · PROBLEM 10 OF 20

1423. Maximum Points You Can Obtain from Cards

Medium · Array, Prefix Sum, Sliding Window

leetcode.com/problems/maximum-points-you-can-obtain-from-cards

Also appears in pattern 35 Sliding Window Maximum / Minimum (Specific Variants)

PROBLEM

There are several cards **arranged in a row**, and each card has an associated number of points. The points are given in the integer array `cardPoints`.

In one step, you can take one card from the beginning or from the end of the row. You have to take exactly `k` cards.

Your score is the sum of the points of the cards you have taken.

Given the integer array `cardPoints` and the integer `k`, return the *maximum score* you can obtain.

Example 1:

```
Input: cardPoints = [1,2,3,4,5,6,1], k = 3
Output: 12
Explanation: After the first step, your score will always be 1. However, choosing the rightmost card
first will maximize your total score. The optimal strategy is to take the three cards on the right,
giving a final score of 1 + 6 + 5 = 12.
```

Example 2:

```
Input: cardPoints = [2,2,2], k = 2
Output: 4
Explanation: Regardless of which two cards you take, your score will always be 4.
```

Example 3:

```
Input: cardPoints = [9,7,7,9,7,7,9], k = 7
Output: 55
Explanation: You have to take all the cards. Your score is the sum of points of all cards.
```

Constraints:

- `1 <= cardPoints.length <= 10^5`
- `1 <= cardPoints[i] <= 10^4`
- `1 <= k <= cardPoints.length`

SOLUTION (PYTHON 3)

Solution 1: Sliding Window

> **How to think about it**
>
> Taking k cards from the two ends means i from the left and k-i from the right. n≤ 10^5, so we cannot resumm each i. Start with the rightmost k cards, then replace the leftmost of those with the next left-end card, updating the sum in O(1) and keeping the maximum.

We can use a sliding window of length k to simulate this process.

Initially, we place the window at the end of the array, i.e., the k positions from index n-k to index n-1. The sum of the points of the cards in the window is denoted as s, and the initial value of the answer ans is also s.

Next, we consider the situation where we take 1, 2, ..., k cards from the beginning of the array in turn. Suppose the card taken is cardPoints[i]. Then we add it to s. Due to the length limit of the window is k, we need to subtract cardPoints[n-k+i] from s. In this way, we can calculate the sum of the points of the k cards taken and update the answer ans.

The time complexity is O(k), where k is the integer given in the problem. The space complexity is O(1).

Python 3

```
class Solution:
    def maxScore(self, cardPoints: List[int], k: int) -> int:
        ans = s = sum(cardPoints[-k:])
        for i, x in enumerate(cardPoints[:k]):
            s += x - cardPoints[-k + i]
            ans = max(ans, s)
        return ans
```

    return best
```

576. Out of Boundary Paths

Medium · Dynamic Programming

leetcode.com/problems/out-of-boundary-paths

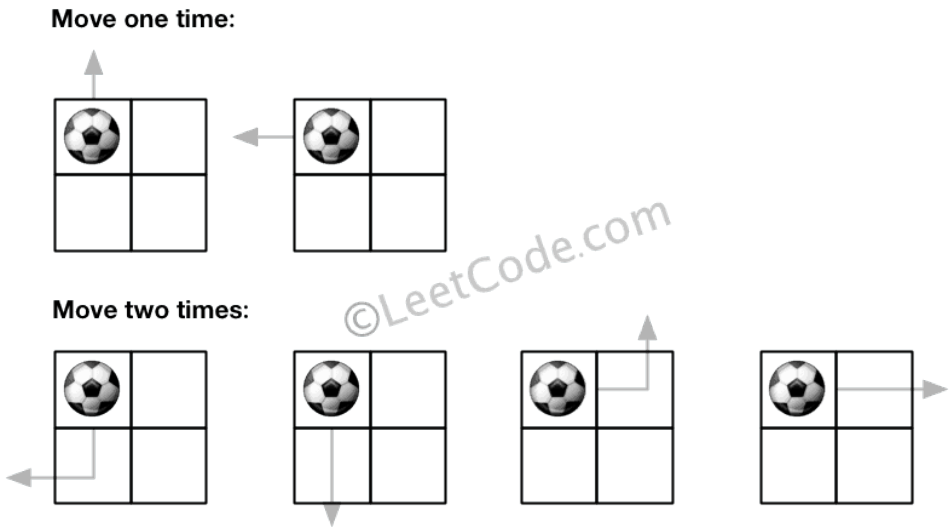
Also appears in pattern 36 Simulation / Array Rearrangement

PROBLEM

There is an `m x n` grid with a ball. The ball is initially at the position `[startRow, startColumn]`. You are allowed to move the ball to one of the four adjacent cells in the grid (possibly out of the grid crossing the grid boundary). You can apply **at most** `maxMove` moves to the ball.

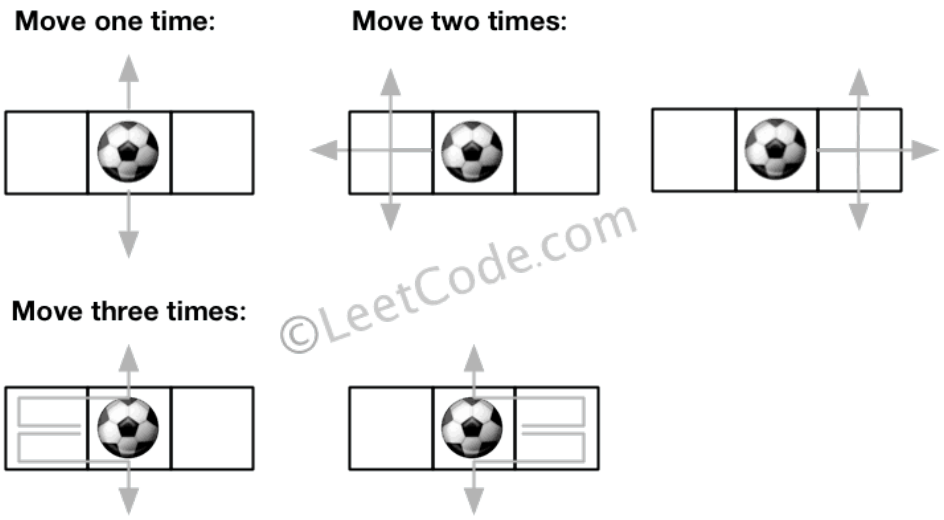
Given the five integers `m`, `n`, `maxMove`, `startRow`, `startColumn`, return the number of paths to move the ball out of the grid boundary. Since the answer can be very large, return it **modulo** $10^9 + 7$.

Example 1:



```
Input: m = 2, n = 2, maxMove = 2, startRow = 0, startColumn = 0
Output: 6
```

Example 2:



```
Input: m = 1, n = 3, maxMove = 3, startRow = 0, startColumn = 1
Output: 12
```

Constraints:

- `1 <= m, n <= 50`
- `0 <= maxMove <= 50`
- `0 <= startRow < m`
- `0 <= startColumn < n`

SOLUTION (PYTHON 3)

Solution 1: Memoization Search

How to think about it

From a cell we may step in four directions, at most k times, and we count paths that leave the grid. Unmemoized search repeats the same cell and remaining steps. dfs(i,j,k) is the number of out-of-bound paths from (i,j) with k steps left. Off-grid with $k \geq 0$ scores 1; no steps left scores 0. Four-way transitions modulo 10^9+7. Each triple is computed once.

We define a function dfs(i, j, k) to represent the number of paths that can move out of the boundary starting from coordinates (i, j) with k steps remaining.

In the function dfs(i, j, k), we first handle the boundary cases. If the current coordinates (i, j) are out of the grid range, return 1 if $k \geq 0$, otherwise return 0. If $k \leq 0$, it means we are still within the grid but have no remaining moves, so return 0. Next, we iterate over the four directions, move to the next coordinates (x, y), then recursively call dfs(x, y, k - 1), and accumulate the results to the answer.

In the main function, we call dfs(startRow, startColumn, maxMove), which represents the number of paths that can move out of the boundary starting from the initial coordinates (startRow, startColumn) with maxMove steps remaining.

To avoid redundant calculations, we can use memoization.

The time complexity is $O(m \times n \times k)$, and the space complexity is $O(m \times n \times k)$. Here, m and n are the number of rows and columns of the grid, and k is the number of steps that can be moved, with $k = maxMove \leq 50$.

Python 3

```python
class Solution:
    def findPaths(
        self, m: int, n: int, maxMove: int, startRow: int, startColumn: int
    ) -> int:
        @cache
        def dfs(i: int, j: int, k: int) -> int:
            if not 0 <= i < m or not 0 <= j < n:
                return int(k >= 0)
            if k <= 0:
                return 0
            ans = 0
            for a, b in pairwise(dirs):
                x, y = i + a, j + b
                ans = (ans + dfs(x, y, k - 1)) % mod
            return ans

        mod = 10**9 + 7
        dirs = (-1, 0, 1, 0, -1)
        return dfs(startRow, startColumn, maxMove)
```

PATTERN 22 · DYNAMIC PROGRAMMING - 2D / GRID · PROBLEM 13 OF 20

72. Edit Distance

Medium · String, Dynamic Programming

leetcode.com/problems/edit-distance

★ **TOP 10 PROBLEM** in Dynamic Programming - 2D / Grid: master this one first

PROBLEM

Given two strings `word1` and `word2`, return *the minimum number of operations required to convert* `word1` *to* `word2`.

You have the following three operations permitted on a word:

- Insert a character
- Delete a character
- Replace a character

Example 1:

```
Input: word1 = "horse", word2 = "ros"
Output: 3
Explanation:
horse -> rorse (replace 'h' with 'r')
rorse -> rose (remove 'r')
rose -> ros (remove 'e')
```

Example 2:

```
Input: word1 = "intention", word2 = "execution"
Output: 5
Explanation:
intention -> inention (remove 't')
inention -> enention (replace 'i' with 'e')
enention -> exention (replace 'n' with 'x')
exention -> exection (replace 'n' with 'c')
exection -> execution (insert 'u')
```

Constraints:

- `0 <= word1.length, word2.length <= 500`
- `word1` and `word2` consist of lowercase English letters.

SOLUTION (PYTHON 3)

Solution 1: Dynamic Programming

How to think about it

The first idea is recursion: at each position of word1 try insert, delete, or replace, then take the best. Correct, but exponential. m,n ≤ 500 needs a polynomial. The bottleneck is overlapping subproblems — converting prefix i into prefix j is solved many times. Let f[i][j] be that minimum. Equal last characters inherit the diagonal; otherwise the three operations map to three neighbors, take min plus one. Empty-string borders are delete-all / insert-all. The answer is f[m][n].

We define f[i][j] as the minimum number of operations to convert word1 of length i to word2 of length j. f[i][0] = i, f[0][j] = j, $i \in [1, m]$, $j \in [0, n]$.

We consider f[i][j]:

- If word1[i - 1] = word2[j - 1], then we only need to consider the minimum number of operations to convert word1 of length i - 1 to word2 of length j - 1, so f[i][j] = f[i - 1][j - 1];

- Otherwise, we can consider insert, delete, and replace operations, then f[i][j] = min(f[i - 1][j], f[i][j - 1], f[i - 1][j - 1]) + 1.

Finally, we can get the state transition equation:

f[i][j] = cases i, & if j = 0 \ j, & if i = 0 \ f[i - 1][j - 1], & if word1[i - 1] = word2[j - 1] \ min(f[i - 1][j], f[i][j - 1], f[i - 1][j - 1]) + 1, & otherwise cases

Finally, we return f[m][n].

The time complexity is O(m × n), and the space complexity is O(m × n). m and n are the lengths of word1 and word2 respectively.

Python 3

```
class Solution:
    def minDistance(self, word1: str, word2: str) -> int:
        m, n = len(word1), len(word2)
        f = [[0] * (n + 1) for _ in range(m + 1)]
        for j in range(1, n + 1):
            f[0][j] = j
        for i, a in enumerate(word1, 1):
            f[i][0] = i
            for j, b in enumerate(word2, 1):
                if a == b:
                    f[i][j] = f[i - 1][j - 1]
                else:
                    f[i][j] = min(f[i - 1][j], f[i][j - 1], f[i - 1][j - 1]) + 1
        return f[m][n]
```

```

115. Distinct Subsequences

Hard · String, Dynamic Programming

leetcode.com/problems/distinct-subsequences

★ **TOP 10 PROBLEM** in Dynamic Programming - 2D / Grid: master this one first

PROBLEM

Given two strings s and t, return *the number of distinct* ***subsequences*** *of* s *which equals* t.

The test cases are generated so that the answer fits on a 32-bit signed integer.

Example 1:

```
Input: s = "rabbbit", t = "rabbit"
Output: 3
Explanation:
As shown below, there are 3 ways you can generate "rabbit" from s.
rabbbit
rabbbit
rabbbit
```

Example 2:

```
Input: s = "babgbag", t = "bag"
Output: 5
Explanation:
As shown below, there are 5 ways you can generate "bag" from s.
babgbag
babgbag
babgbag
babgbag
babgbag
```

Constraints:

- `1 <= s.length, t.length <= 1000`
- `s` and `t` consist of English letters.

SOLUTIONS (PYTHON 3)

Solution 1: Dynamic Programming

How to think about it

Count subsequences of s that equal t. Choosing to take or skip each character of s explodes when both lengths reach 1000; naive recursion repeats the same suffix pairs. The state is how much of s and t we have used. f[i][j] is the number of ways the first i characters of s form the first j of t. When the current characters match, we add the transition that consumes both. The empty t has exactly one empty subsequence.

We define f[i][j] as the number of schemes where the first i characters of string s form the first j characters of string t. Initially, f[i][0]=1 for all $i \in [0,m]$.

When i > 0, we consider the calculation of f[i][j]:

- When s[i-1] ≠ t[j-1], we cannot select s[i-1], so f[i][j]=f[i-1][j];
- Otherwise, we can select s[i-1], so f[i][j]=f[i-1][j-1].

Therefore, we have the following state transition equation:

$$f[i][j]=\{ \text{aligned } \&f[i-1][j], \&s[i-1] \neq t[j-1] \backslash \&f[i-1][j-1]+f[i-1][j], \&s[i-1]=t[j-1] \text{ aligned } .$$

The final answer is f[m][n], where m and n are the lengths of strings s and t respectively.

The time complexity is O(m × n), and the space complexity is O(m × n).

Python 3

```python
class Solution:
    def numDistinct(self, s: str, t: str) -> int:
        m, n = len(s), len(t)
        f = [[0] * (n + 1) for _ in range(m + 1)]
        for i in range(m + 1):
            f[i][0] = 1
        for i, a in enumerate(s, 1):
            for j, b in enumerate(t, 1):
                f[i][j] = f[i - 1][j]
                if a == b:
                    f[i][j] += f[i - 1][j - 1]
        return f[m][n]
```

Solution 2: Optimized Dynamic Programming

> **How to think about it**
>
> In Solution 1, f[i][j] depends only on the previous row. After collapsing to one dimension we must update j from the right, so f[j-1] is not overwritten too early. Space becomes O(|t|).

f[i][j] depends only on the previous row, so the first dimension can be dropped. Update j from large to small so f[j-1] is not overwritten. The space complexity becomes O(n).

Python 3

```python
class Solution:
    def numDistinct(self, s: str, t: str) -> int:
        n = len(t)
        f = [1] + [0] * n
        for a in s:
            for j in range(n, 0, -1):
                if a == t[j - 1]:
                    f[j] += f[j - 1]
        return f[n]
```

    positions.reverse()
    return positions
```

174. Dungeon Game

Hard · Array, Dynamic Programming, Matrix

leetcode.com/problems/dungeon-game

★ **TOP 10 PROBLEM** in Dynamic Programming - 2D / Grid: master this one first

PROBLEM

The demons had captured the princess and imprisoned her in **the bottom-right corner** of a `dungeon`. The `dungeon` consists of `m x n` rooms laid out in a 2D grid. Our valiant knight was initially positioned in **the top-left room** and must fight his way through `dungeon` to rescue the princess.

The knight has an initial health point represented by a positive integer. If at any point his health point drops to `0` or below, he dies immediately.

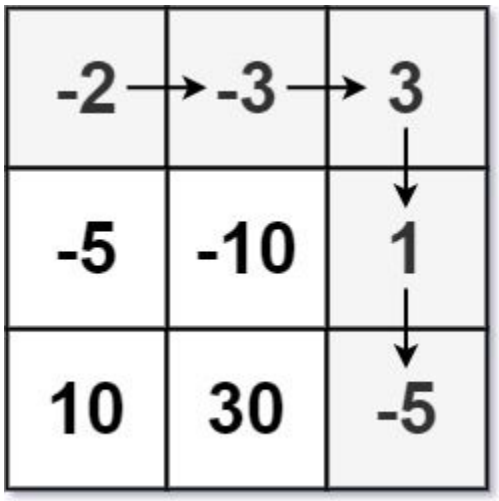
Some of the rooms are guarded by demons (represented by negative integers), so the knight loses health upon entering these rooms; other rooms are either empty (represented as 0) or contain magic orbs that increase the knight's health (represented by positive integers).

To reach the princess as quickly as possible, the knight decides to move only **rightward** or **downward** in each step.

Return *the knight's minimum initial health so that he can rescue the princess*.

Note that any room can contain threats or power-ups, even the first room the knight enters and the bottom-right room where the princess is imprisoned.

Example 1:



```
Input: dungeon = [[-2,-3,3],[-5,-10,1],[10,30,-5]]
Output: 7
Explanation: The initial health of the knight must be at least 7 if he follows the optimal path:
RIGHT-> RIGHT -> DOWN -> DOWN.
```

Example 2:

```
Input: dungeon = [[0]]
Output: 1
```

Constraints:

- `m == dungeon.length`
- `n == dungeon[i].length`
- `1 <= m, n <= 200`

- `-1000 <= dungeon[i][j] <= 1000`

SOLUTION (PYTHON 3)

Solution 1: Dynamic Programming

> **How to think about it**
>
> The knight may only move right or down and must stay at least at 1 HP; we want the minimum starting HP. Enumerating paths on a 200× 200 grid is impossible. The HP needed ahead fixes the requirement here, so we work backward from the princess: next-cell need minus this cell's value, then at least 1. Take the cheaper of the two exits.

We define dp[i][j] as the minimum initial value needed from (i, j) to the end point. The value of dp[i][j] can be obtained from dp[i+1][j] and dp[i][j+1], that is:

$$dp[i][j] = \max(\min(dp[i+1][j], dp[i][j+1]) - dungeon[i][j], 1)$$

Initially, dp[m][n-1] and dp[m-1][n] are both 1, and the values at other positions are maximum.

The time complexity is O(m × n), and the space complexity is O(m × n). Where m and n are the number of rows and columns of the dungeon, respectively.

Python 3

```python
class Solution:
    def calculateMinimumHP(self, dungeon: List[List[int]]) -> int:
        m, n = len(dungeon), len(dungeon[0])
        dp = [[inf] * (n + 1) for _ in range(m + 1)]
        dp[m][n - 1] = dp[m - 1][n] = 1
        for i in range(m - 1, -1, -1):
            for j in range(n - 1, -1, -1):
                dp[i][j] = max(1, min(dp[i + 1][j], dp[i][j + 1]) - dungeon[i][j])
        return dp[0][0]
```

```

741. Cherry Pickup

Hard · Array, Dynamic Programming, Matrix

leetcode.com/problems/cherry-pickup

PROBLEM

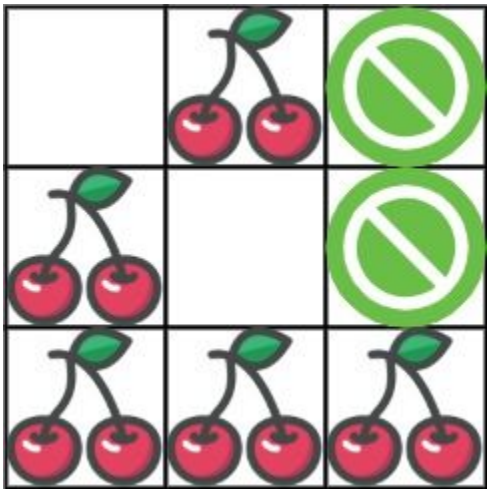
You are given an `n x n grid` representing a field of cherries, each cell is one of three possible integers.

- `0` means the cell is empty, so you can pass through,
- `1` means the cell contains a cherry that you can pick up and pass through, or
- `-1` means the cell contains a thorn that blocks your way.

Return *the maximum number of cherries you can collect by following the rules below*:

- Starting at the position `(0, 0)` and reaching `(n - 1, n - 1)` by moving right or down through valid path cells (cells with value `0` or `1`).
- After reaching `(n - 1, n - 1)`, returning to `(0, 0)` by moving left or up through valid path cells.
- When passing through a path cell containing a cherry, you pick it up, and the cell becomes an empty cell `0`.
- If there is no valid path between `(0, 0)` and `(n - 1, n - 1)`, then no cherries can be collected.

Example 1:



```
Input: grid = [[0,1,-1],[1,0,-1],[1,1,1]]
Output: 5
Explanation: The player started at (0, 0) and went down, down, right right to reach (2, 2).
4 cherries were picked up during this single trip, and the matrix becomes [[0,1,-1],[0,0,-1],[0,0,0]].
Then, the player went left, up, up, left to return home, picking up one more cherry.
The total number of cherries picked up is 5, and this is the maximum possible.
```

Example 2:

```
Input: grid = [[1,1,-1],[1,-1,1],[-1,1,1]]
Output: 0
```

Constraints:

- `n == grid.length`
- `n == grid[i].length`
- `1 <= n <= 50`
- `grid[i][j]` is `-1`, `0`, or `1`.
- `grid[0][0] != -1`

- `grid[n - 1][n - 1] != -1`

SOLUTION (PYTHON 3)

Solution 1: Dynamic Programming

How to think about it

Walk to the far corner and back; n≤ 50. Two independent paths explode, and overlapping cherries are hard to charge only once. The round trip is two walks of k steps from the start. With a shared step count, columns are determined by rows, so the state is (k,i_1,i_2). A shared cell is counted once; a thorn is unreachable. $f[k][i_1][i_2]$ comes from the previous rows i_1 or i_1-1 and i_2 or i_2-1, plus the current cherries. The answer is max(0, f[2n-2][n-1][n-1]).

According to the problem description, the player starts from (0, 0), reaches (n-1, n-1), and then returns to the starting point (0, 0). We can consider the player as starting from (0, 0) to (n-1, n-1) twice.

Therefore, we define $f[k][i_1][i_2]$ as the maximum number of cherries that can be picked when both have walked k steps and reached $(i_1, k-i_1)$ and $(i_2, k-i_2)$ respectively. Initially, f[0][0][0] = grid[0][0]. The initial values of other $f[k][i_1][i_2]$ are negative infinity. The answer is max(0, f[2n-2][n-1][n-1]).

According to the problem description, we can get the state transition equation:

$$f[k][i_1][i_2] = \max(f[k-1][x_1][x_2] + t, f[k][i_1][i_2])$$

Where t represents the number of cherries at positions $(i_1, k-i_1)$ and $(i_2, k-i_2)$, and x_1, x_2 represent the previous step positions of $(i_1, k-i_1)$ and $(i_2, k-i_2)$ respectively.

The time complexity is $O(n^3)$, and the space complexity is $O(n^3)$. Where n is the side length of the grid.

Python 3

```python
class Solution:
    def cherryPickup(self, grid: List[List[int]]) -> int:
        n = len(grid)
        f = [[[-inf] * n for _ in range(n)] for _ in range((n << 1) - 1)]
        f[0][0][0] = grid[0][0]
        for k in range(1, (n << 1) - 1):
            for i1 in range(n):
                for i2 in range(n):
                    j1, j2 = k - i1, k - i2
                    if (
                        not 0 <= j1 < n
                        or not 0 <= j2 < n
                        or grid[i1][j1] == -1
                        or grid[i2][j2] == -1
                    ):
                        continue
                    t = grid[i1][j1]
                    if i1 != i2:
                        t += grid[i2][j2]
                    for x1 in range(i1 - 1, i1 + 1):
                        for x2 in range(i2 - 1, i2 + 1):
                            if x1 >= 0 and x2 >= 0:
                                f[k][i1][i2] = max(f[k][i1][i2], f[k - 1][x1][x2] + t)
        return max(0, f[-1][-1][-1])
```

1463. Cherry Pickup II

Hard · Array, Dynamic Programming, Matrix

leetcode.com/problems/cherry-pickup-ii

PROBLEM

You are given a `rows x cols` matrix `grid` representing a field of cherries where `grid[i][j]` represents the number of cherries that you can collect from the `(i, j)` cell.

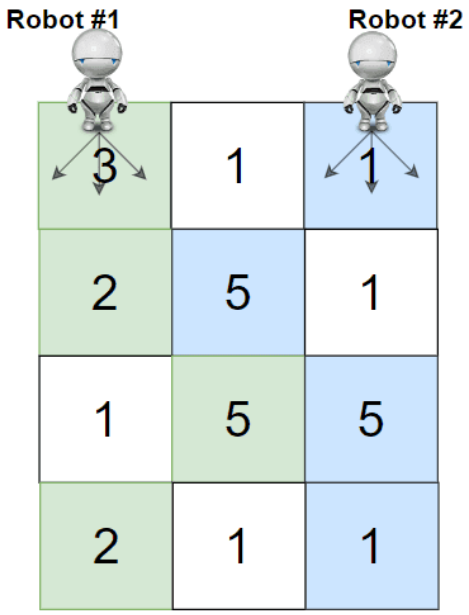
You have two robots that can collect cherries for you:

- **Robot #1** is located at the **top-left corner** `(0, 0)`, and
- **Robot #2** is located at the **top-right corner** `(0, cols - 1)`.

Return *the maximum number of cherries collection using both robots by following the rules below*:

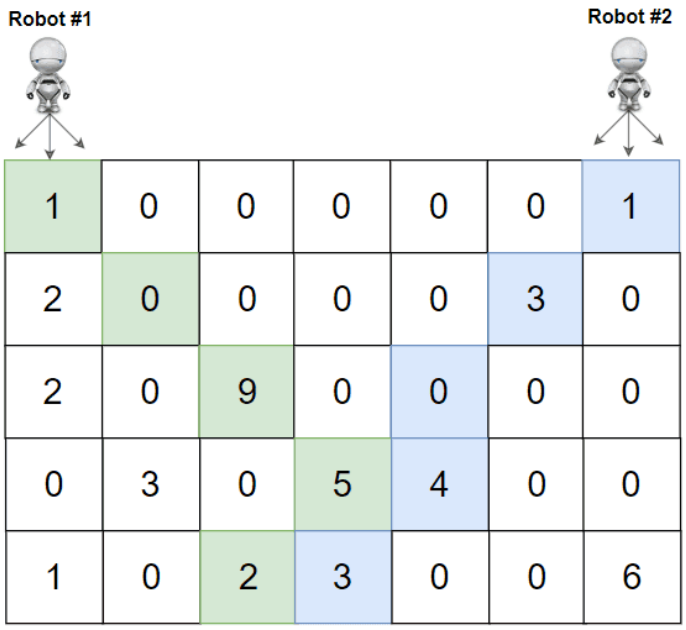
- From a cell `(i, j)`, robots can move to cell `(i + 1, j - 1)`, `(i + 1, j)`, or `(i + 1, j + 1)`.
- When any robot passes through a cell, It picks up all cherries, and the cell becomes an empty cell.
- When both robots stay in the same cell, only one takes the cherries.
- Both robots cannot move outside of the grid at any moment.
- Both robots should reach the bottom row in `grid`.

Example 1:



```
Input: grid = [[3,1,1],[2,5,1],[1,5,5],[2,1,1]]
Output: 24
Explanation: Path of robot #1 and #2 are described in color green and blue respectively.
Cherries taken by Robot #1, (3 + 2 + 5 + 2) = 12.
Cherries taken by Robot #2, (1 + 5 + 5 + 1) = 12.
Total of cherries: 12 + 12 = 24.
```

Example 2:



```
Input: grid = [[1,0,0,0,0,0,1],[2,0,0,0,0,3,0],[2,0,9,0,0,0,0],[0,3,0,5,4,0,0],[1,0,2,3,0,0,6]]
Output: 28
Explanation: Path of robot #1 and #2 are described in color green and blue respectively.
Cherries taken by Robot #1, (1 + 9 + 5 + 2) = 17.
Cherries taken by Robot #2, (1 + 3 + 4 + 3) = 11.
Total of cherries: 17 + 11 = 28.
```

Constraints:

- `rows == grid.length`
- `cols == grid[i].length`
- `2 <= rows, cols <= 70`
- `0 <= grid[i][j] <= 100`

SOLUTIONS (PYTHON 3)

Solution 1: Dynamic Programming

How to think about it

Two robots move down a row together, each stepping left/stay/right. rows,cols≤ 70. After synchronizing rows, the state is the row and the two columns. f[i][j_1][j_2] is the best score with both robots on row i. A shared cell is counted once. Transition from the nine neighboring column pairs. Take the max on the last row.

We define f[i][j_1][j_2] as the maximum number of cherries that can be picked when the two robots are at positions j_1 and j_2 in the i-th row. Initially, f[0][0][n-1] = grid[0][0] + grid[0][n-1], and the other values are -1. The answer is $\max_{0 \le j_1, j_2 < n}$ f[m-1][j_1][j_2].

Consider f[i][j_1][j_2]. If $j_1 \neq j_2$, then the number of cherries that the robots can pick in the i-th row is grid[i][j_1] + grid[i][j_2]. If $j_1 = j_2$, then the number of cherries that the robots can pick in the i-th row is grid[i][j_1]. We can enumerate the previous state of the two robots f[i-1][y1][y2], where y_1, y_2 are the positions of the two robots in the (i-1)-th row, then $y_1 \in \{j_1-1, j_1, j_1+1\}$ and $y_2 \in \{j_2-1, j_2, j_2+1\}$. The state transition equation is as follows:

f[i][j_1][j_2] = $\max_{y_1 \in \{j_1-1, j_1, j_1+1\}, y_2 \in \{j_2-1, j_2, j_2+1\}}$ f[i-1][y_1][y_2] + cases grid[i][j_1] + grid[i][j_2], & $j_1 \neq j_2$ \ grid[i][j_1], & $j_1 = j_2$ cases

Where f[i-1][y_1][y_2] is ignored when it is -1.

The final answer is $\max_{0 \le j_1, j_2 < n}$ f[m-1][j_1][j_2].

The time complexity is $O(m \times n^2)$, and the space complexity is $O(m \times n^2)$. Where m and n are the number of rows and columns of the grid, respectively.

Python 3

```python
class Solution:
    def cherryPickup(self, grid: List[List[int]]) -> int:
        m, n = len(grid), len(grid[0])
        f = [[[-1] * n for _ in range(n)] for _ in range(m)]
        f[0][0][n - 1] = grid[0][0] + grid[0][n - 1]
        for i in range(1, m):
            for j1 in range(n):
                for j2 in range(n):
                    x = grid[i][j1] + (0 if j1 == j2 else grid[i][j2])
                    for y1 in range(j1 - 1, j1 + 2):
                        for y2 in range(j2 - 1, j2 + 2):
                            if 0 <= y1 < n and 0 <= y2 < n and f[i - 1][y1][y2] != -1:
                                f[i][j1][j2] = max(f[i][j1][j2], f[i - 1][y1][y2] + x)
        return max(f[-1][j1][j2] for j1, j2 in product(range(n), range(n)))
```

Solution 2: Dynamic Programming (Space Optimization)

> **How to think about it**
>
> Layer i of method 1 depends only on layer i-1. Two n× n tables rolled in place drop a dimension without changing the transitions.

Notice that the calculation of f[i][j_1][j_2] is only related to f[i-1][y_1][y_2]. Therefore, we can use a rolling array to optimize the space complexity. After optimizing the space complexity, the time complexity is $O(n^2)$.

Python 3

```python
class Solution:
    def cherryPickup(self, grid: List[List[int]]) -> int:
        m, n = len(grid), len(grid[0])
        f = [[-1] * n for _ in range(n)]
        g = [[-1] * n for _ in range(n)]
        f[0][n - 1] = grid[0][0] + grid[0][n - 1]
        for i in range(1, m):
            for j1 in range(n):
                for j2 in range(n):
                    x = grid[i][j1] + (0 if j1 == j2 else grid[i][j2])
                    for y1 in range(j1 - 1, j1 + 2):
                        for y2 in range(j2 - 1, j2 + 2):
                            if 0 <= y1 < n and 0 <= y2 < n and f[y1][y2] != -1:
                                g[j1][j2] = max(g[j1][j2], f[y1][y2] + x)
            f, g = g, f
        return max(f[j1][j2] for j1, j2 in product(range(n), range(n)))
```

    return best_value
```

1289. Minimum Falling Path Sum II

Hard · Array, Dynamic Programming, Matrix

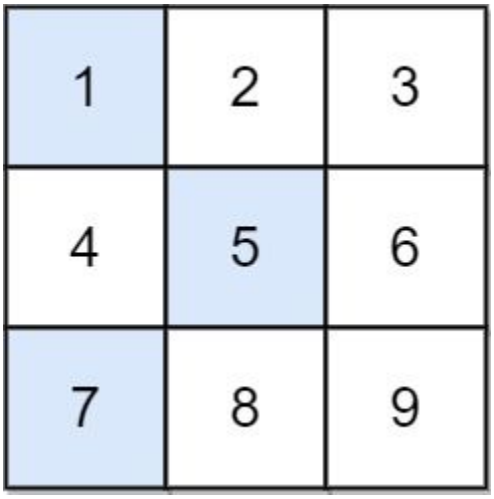
leetcode.com/problems/minimum-falling-path-sum-ii

PROBLEM

Given an `n x n` integer matrix `grid`, return *the minimum sum of a* ***falling path with non-zero shifts***.

A **falling path with non-zero shifts** is a choice of exactly one element from each row of `grid` such that no two elements chosen in adjacent rows are in the same column.

Example 1:



```
Input: grid = [[1,2,3],[4,5,6],[7,8,9]]
Output: 13
Explanation:
The possible falling paths are:
[1,5,9], [1,5,7], [1,6,7], [1,6,8],
[2,4,8], [2,4,9], [2,6,7], [2,6,8],
[3,4,8], [3,4,9], [3,5,7], [3,5,9]
The falling path with the smallest sum is [1,5,7], so the answer is 13.
```

Example 2:

```
Input: grid = [[7]]
Output: 7
```

Constraints:

- `n == grid.length == grid[i].length`
- `1 <= n <= 200`
- `-99 <= grid[i][j] <= 99`

SOLUTION (PYTHON 3)

Solution 1: Dynamic Programming (Rolling Array)

How to think about it

A falling path cannot reuse a column on the next row. n ≤ 200 allows $O(n^3)$. The best way to end row i in column j is the previous row's minimum excluding j, plus grid[i][j]. We keep only the previous n values and add “min except this column” in place. A rolling array drops the row dimension.

Let f[i][j] be the minimum path sum using the first i rows and ending in column j:

$$f[i][j] = \min_{k \neq j} f[i - 1][k] + grid[i - 1][j]$$

The answer is $\min_{0 \leq j < n} f[n][j]$. After rolling, only the last row remains, so this is the minimum of the 1D array f.

f[i][j] depends only on the previous row, so we keep two arrays f and g of length n.

The time complexity is $O(n^3)$ and the space complexity is O(n), where n is the number of rows.

Python 3

```
class Solution:
    def minFallingPathSum(self, grid: List[List[int]]) -> int:
        n = len(grid)
        f = [0] * n
        for row in grid:
            g = row[:]
            for i in range(n):
                g[i] += min((f[j] for j in range(n) if j != i), default=0)
            f = g
        return min(f)
```

PATTERN 22 · DYNAMIC PROGRAMMING - 2D / GRID · PROBLEM 20 OF 20

329. Longest Increasing Path in a Matrix

Hard · Depth-First Search, Breadth-First Search, Graph, Topological Sort, Memoization, Array, Dynamic Programming, Directed Acyclic Graph, Matrix

leetcode.com/problems/longest-increasing-path-in-a-matrix

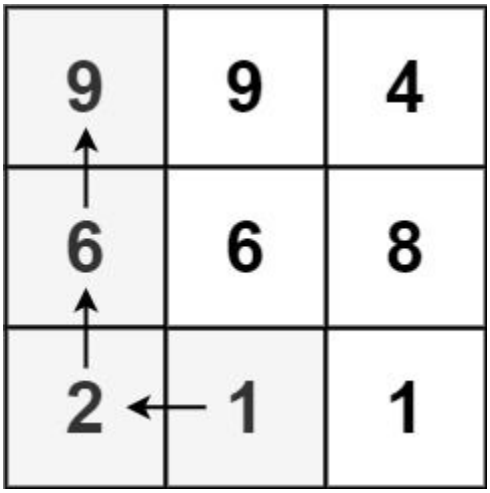
★ **TOP 10 PROBLEM** in Dynamic Programming - 2D / Grid: master this one first

PROBLEM

Given an `m x n` integers `matrix`, return *the length of the longest increasing path in* `matrix`.

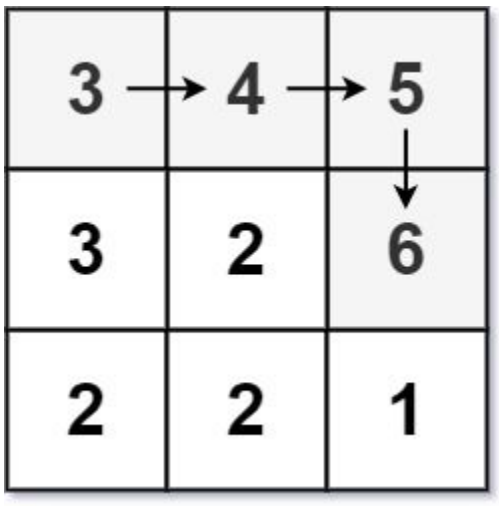
From each cell, you can either move in four directions: left, right, up, or down. You **may not** move **diagonally** or move **outside the boundary** (i.e., wrap-around is not allowed).

Example 1:



```
Input: matrix = [[9,9,4],[6,6,8],[2,1,1]]
Output: 4
Explanation: The longest increasing path is [1, 2, 6, 9].
```

Example 2:



```
Input: matrix = [[3,4,5],[3,2,6],[2,2,1]]
Output: 4
Explanation: The longest increasing path is [3, 4, 5, 6]. Moving diagonally is not allowed.
```

Example 3:

```
Input: matrix = [[1]]
Output: 1
```

Constraints:

- `m == matrix.length`
- `n == matrix[i].length`
- `1 <= m, n <= 200`
- `0 <= matrix[i][j] <= 2^31 - 1`

SOLUTION (PYTHON 3)

Solution 1: Memoization Search

> **How to think about it**
>
> Longest strictly increasing four-direction path. Plain DFS restarts from the same cell many times. Strict increase makes the graph acyclic. dfs(i,j) is one plus the best neighbor with a larger value. Memoization evaluates each cell once; the answer is the max over all starts.

We design a function dfs(i, j), which represents the length of the longest increasing path that can be obtained starting from the coordinate (i, j) in the matrix. The answer is $\max_{i,j} \text{dfs}(i, j)$.

The execution logic of the function dfs(i, j) is as follows:

- If (i, j) has been visited, directly return f(i, j);
- Otherwise, search (i, j), search the coordinates (x, y) in four directions. If $0 \le x < m$, $0 \le y < n$ and matrix[x][y] > matrix[i][j], then search (x, y). After the search is over, update f(i, j) to f(i, j) = max(f(i, j), f(x, y) + 1). Finally, return f(i, j).

The time complexity is $O(m \times n)$, and the space complexity is $O(m \times n)$. Where m and n are the number of rows and columns of the matrix, respectively.

PATTERN 23 · SORTING · PROBLEM 1 OF 20

88. Merge Sorted Array

Easy · Array, Two Pointers, Sorting

leetcode.com/problems/merge-sorted-array

★ **TOP 10 PROBLEM** in Sorting, K-way Merge: master this one first

Also appears in pattern 38 K-way Merge

PROBLEM

You are given two integer arrays `nums1` and `nums2`, sorted in **non-decreasing order**, and two integers `m` and `n`, representing the number of elements in `nums1` and `nums2` respectively.

Merge `nums1` and `nums2` into a single array sorted in **non-decreasing order**.

The final sorted array should not be returned by the function, but instead be *stored inside the array* `nums1`. To accommodate this, `nums1` has a length of `m + n`, where the first `m` elements denote the elements that should be merged, and the last `n` elements are set to `0` and should be ignored. `nums2` has a length of `n`.

Example 1:

```
Input: nums1 = [1,2,3,0,0,0], m = 3, nums2 = [2,5,6], n = 3
Output: [1,2,2,3,5,6]
Explanation: The arrays we are merging are [1,2,3] and [2,5,6].
The result of the merge is [1,2,2,3,5,6] with the underlined elements coming from nums1.
```

Example 2:

```
Input: nums1 = [1], m = 1, nums2 = [], n = 0
Output: [1]
Explanation: The arrays we are merging are [1] and [].
The result of the merge is [1].
```

Example 3:

```
Input: nums1 = [0], m = 0, nums2 = [1], n = 1
Output: [1]
Explanation: The arrays we are merging are [] and [1].
The result of the merge is [1].
Note that because m = 0, there are no elements in nums1. The 0 is only there to ensure the merge result
can fit in nums1.
```

Constraints:

- `nums1.length == m + n`
- `nums2.length == n`
- `0 <= m, n <= 200`
- `1 <= m + n <= 200`
- -10^9 `<= nums1[i], nums2[j] <=` 10^9

Follow up: Can you come up with an algorithm that runs in `O(m + n)` time?

SOLUTION (PYTHON 3)

Solution 1: Two Pointers

How to think about it

The first idea is allocate another array, merge from the front, copy back into nums1. Correct, and m + n ≤ 200 is tiny, but that uses O(m + n) extra space and is not in-place. The bottleneck is writing from the left: it overwrites values in nums1 we have not consumed. The spare slots sit at the tail. So merge from the back. The tail of nums1 is empty; placing the current larger value there never steps on unread elements. Pointers i, j walk the two ends, k writes the merged end, until nums2 is exhausted.

We use two pointers i and j pointing to the end of two arrays, and a pointer k pointing to the end of the merged array.

Every time we compare the two elements at the end of the two arrays, and move the larger one to the end of the merged array. Then we move the pointer one step forward, and repeat this process until the two pointers reach the start of the arrays.

The time complexity is O(m + n), where m and n are the lengths of two arrays. The space complexity is O(1).

Python 3

```
class Solution:
    def merge(self, nums1: List[int], m: int, nums2: List[int], n: int) -> None:
        k = m + n - 1
        i, j = m - 1, n - 1
        while j >= 0:
            if i >= 0 and nums1[i] > nums2[j]:
                nums1[k] = nums1[i]
                i -= 1
            else:
                nums1[k] = nums2[j]
                j -= 1
            k -= 1
```

905. Sort Array By Parity

Easy · Array, Two Pointers, Sorting

leetcode.com/problems/sort-array-by-parity

★ **TOP 10 PROBLEM** in Sorting: master this one first

PROBLEM

Given an integer array `nums`, move all the even integers at the beginning of the array followed by all the odd integers.

Return ***any array*** *that satisfies this condition*.

Example 1:

```
Input: nums = [3,1,2,4]
Output: [2,4,3,1]
Explanation: The outputs [4,2,3,1], [2,4,1,3], and [4,2,1,3] would also be accepted.
```

Example 2:

```
Input: nums = [0]
Output: [0]
```

Constraints:

- `1 <= nums.length <= 5000`
- `0 <= nums[i] <= 5000`

SOLUTION (PYTHON 3)

Solution 1: Two Pointers

How to think about it

Even numbers should precede odds; relative order is free. An extra array would work, but the permutation can be done in place. Two pointers move inward: advance the left on an even, the right on an odd, otherwise swap. Each index is visited a constant number of times.

We use two pointers i and j to point to the beginning and end of the array respectively. When i < j, we perform the following operations.

- If nums[i] is even, then increment i by 1.
- If nums[j] is odd, then decrement j by 1.
- If nums[i] is odd and nums[j] is even, then swap nums[i] and nums[j]. Then increment i by 1, and decrement j by 1.

Finally, return the array nums.

The time complexity is O(n), where n is the length of the array nums. The space complexity is O(1).

Python 3

```python
class Solution:
    def sortArrayByParity(self, nums: List[int]) -> List[int]:
        i, j = 0, len(nums) - 1
        while i < j:
            if nums[i] % 2 == 0:
                i += 1
            elif nums[j] % 2 == 1:
                j -= 1
            else:
                nums[i], nums[j] = nums[j], nums[i]
                i, j = i + 1, j - 1
        return nums
```

PATTERN 23 · SORTING · PROBLEM 3 OF 20

1122. Relative Sort Array

Easy · Array, Hash Table, Bubble Sort, Counting Sort, Sorting, Quick Sort

leetcode.com/problems/relative-sort-array

★ **TOP 10 PROBLEM** in Sorting: master this one first

PROBLEM

Given two arrays `arr1` and `arr2`, the elements of `arr2` are distinct, and all elements in `arr2` are also in `arr1`.

Sort the elements of `arr1` such that the relative ordering of items in `arr1` are the same as in `arr2`. Elements that do not appear in `arr2` should be placed at the end of `arr1` in **ascending** order.

Example 1:

```
Input: arr1 = [2,3,1,3,2,4,6,7,9,2,19], arr2 = [2,1,4,3,9,6]
Output: [2,2,2,1,4,3,3,9,6,7,19]
```

Example 2:

```
Input: arr1 = [28,6,22,8,44,17], arr2 = [22,28,8,6]
Output: [22,28,8,6,17,44]
```

Constraints:

- `1 <= arr1.length, arr2.length <= 1000`
- `0 <= arr1[i], arr2[i] <= 1000`
- All the elements of `arr2` are **distinct**.
- Each `arr2[i]` is in `arr1`.

SOLUTIONS (PYTHON 3)

Solution 1: Custom Sorting

How to think about it

The sort key is the relative order in arr2; values absent from arr2 follow, sorted by themselves. A map stores each arr2 index; the comparator uses that index if present and 1000+x otherwise, so one sort handles both groups. Values in arr2 are unique, so indices are a stable order.

First, we use a hash table pos to record the position of each element in array arr2. Then, we map each element in array arr1 to a tuple (pos.get(x, 1000 + x), x), and sort these tuples. Finally, we take out the second element of all tuples and return it.

The time complexity is O(n × log n + m), and the space complexity is O(n + m). Here, n and m are the lengths of arrays arr1 and arr2, respectively.

Python 3

```python
class Solution:
    def relativeSortArray(self, arr1: List[int], arr2: List[int]) -> List[int]:
        pos = {x: i for i, x in enumerate(arr2)}
        return sorted(arr1, key=lambda x: pos.get(x, 1000 + x))
```

Solution 2: Counting Sort

> **How to think about it**
>
> Method 1's comparison sort is O(nlog n). When the value range is small, count frequencies in arr1, emit values in arr2 order, then scan the leftovers by value, which is linear.

We can use the idea of counting sort. First, count the occurrence of each element in array arr1. Then, according to the order in array arr2, put the elements in arr1 into the answer array ans according to their occurrence. Finally, we traverse all elements in arr1 and put the elements that do not appear in arr2 in ascending order at the end of the answer array ans.

The time complexity is O(n + m), and the space complexity is O(n). Where n and m are the lengths of arrays arr1 and arr2 respectively.

Python 3

```python
class Solution:
    def relativeSortArray(self, arr1: List[int], arr2: List[int]) -> List[int]:
        cnt = Counter(arr1)
        ans = []
        for x in arr2:
            ans.extend([x] * cnt[x])
            cnt.pop(x)
        mi, mx = min(arr1), max(arr1)
        for x in range(mi, mx + 1):
            ans.extend([x] * cnt[x])
        return ans
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

    return result
```

PATTERN 23 · SORTING · PROBLEM 4 OF 20

2418. Sort the People

Easy · Array, Hash Table, String, Sorting

leetcode.com/problems/sort-the-people

PROBLEM

You are given an array of strings `names`, and an array `heights` that consists of **distinct** positive integers. Both arrays are of length `n`.

For each index `i`, `names[i]` and `heights[i]` denote the name and height of the i^{th} person.

Return `names` *sorted in* ***descending*** *order by the people's heights*.

Example 1:

```
Input: names = ["Mary","John","Emma"], heights = [180,165,170]
Output: ["Mary","Emma","John"]
Explanation: Mary is the tallest, followed by Emma and John.
```

Example 2:

```
Input: names = ["Alice","Bob","Bob"], heights = [155,185,150]
Output: ["Bob","Alice","Bob"]
Explanation: The first Bob is the tallest, followed by Alice and the second Bob.
```

Constraints:

- `n == names.length == heights.length`
- `1 <= n <= 10^3`
- `1 <= names[i].length <= 20`
- `1 <= heights[i] <= 10^5`
- `names[i]` consists of lower and upper case English letters.
- All the values of `heights` are distinct.

SOLUTIONS (PYTHON 3)

Solution 1: Sorting

How to think about it

With n≤ 10^3, sort names by descending height. Heights are unique, so the key is total. Sort indices by heights descending, then emit names[i].

According to the problem description, we can create an index array idx of length n, where idx[i]=i. Then we sort each index in idx in descending order according to the corresponding height in heights. Finally, we traverse each index i in the sorted idx and add names[i] to the answer array.

We can also create an array arr of length n, where each element is a tuple (heights[i], i). Then we sort arr in descending order by height. Finally, we traverse each element (heights[i], i) in the sorted arr and add names[i] to the answer array.

The time complexity is O(n × log n), and the space complexity is O(n). Here, n is the length of the arrays names and heights.

Python 3

```python
class Solution:
    def sortPeople(self, names: List[str], heights: List[int]) -> List[str]:
        idx = list(range(len(heights)))
        idx.sort(key=lambda i: -heights[i])
        return [names[i] for i in idx]
```

Solution 2

> **How to think about it**
>
> Method 1 already sorts via an index array. Zipping height with name and sorting that pair descending removes the extra index array; the order is the same.

Python 3

```
class Solution:
    def sortPeople(self, names: List[str], heights: List[int]) -> List[str]:
        return [name for _, name in sorted(zip(heights, names), reverse=True)]
```

Complexity. Time: O(n log n). Space: O(n).

```

PATTERN 23 · SORTING · PROBLEM 5 OF 20

1636. Sort Array by Increasing Frequency

Easy · Array, Hash Table, Sorting

leetcode.com/problems/sort-array-by-increasing-frequency

PROBLEM

Given an array of integers `nums`, sort the array in **increasing** order based on the frequency of the values. If multiple values have the same frequency, sort them in **decreasing** order.

Return the *sorted array*.

Example 1:

```
Input: nums = [1,1,2,2,2,3]
Output: [3,1,1,2,2,2]
Explanation: '3' has a frequency of 1, '1' has a frequency of 2, and '2' has a frequency of 3.
```

Example 2:

```
Input: nums = [2,3,1,3,2]
Output: [1,3,3,2,2]
Explanation: '2' and '3' both have a frequency of 2, so they are sorted in decreasing order.
```

Example 3:

```
Input: nums = [-1,1,-6,4,5,-6,1,4,1]
Output: [5,-1,4,4,-6,-6,1,1,1]
```

Constraints:

- `1 <= nums.length <= 100`
- `-100 <= nums[i] <= 100`

SOLUTION (PYTHON 3)

Solution 1

How to think about it

The order is increasing frequency, then decreasing value on ties. n ≤ 100, so count then sort with a key. A counter (or a shifted array) yields cnt; the sort key is (cnt[x], -x).

Python 3

```python
class Solution:
    def frequencySort(self, nums: List[int]) -> List[int]:
        cnt = Counter(nums)
        return sorted(nums, key=lambda x: (cnt[x], -x))
```

Complexity. Time: O(n log n). Space: O(n).

# ============================================================

# ---- follow-up 2: function ----
# Answer: Python's sort is stable, so sorting only by the
# count keeps the original order of equal counts.
# Time: O(n log n).  Space: O(n).
def sort_by_frequency_stable(nums):
    count = {}
    for x in nums:
        count[x] = count.get(x, 0) + 1
    return sorted(nums, key=lambda x: count[x])
```

1356. Sort Integers by The Number of 1 Bits

Easy · Bit Manipulation, Array, Counting, Sorting

leetcode.com/problems/sort-integers-by-the-number-of-1-bits

PROBLEM

You are given an integer array `arr`. Sort the integers in the array in ascending order by the number of `1`'s in their binary representation and in case of two or more integers have the same number of `1`'s you have to sort them in ascending order.

Return *the array after sorting it*.

Example 1:

```
Input: arr = [0,1,2,3,4,5,6,7,8]
Output: [0,1,2,4,8,3,5,6,7]
Explantion: [0] is the only integer with 0 bits.
[1,2,4,8] all have 1 bit.
[3,5,6] have 2 bits.
[7] has 3 bits.
The sorted array by bits is [0,1,2,4,8,3,5,6,7]
```

Example 2:

```
Input: arr = [1024,512,256,128,64,32,16,8,4,2,1]
Output: [1,2,4,8,16,32,64,128,256,512,1024]
Explantion: All integers have 1 bit in the binary representation, you should just sort them in
ascending order.
```

Constraints:

- `1 <= arr.length <= 500`
- `0 <= arr[i] <= 10^4`

SOLUTION (PYTHON 3)

Solution 1: Custom Sorting

> **How to think about it**
>
> Order by the number of one-bits, then by the integer itself. The key (x.bit_count(), x) encodes both levels in one comparison.

We sort the array arr according to the requirements of the problem, that is, sort in ascending order according to the number of 1s in the binary representation. If there are multiple numbers with the same number of 1s in the binary representation, they must be sorted in ascending order by numerical value.

The time complexity is O(n log n), and the space complexity is O(n). Where n is the length of the array arr.

Python 3

```python
class Solution:
    def sortByBits(self, arr: List[int]) -> List[int]:
        return sorted(arr, key=lambda x: (x.bit_count(), x))
```

```

PATTERN 23 · SORTING · PROBLEM 8 OF 20

179. Largest Number

Medium · Greedy, Array, String, Sorting

leetcode.com/problems/largest-number

★ **TOP 10 PROBLEM** in Sorting: master this one first

PROBLEM

Given a list of non-negative integers `nums`, arrange them such that they form the largest number and return it.

Since the result may be very large, so you need to return a string instead of an integer.

Example 1:

```
Input: nums = [10,2]
Output: "210"
```

Example 2:

```
Input: nums = [3,30,34,5,9]
Output: "9534330"
```

Constraints:

- `1 <= nums.length <= 100`
- `0 <= nums[i] <= 10^9`

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Form the largest number by concatenation. Numeric order and plain lexicographic order both fail: 9 should precede 98 because 998>989. n≤ 100. Compare a+b with b+a to order two strings, sort by that, and join. If the first character is 0, every value was zero, so return "0".

Python 3

```python
class Solution:
    def largestNumber(self, nums: List[int]) -> str:
        nums = [str(v) for v in nums]
        nums.sort(key=cmp_to_key(lambda a, b: 1 if a + b < b + a else -1))
        return "0" if nums[0] == "0" else "".join(nums)
```

Complexity. Time: O(n log n * d), d = digits per number (at most 10). Space: O(n).

```

PATTERN 23 · SORTING · PROBLEM 12 OF 20

324. Wiggle Sort II

Medium · Greedy, Array, Divide and Conquer, Quickselect, Sorting

leetcode.com/problems/wiggle-sort-ii

Also appears in pattern 33 Cyclic Sort

PROBLEM

Given an integer array `nums`, reorder it such that `nums[0] < nums[1] > nums[2] < nums[3]...`.

You may assume the input array always has a valid answer.

Example 1:

```
Input: nums = [1,5,1,1,6,4]
Output: [1,6,1,5,1,4]
Explanation: [1,4,1,5,1,6] is also accepted.
```

Example 2:

```
Input: nums = [1,3,2,2,3,1]
Output: [2,3,1,3,1,2]
```

Constraints:

- `1 <= nums.length <= 5 * 10^4`
- `0 <= nums[i] <= 5000`
- It is guaranteed that there will be an answer for the given input `nums`.

Follow Up:

Can you do it in

`O(n)`

time and/or

in-place

with

`O(1)`

extra space?

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

We need nums[0]<nums[1]>nums[2]<… and may reorder in place. Sort, then fill even indices from the median downward and odd indices from the end downward. Reversed halves keep equal values from sitting next to each other.

Python 3

```python
class Solution:
    def wiggleSort(self, nums: List[int]) -> None:
        """
        Do not return anything, modify nums in-place instead.
        """
        arr = sorted(nums)
        n = len(arr)
        i, j = (n - 1) >> 1, n - 1
        for k in range(n):
            if k % 2 == 0:
                nums[k] = arr[i]
                i -= 1
            else:
                nums[k] = arr[j]
                j -= 1
```

Complexity. Time: O(n log n). Space: O(n).

Solution 2

> **How to think about it**
>
> Method 1 sorts in O(nlog n) and uses an extra array. Values lie in [0,5000]: count-sort, then emit large values onto odd indices first and even indices next. Peaks get large numbers in linear time.

Python 3

```python
class Solution:
    def wiggleSort(self, nums: List[int]) -> None:
        """
        Do not return anything, modify nums in-place instead.
        """
        bucket = [0] * 5001
        for v in nums:
            bucket[v] += 1
        n = len(nums)
        j = 5000
        for i in range(1, n, 2):
            while bucket[j] == 0:
                j -= 1
            nums[i] = j
            bucket[j] -= 1
        for i in range(0, n, 2):
            while bucket[j] == 0:
                j -= 1
            nums[i] = j
            bucket[j] -= 1
```

PATTERN 23 · SORTING · PROBLEM 14 OF 20

164. Maximum Gap

Medium · Array, Bucket Sort, Radix Sort, Sorting, Pigeonhole Principle

leetcode.com/problems/maximum-gap

★ **TOP 10 PROBLEM** in Sorting: master this one first

PROBLEM

Given an integer array `nums`, return *the maximum difference between two successive elements in its sorted form*. If the array contains less than two elements, return `0`.

You must write an algorithm that runs in linear time and uses linear extra space.

Example 1:

```
Input: nums = [3,6,9,1]
Output: 3
Explanation: The sorted form of the array is [1,3,6,9], either (3,6) or (6,9) has the maximum
difference 3.
```

Example 2:

```
Input: nums = [10]
Output: 0
Explanation: The array contains less than 2 elements, therefore return 0.
```

Constraints:

- `1 <= nums.length <= 10^5`
- `0 <= nums[i] <= 10^9`

SOLUTION (PYTHON 3)

Solution 1: Bucket Sort

How to think about it

Maximum gap after sorting, in linear time. Comparison sorts are O(nlog n); n≤ 10^5. The max adjacent gap is at least (max-min)/(n-1). Bucket by that width: gaps inside a bucket are smaller than this lower bound, so the answer is between consecutive non-empty buckets (next min minus previous max). Each bucket stores only min and max.

Suppose nums has n elements. After sorting them into $nums_0 \le \dots \le nums_{n-1}$, the maximum adjacent gap maxGap satisfies

$$nums_{n-1} - nums_0 = \sum_{i=1}^{n-1}(nums_i - nums_{i-1}) \le maxGap \times (n-1).$$

Hence $maxGap \ge (nums_{n-1} - nums_0)/(n-1)$.

Use that lower bound as the bucket width, and at least 1 when every value is equal. Values that fall in the same bucket differ by less than maxGap, so a gap of size maxGap always crosses two buckets. Each bucket keeps only its minimum and its maximum, initialized to +∞ and -∞ to mark an empty bucket.

Place every value v into bucket floor((v - min) / bucketSize). Smaller indices then hold smaller values. Scan the buckets from left to right. The minimum of the current non-empty bucket and the maximum of the previous non-empty bucket are adjacent in sorted order; their difference updates the answer. There is no gap before the first non-empty bucket.

The time complexity is O(n), and the space complexity is O(n), where n is the length of nums.

Python 3

```python
class Solution:
    def maximumGap(self, nums: List[int]) -> int:
        n = len(nums)
        if n < 2:
            return 0
        mi, mx = min(nums), max(nums)
        bucket_size = max(1, (mx - mi) // (n - 1))
        bucket_count = (mx - mi) // bucket_size + 1
        buckets = [[inf, -inf] for _ in range(bucket_count)]
        for v in nums:
            i = (v - mi) // bucket_size
            buckets[i][0] = min(buckets[i][0], v)
            buckets[i][1] = max(buckets[i][1], v)
        ans = 0
        prev = inf
        for curmin, curmax in buckets:
            if curmin > curmax:
                continue
            ans = max(ans, curmin - prev)
            prev = curmax
        return ans
```

791. Custom Sort String

Medium · Hash Table, String, Sorting

leetcode.com/problems/custom-sort-string

PROBLEM

You are given two strings `order` and `s`. All the characters of `order` are **unique** and were sorted in some custom order previously.

Permute the characters of `s` so that they match the order that `order` was sorted. More specifically, if a character `x` occurs before a character `y` in `order`, then `x` should occur before `y` in the permuted string.

Return *any permutation of* `s` *that satisfies this property*.

Example 1:

Input: order = "cba", s = "abcd"

Output: "cbad"

Explanation: `"a"`, `"b"`, `"c"` appear in order, so the order of `"a"`, `"b"`, `"c"` should be `"c"`, `"b"`, and `"a"`.

Since `"d"` does not appear in `order`, it can be at any position in the returned string. `"dcba"`, `"cdba"`, `"cbda"` are also valid outputs.

Example 2:

Input: order = "bcafg", s = "abcd"

Output: "bcad"

Explanation: The characters `"b"`, `"c"`, and `"a"` from `order` dictate the order for the characters in `s`. The character `"d"` in `s` does not appear in `order`, so its position is flexible.

Following the order of appearance in `order`, `"b"`, `"c"`, and `"a"` from `s` should be arranged as `"b"`, `"c"`, `"a"`. `"d"` can be placed at any position since it's not in order. The output `"bcad"` correctly follows this rule. Other arrangements like `"dbca"` or `"bcda"` would also be valid, as long as `"b"`, `"c"`, `"a"` maintain their order.

Constraints:

- `1 <= order.length <= 26`
- `1 <= s.length <= 200`
- `order` and `s` consist of lowercase English letters.
- All the characters of `order` are **unique**.

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

Reorder s by the relative order in order. Sorting by the index in order does that. Missing letters get key 0 and gather at the front, which is allowed.

Python 3

```python
class Solution:
    def customSortString(self, order: str, s: str) -> str:
        d = {c: i for i, c in enumerate(order)}
        return ''.join(sorted(s, key=lambda x: d.get(x, 0)))
```

Complexity. Time: O(n log n). Space: O(n).

Solution 2

> **How to think about it**
>
> Sorting is nlog n. Count s, emit each order character that many times, then append the rest. Linear.

Python 3

```
class Solution:
    def customSortString(self, order: str, s: str) -> str:
        cnt = Counter(s)
        ans = []
        for c in order:
            ans.append(c * cnt[c])
            cnt[c] = 0
        for c, v in cnt.items():
            ans.append(c * v)
        return ''.join(ans)
```

Complexity. Time: O(n + m), m = len(order). Space: O(C), C = 26 letters (plus the answer).

    return True
```

PATTERN 23 · SORTING · PROBLEM 16 OF 20

274. H-Index

Medium · Array, Counting Sort, Sorting

leetcode.com/problems/h-index

PROBLEM

Given an array of integers `citations` where `citations[i]` is the number of citations a researcher received for their i^{th} paper, return *the researcher's h-index*.

According to the definition of h-index on Wikipedia: The h-index is defined as the maximum value of `h` such that the given researcher has published at least `h` papers that have each been cited at least `h` times.

Example 1:

```
Input: citations = [3,0,6,1,5]
Output: 3
Explanation: [3,0,6,1,5] means the researcher has 5 papers in total and each of them had received 3, 0, 6, 1, 5 citations respectively.
Since the researcher has 3 papers with at least 3 citations each and the remaining two with no more than 3 citations each, their h-index is 3.
```

Example 2:

```
Input: citations = [1,3,1]
Output: 1
```

Constraints:

- `n == citations.length`
- `1 <= n <= 5000`
- `0 <= citations[i] <= 1000`

SOLUTIONS (PYTHON 3)

Solution 1: Sorting

> **How to think about it**
>
> The h-index is the largest h such that at least h papers have ≥ h citations. After sorting descending, citations[h-1]≥ h is the test; search h from large to small.

We can sort the array `citations` in descending order. Then we enumerate the value h from large to small, if there is an h value satisfying citations[h-1] ≥ h, it means that there are at least h papers that have been cited at least h times, just return h directly. If we cannot find such an h value, it means that all the papers have not been cited, return 0.

Time complexity O(n × log n), space complexity O(log n). Here n is the length of the array `citations`.

Python 3

```python
class Solution:
    def hIndex(self, citations: List[int]) -> int:
        citations.sort(reverse=True)
        for h in range(len(citations), 0, -1):
            if citations[h - 1] >= h:
                return h
        return 0
```

Solution 2: Counting + Sum

> **How to think about it**
>
> Sorting is O(nlog n). h≤ n, so cap citations at n, count, and accumulate from high to low until s≥ h.

We can use an array cnt of length n+1, where cnt[i] represents the number of papers with the reference count of i. We traverse the array `citations` and treat the papers with the reference count greater than n as papers with a reference count of n. Then we use the reference count as the index and add 1 to the corresponding element of cnt for each paper. In this way, we have counted the number of papers for each reference count.

Then we enumerate the value h from large to small, and add the element value of cnt with the index of h to the variable s, where s represents the number of papers with a reference count greater than or equal to h. If s ≥ h, it means that at least h papers have been cited at least h times, just return h directly.

Time complexity O(n), space complexity O(n). Here n is the length of the array `citations`.

Python 3

```
class Solution:
    def hIndex(self, citations: List[int]) -> int:
        n = len(citations)
        cnt = [0] * (n + 1)
        for x in citations:
            cnt[min(x, n)] += 1
        s = 0
        for h in range(n, -1, -1):
            s += cnt[h]
            if s >= h:
                return h
```

Solution 3: Binary Search

> **How to think about it**
>
> The predicate “at least h papers have ≥ h citations” is monotone, so we binary-search the largest feasible h by counting values ≥ mid.

We notice that if there is a h value that satisfies at least h papers are cited at least h times, then for any h'<h, at least h' papers are cited at least h' times. Therefore, we can use the binary search method to find the largest h such that at least h papers are cited at least h times.

We define the left boundary of binary search l=0 and the right boundary r=n. Each time we take mid = floor((l + r + 1)/2), where floor(x) represents floor x. Then we count the number of elements in array `citations` that are greater than or equal to mid, and denote it as s. If s ≥ mid, it means that at least mid papers are cited at least mid times. In this case, we change the left boundary l to mid. Otherwise, we change the right boundary r to mid-1. When the left boundary l is equal to the right boundary r, we find the largest h value, which is l or r.

Time complexity O(n × log n), where n is the length of array `citations`. Space complexity O(1).

Python 3

```
class Solution:
    def hIndex(self, citations: List[int]) -> int:
        l, r = 0, len(citations)
        while l < r:
            mid = (l + r + 1) >> 1
            if sum(x >= mid for x in citations) >= mid:
                l = mid
            else:
                r = mid - 1
        return l
```

```

PATTERN 23 · SORTING · PROBLEM 17 OF 20

945. Minimum Increment to Make Array Unique

Medium · Greedy, Array, Counting, Sorting

leetcode.com/problems/minimum-increment-to-make-array-unique

PROBLEM

You are given an integer array `nums`. In one move, you can pick an index `i` where `0 <= i < nums.length` and increment `nums[i]` by `1`.

Return *the minimum number of moves to make every value in* `nums` ***unique***.

The test cases are generated so that the answer fits in a 32-bit integer.

Example 1:

```
Input: nums = [1,2,2]
Output: 1
Explanation: After 1 move, the array could be [1, 2, 3].
```

Example 2:

```
Input: nums = [3,2,1,2,1,7]
Output: 6
Explanation: After 6 moves, the array could be [3, 4, 1, 2, 5, 7].
It can be shown that it is impossible for the array to have all unique values with 5 or less moves.
```

Constraints:

- `1 <= nums.length <= 10^5`
- `0 <= nums[i] <= 10^5`

SOLUTIONS (PYTHON 3)

Solution 1: Sorting + Greedy

> **How to think about it**
>
> Each move increments one element; we want all values distinct at minimum cost. After sorting, each x should occupy the next free slot y. Set y←max(y+1,x) and add y-x.

First, we sort the array nums, and use a variable y to record the current maximum value, initially y = -1.

Then, we iterate through the array nums. For each element x, we update y to max(y + 1, x), and accumulate the operation count y - x into the result.

After completing the iteration, we return the result.

The time complexity is O(n log n), and the space complexity is O(log n). Here, n is the length of the array nums.

Python 3

```python
class Solution:
    def minIncrementForUnique(self, nums: List[int]) -> int:
        nums.sort()
        ans, y = 0, -1
        for x in nums:
            y = max(y + 1, x)
            ans += y - x
        return ans
```

Solution 2: Counting + Greedy

> **How to think about it**
>
> Sorting costs O(nlog n). With an upper bound m=max+n, a count array works: from low to high, the surplus cnt[i]-1 copies of i move to i+1, a linear sweep of the range.

According to the problem description, the maximum value of the result array m = max(nums) + len(nums). We can use a counting array cnt to record the occurrence count of each element.

Then, we iterate from 0 to m - 1. For each element i, if its occurrence count cnt[i] is greater than 1, then we add cnt[i] - 1 elements to i + 1, and accumulate the operation count into the result.

After completing the iteration, we return the result.

The time complexity is O(m), and the space complexity is O(m). Here, m is the length of the array nums plus the maximum value in the array.

Python 3

```python
class Solution:
    def minIncrementForUnique(self, nums: List[int]) -> int:
        m = max(nums) + len(nums)
        cnt = Counter(nums)
        ans = 0
        for i in range(m - 1):
            if (diff := cnt[i] - 1) > 0:
                cnt[i + 1] += diff
                ans += diff
        return ans
```

            moves += extras                         # every remaining copy moves one step up
    return moves
```

969. Pancake Sorting

Medium · Greedy, Array, Two Pointers, Sorting

leetcode.com/problems/pancake-sorting

PROBLEM

Given an array of integers `arr`, sort the array by performing a series of **pancake flips**.

In one pancake flip we do the following steps:

- Choose an integer `k` where `1 <= k <= arr.length`.
- Reverse the sub-array `arr[0...k-1]` (**0-indexed**).

For example, if `arr = [3,2,1,4]` and we performed a pancake flip choosing `k = 3`, we reverse the sub-array `[3,2,1]`, so `arr = [1,2,3,4]` after the pancake flip at `k = 3`.

Return *an array of the* `k`*-values corresponding to a sequence of pancake flips that sort* `arr`. Any valid answer that sorts the array within `10 * arr.length` flips will be judged as correct.

Example 1:

```
Input: arr = [3,2,4,1]
Output: [4,2,4,3]
Explanation:
We perform 4 pancake flips, with k values 4, 2, 4, and 3.
Starting state: arr = [3, 2, 4, 1]
After 1st flip (k = 4): arr = [1, 4, 2, 3]
After 2nd flip (k = 2): arr = [4, 1, 2, 3]
After 3rd flip (k = 4): arr = [3, 2, 1, 4]
After 4th flip (k = 3): arr = [1, 2, 3, 4], which is sorted.
```

Example 2:

```
Input: arr = [1,2,3]
Output: []
Explanation: The input is already sorted, so there is no need to flip anything.
Note that other answers, such as [3, 3], would also be accepted.
```

Constraints:

- `1 <= arr.length <= 100`
- `1 <= arr[i] <= arr.length`
- All integers in `arr` are unique (i.e. `arr` is a permutation of the integers from `1` to `arr.length`).

SOLUTION (PYTHON 3)

Solution 1

How to think about it

A pancake flip reverses a prefix. The array is a permutation of 1..n, so we can place values from large to small: flip k to the front, then flip it to its final index k. Record the two prefix lengths. A suffix that is already placed is left untouched.

Python 3

```
class Solution:
    def pancakeSort(self, arr: List[int]) -> List[int]:
        def reverse(arr, j):
            i = 0
            while i < j:
                arr[i], arr[j] = arr[j], arr[i]
                i, j = i + 1, j - 1

        n = len(arr)
        ans = []
        for i in range(n - 1, 0, -1):
            j = i
            while j > 0 and arr[j] != i + 1:
                j -= 1
            if j < i:
                if j > 0:
                    ans.append(j + 1)
                    reverse(arr, j)
                ans.append(i + 1)
                reverse(arr, i)
        return ans
```

Complexity. Time: O(n^2). Space: O(1) extra (the answer is O(n)).

```

PATTERN 23 · SORTING · PROBLEM 19 OF 20

1329. Sort the Matrix Diagonally

Medium · Array, Matrix, Sorting

leetcode.com/problems/sort-the-matrix-diagonally

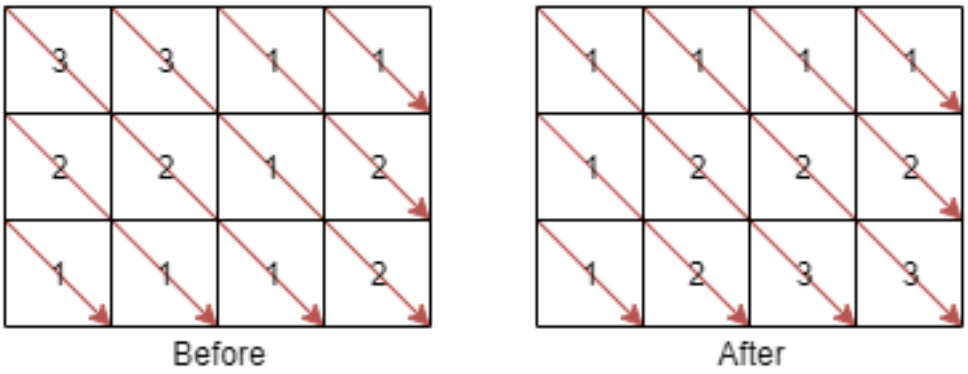
Also appears in pattern 38 K-way Merge

PROBLEM

A **matrix diagonal** is a diagonal line of cells starting from some cell in either the topmost row or leftmost column and going in the bottom-right direction until reaching the matrix's end. For example, the **matrix diagonal** starting from `mat[2][0]`, where `mat` is a `6 x 3` matrix, includes cells `mat[2][0]`, `mat[3][1]`, and `mat[4][2]`.

Given an `m x n` matrix `mat` of integers, sort each **matrix diagonal** in ascending order and return *the resulting matrix*.

Example 1:



```
Input: mat = [[3,3,1,1],[2,2,1,2],[1,1,1,2]]
Output: [[1,1,1,1],[1,2,2,2],[1,2,3,3]]
```

Example 2:

```
Input: mat =
[[11,25,66,1,69,7],[23,55,17,45,15,52],[75,31,36,44,58,8],[22,27,33,25,68,4],[84,28,14,11,5,50]]
Output:
[[5,17,4,1,52,7],[11,11,25,45,8,69],[14,23,25,44,58,15],[22,27,31,36,50,66],[84,28,75,33,55,68]]
```

Constraints:

- `m == mat.length`
- `n == mat[i].length`
- `1 <= m, n <= 100`
- `1 <= mat[i][j] <= 100`

SOLUTION (PYTHON 3)

Solution 1: Sorting

How to think about it

Cells on one diagonal share j-i. Extract each diagonal, sort it, and write it back. Mapping by m-i+j gives a nonnegative bucket; sorting those buckets in reverse and popping while scanning restores increasing order from top-left to bottom-right.

We can treat each diagonal of the matrix as an array, sort these arrays, and then fill the sorted elements back into the original matrix.

Specifically, we denote the number of rows in the matrix as m and the number of columns as n. Since any two elements (i_1, j_1) and (i_2, j_2) on the same diagonal satisfy $j_1 - i_1 = j_2 - i_2$, we can determine each diagonal based on the value of j - i. To ensure the value is positive, we add an offset m, that is, m - i + j.

Finally, we fill the sorted elements of each diagonal back into the original matrix.

The time complexity is O(m × n × log min(m, n)), and the space complexity is O(m × n). Where m and n are the number of rows and columns in the matrix, respectively.

Python 3

```python
class Solution:
    def diagonalSort(self, mat: List[List[int]]) -> List[List[int]]:
        m, n = len(mat), len(mat[0])
        g = [[] for _ in range(m + n)]
        for i, row in enumerate(mat):
            for j, x in enumerate(row):
                g[m - i + j].append(x)
        for e in g:
            e.sort(reverse=True)
        for i in range(m):
            for j in range(n):
                mat[i][j] = g[m - i + j].pop()
        return mat
```

141. Linked List Cycle

Easy · Hash Table, Linked List, Two Pointers, Floyd Cycle Detection

leetcode.com/problems/linked-list-cycle

★ **TOP 10 PROBLEM** in Fast & Slow Pointers (Linked List): master this one first

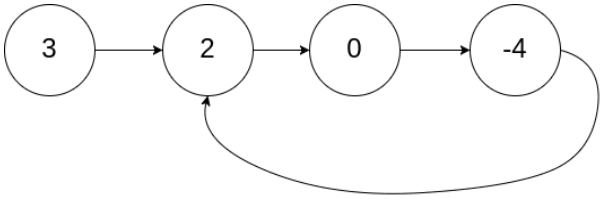
PROBLEM

Given `head`, the head of a linked list, determine if the linked list has a cycle in it.

There is a cycle in a linked list if there is some node in the list that can be reached again by continuously following the `next` pointer. Internally, `pos` is used to denote the index of the node that tail's `next` pointer is connected to. **Note that `pos` is not passed as a parameter**.

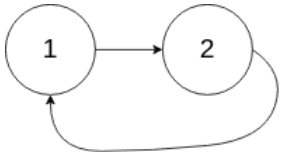
Return `true` *if there is a cycle in the linked list*. Otherwise, return `false`.

Example 1:



```
Input: head = [3,2,0,-4], pos = 1
Output: true
Explanation: There is a cycle in the linked list, where the tail connects to the 1st node (0-indexed).
```

Example 2:



```
Input: head = [1,2], pos = 0
Output: true
Explanation: There is a cycle in the linked list, where the tail connects to the 0th node.
```

Example 3:

```
Input: head = [1], pos = -1
Output: false
Explanation: There is no cycle in the linked list.
```

Constraints:

- The number of the nodes in the list is in the range `[0, 10^4]`.
- `-10^5 <= Node.val <= 10^5`
- `pos` is `-1` or a **valid index** in the linked-list.

Follow up: Can you solve it using `O(1)` (i.e. constant) memory?

SOLUTIONS (PYTHON 3)

Solution 1: Hash Table

> **How to think about it**
>
> Detect a cycle. n≤ 10^4. Store visited nodes in a set; a repeat means a cycle, null means none. Simple, O(n) space. The follow-up asks for constant space.

We can traverse the linked list and use a hash table s to record each node. When a node appears for the second time, it indicates that there is a cycle, and we directly return `true`. Otherwise, when the linked list traversal ends, we return `false`.

The time complexity is O(n), and the space complexity is O(n), where n is the number of nodes in the linked list.

Python 3

```
# Definition for singly-linked list.
# class ListNode:
#     def __init__(self, x):
#         self.val = x
#         self.next = None

class Solution:
    def hasCycle(self, head: Optional[ListNode]) -> bool:
        s = set()
        while head:
            if head in s:
                return True
            s.add(head)
            head = head.next
        return False
```

Solution 2: Fast and Slow Pointers

> **How to think about it**
>
> Solution 1 uses linear extra space. A fast pointer of two steps and a slow pointer of one must meet inside a cycle, or the fast pointer hits the end. Only two pointers.

We define two pointers, fast and slow, both initially pointing to head.

The fast pointer moves two steps at a time, and the slow pointer moves one step at a time, in a continuous loop. When the fast and slow pointers meet, it indicates that there is a cycle in the linked list. If the loop ends without the pointers meeting, it indicates that there is no cycle in the linked list.

The time complexity is O(n), and the space complexity is O(1), where n is the number of nodes in the linked list.

Python 3

```
# Definition for singly-linked list.
# class ListNode:
#     def __init__(self, x):
#         self.val = x
#         self.next = None

class Solution:
    def hasCycle(self, head: ListNode) -> bool:
        slow = fast = head
        while fast and fast.next:
            slow, fast = slow.next, fast.next.next
            if slow == fast:
                return True
        return False
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

        seen.add(node)
        node = node.next
    return False
```

PATTERN 24 · FAST & SLOW POINTERS (LINKED LIST) · PROBLEM 2 OF 20

876. Middle of the Linked List

Easy · Linked List, Two Pointers

leetcode.com/problems/middle-of-the-linked-list

★ **TOP 10 PROBLEM** in Fast & Slow Pointers (Linked List): master this one first

PROBLEM

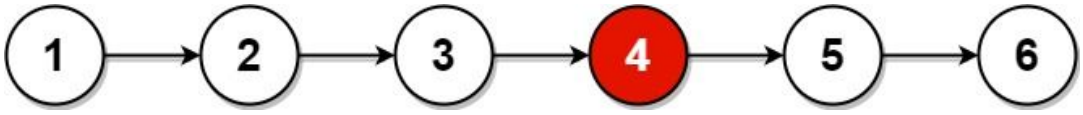
Given the `head` of a singly linked list, return *the middle node of the linked list*.

If there are two middle nodes, return **the second middle** node.

Example 1:

```
Input: head = [1,2,3,4,5]
Output: [3,4,5]
Explanation: The middle node of the list is node 3.
```

Example 2:



```
Input: head = [1,2,3,4,5,6]
Output: [4,5,6]
Explanation: Since the list has two middle nodes with values 3 and 4, we return the second one.
```

Constraints:

- The number of nodes in the list is in the range `[1, 100]`.
- `1 <= Node.val <= 100`

SOLUTION (PYTHON 3)

Solution 1: Fast and Slow Pointers

How to think about it

Return the middle node, the later one when the length is even. Counting the length then walking half needs two passes. A fast pointer moves two steps and a slow pointer one; when the fast pointer ends, the slow pointer is at the middle. One walk is enough.

We define two pointers fast and slow, both initially pointing to the head of the linked list.

The fast pointer fast moves two steps at a time, while the slow pointer slow moves one step at a time. When the fast pointer reaches the end of the linked list, the node pointed to by the slow pointer is the middle node.

The time complexity is O(n), where n is the length of the linked list. The space complexity is O(1).

Python 3

```
# Definition for singly-linked list.
# class ListNode:
#     def __init__(self, val=0, next=None):
#         self.val = val
#         self.next = next
class Solution:
    def middleNode(self, head: ListNode) -> ListNode:
        slow = fast = head
        while fast and fast.next:
            slow, fast = slow.next, fast.next.next
        return slow
```

# it.
# Time: O(n).  Space: O(1).
def split_in_halves(head):
    if head is None:
        return None, None
    slow = fast = head
    while fast.next and fast.next.next:
        slow = slow.next
        fast = fast.next.next
    second = slow.next
    slow.next = None
    return head, second
```

202. Happy Number

Easy · Hash Table, Math, Two Pointers, Floyd Cycle Detection

leetcode.com/problems/happy-number

Also appears in pattern 34 Math / Number Theory

PROBLEM

Write an algorithm to determine if a number `n` is happy.

A **happy number** is a number defined by the following process:

- Starting with any positive integer, replace the number by the sum of the squares of its digits.
- Repeat the process until the number equals 1 (where it will stay), or it **loops endlessly in a cycle** which does not include 1.
- Those numbers for which this process **ends in 1** are happy.

Return `true` *if* `n` *is a happy number, and* `false` *if not*.

Example 1:

```
Input: n = 19
Output: true
Explanation:
12 + 92 = 82
82 + 22 = 68
62 + 82 = 100
12 + 02 + 02 = 1
```

Example 2:

```
Input: n = 2
Output: false
```

Constraints:

- $1 <= n <= 2^{31} - 1$

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

Repeatedly replacing a number by the sum of squares of its digits follows the definition, but the sequence may cycle instead of reaching 1. The values quickly fall into a bounded range, so a hash set can record numbers already seen. A repeat means a cycle (not happy); reaching 1 means it is happy. Simulation and cycle checks run together.

Python 3

```python
class Solution:
    def isHappy(self, n: int) -> bool:
        vis = set()
        while n != 1 and n not in vis:
            vis.add(n)
            x = 0
            while n:
                n, v = divmod(n, 10)
                x += v * v
            n = x
        return n == 1
```

Complexity. Time: O(log n). Space: O(log n).

Solution 2

How to think about it

The hash set is correct but uses extra memory. The square-sum map is a deterministic iteration, so a cycle can be found without storing the full history. Floyd's pointers suffice: the slow pointer moves once and the fast pointer twice; if they meet at 1, the number is happy, and space becomes constant.

Python 3

```python
class Solution:
    def isHappy(self, n: int) -> bool:
        def next(x):
            y = 0
            while x:
                x, v = divmod(x, 10)
                y += v * v
            return y

        slow, fast = n, next(n)
        while slow != fast:
            slow, fast = next(slow), next(next(fast))
        return slow == 1
```

Complexity. Time: O(log n). Space: O(1).

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

```

PATTERN 24 · FAST & SLOW POINTERS (LINKED LIST) · PROBLEM 4 OF 20

234. Palindrome Linked List

Easy · Stack, Recursion, Linked List, Two Pointers

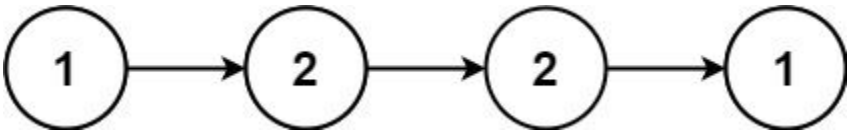
leetcode.com/problems/palindrome-linked-list

★ **TOP 10 PROBLEM** in Fast & Slow Pointers (Linked List): master this one first

PROBLEM

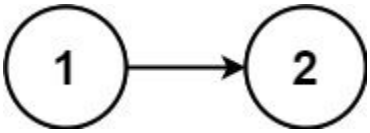
Given the `head` of a singly linked list, return `true` *if it is a palindrome or* `false` *otherwise*.

Example 1:



```
Input: head = [1,2,2,1]
Output: true
```

Example 2:



```
Input: head = [1,2]
Output: false
```

Constraints:

- The number of nodes in the list is in the range `[1, 10^5]`.
- `0 <= Node.val <= 9`

Follow up:

Could you do it in

`O(n)`

time and

`O(1)`

space?

SOLUTION (PYTHON 3)

Solution 1: Fast and Slow Pointers

How to think about it

Copying values into an array works, but we want constant extra space. A palindrome is symmetric about the midpoint, so we find the middle, reverse the second half, and compare. Slow/fast pointers locate the mid; the second half is reversed in place and compared with the first half.

We can use fast and slow pointers to find the middle of the linked list, then reverse the right half of the list. After that, we traverse both halves simultaneously, checking if the corresponding node values are equal. If any pair of values is unequal, it's not a palindrome linked list; otherwise, it is a palindrome linked list.

The time complexity is O(n), where n is the length of the linked list. The space complexity is O(1).

Python 3

```
# Definition for singly-linked list.
# class ListNode:
#     def __init__(self, val=0, next=None):
#         self.val = val
#         self.next = next
class Solution:
    def isPalindrome(self, head: Optional[ListNode]) -> bool:
        slow, fast = head, head.next
        while fast and fast.next:
            slow, fast = slow.next, fast.next.next
        pre, cur = None, slow.next
        while cur:
            t = cur.next
            cur.next = pre
            pre, cur = cur, t
        while pre:
            if pre.val != head.val:
                return False
            pre, head = pre.next, head.next
        return True
```

```

160. Intersection of Two Linked Lists

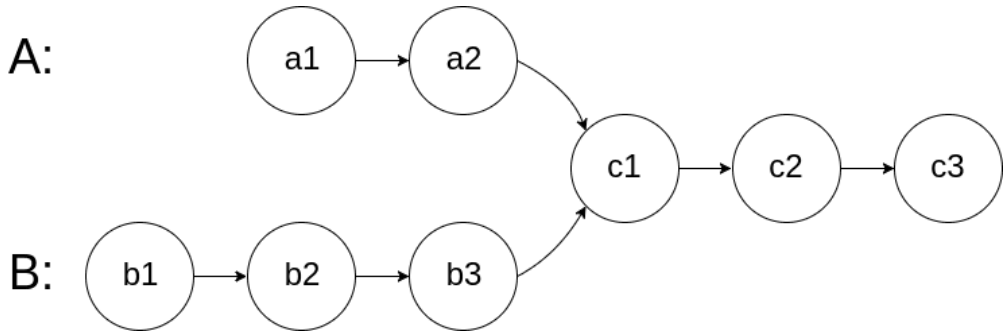
Easy · Hash Table, Linked List, Two Pointers

leetcode.com/problems/intersection-of-two-linked-lists

PROBLEM

Given the heads of two singly linked-lists `headA` and `headB`, return *the node at which the two lists intersect*. If the two linked lists have no intersection at all, return `null`.

For example, the following two linked lists begin to intersect at node `c1`:



The test cases are generated such that there are no cycles anywhere in the entire linked structure.

Note that the linked lists must **retain their original structure** after the function returns.

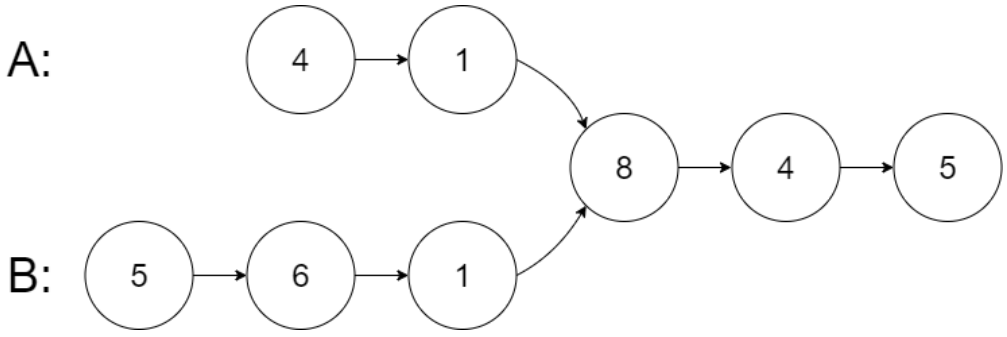
Custom Judge:

The inputs to the **judge** are given as follows (your program is **not** given these inputs):

- `intersectVal` - The value of the node where the intersection occurs. This is `0` if there is no intersected node.
- `listA` - The first linked list.
- `listB` - The second linked list.
- `skipA` - The number of nodes to skip ahead in `listA` (starting from the head) to get to the intersected node.
- `skipB` - The number of nodes to skip ahead in `listB` (starting from the head) to get to the intersected node.

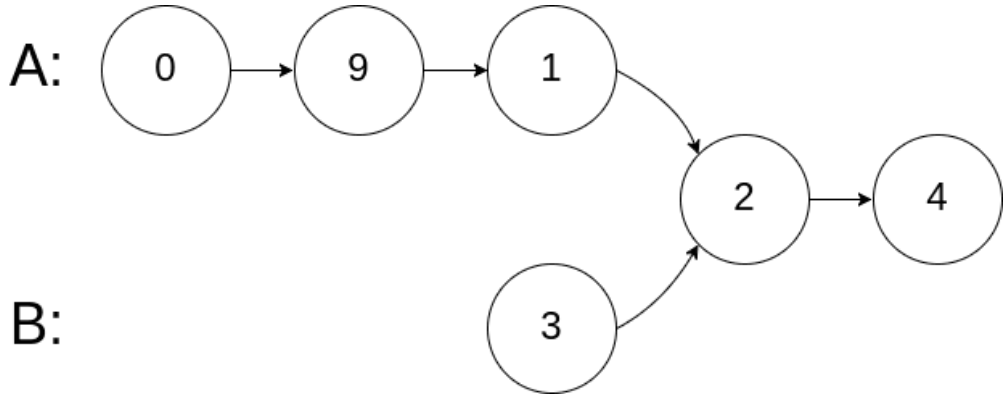
The judge will then create the linked structure based on these inputs and pass the two heads, `headA` and `headB` to your program. If you correctly return the intersected node, then your solution will be **accepted**.

Example 1:



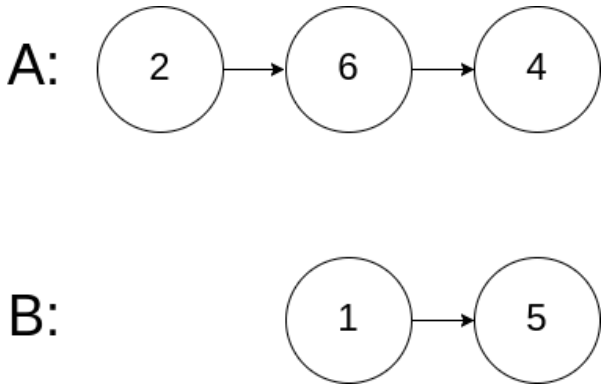
Input: intersectVal = 8, listA = [4,1,8,4,5], listB = [5,6,1,8,4,5], skipA = 2, skipB = 3
Output: Intersected at '8'
Explanation: The intersected node's value is 8 (note that this must not be 0 if the two lists intersect).
From the head of A, it reads as [4,1,8,4,5]. From the head of B, it reads as [5,6,1,8,4,5]. There are 2 nodes before the intersected node in A; There are 3 nodes before the intersected node in B.
- Note that the intersected node's value is not 1 because the nodes with value 1 in A and B (2nd node in A and 3rd node in B) are different node references. In other words, they point to two different locations in memory, while the nodes with value 8 in A and B (3rd node in A and 4th node in B) point to the same location in memory.

Example 2:



Input: intersectVal = 2, listA = [1,9,1,2,4], listB = [3,2,4], skipA = 3, skipB = 1
Output: Intersected at '2'
Explanation: The intersected node's value is 2 (note that this must not be 0 if the two lists intersect).
From the head of A, it reads as [1,9,1,2,4]. From the head of B, it reads as [3,2,4]. There are 3 nodes before the intersected node in A; There are 1 node before the intersected node in B.

Example 3:



Input: intersectVal = 0, listA = [2,6,4], listB = [1,5], skipA = 3, skipB = 2
Output: No intersection
Explanation: From the head of A, it reads as [2,6,4]. From the head of B, it reads as [1,5]. Since the two lists do not intersect, intersectVal must be 0, while skipA and skipB can be arbitrary values.
Explanation: The two lists do not intersect, so return null.

Constraints:

- The number of nodes of `listA` is in the `m`.
- The number of nodes of `listB` is in the `n`.
- `1 <= m, n <= 3 * 10^4`
- `1 <= Node.val <= 10^5`
- `0 <= skipA <= m`

- `0 <= skipB <= n`
- `intersectVal` is `0` if `listA` and `listB` do not intersect.
- `intersectVal == listA[skipA] == listB[skipB]` if `listA` and `listB` intersect.

Follow up:

Could you write a solution that runs in

`O(m + n)`

time and use only

`O(1)`

memory?

SOLUTION (PYTHON 3)

Solution 1: Two Pointers

> **How to think about it**
>
> Find the first common node. Storing one list in a set is O(m+n) time and O(m) space; the follow-up wants O(1) memory. $m,n \leq 3 \times 10^4$. Each pointer walks its list then the other, so both travel a+b. They meet at the intersection, or both hit null. No need to measure lengths first.

We use two pointers a and b to point to the heads of the two linked lists headA and headB, respectively.

Traverse the linked lists simultaneously. When a reaches the end of headA, redirect it to the head of headB. Similarly, when b reaches the end of headB, redirect it to the head of headA.

If the two pointers meet, the node they point to is the first common node. If they do not meet, it means the two linked lists have no common nodes, and both pointers will point to `null`. Return either pointer.

The time complexity is O(m + n), where m and n are the lengths of the linked lists headA and headB, respectively. The space complexity is O(1).

Python 3

```
# Definition for singly-linked list.
# class ListNode:
#     def __init__(self, x):
#         self.val = x
#         self.next = None

class Solution:
    def getIntersectionNode(self, headA: ListNode, headB: ListNode) -> ListNode:
        a, b = headA, headB
        while a != b:
            a = a.next if a else headB
            b = b.next if b else headA
        return a
```

```

83. Remove Duplicates from Sorted List

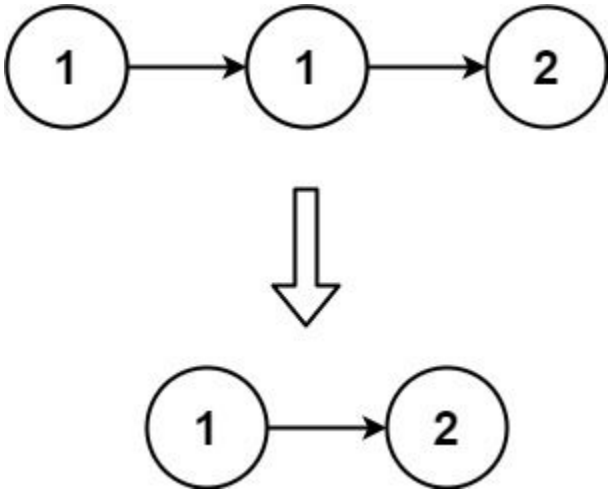
Easy · Linked List

leetcode.com/problems/remove-duplicates-from-sorted-list

PROBLEM

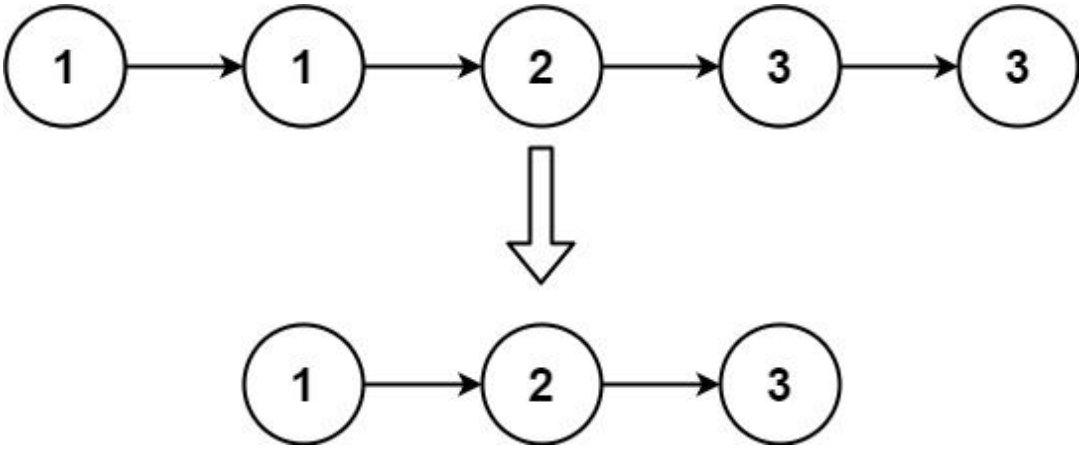
Given the `head` of a sorted linked list, *delete all duplicates such that each element appears only once*. Return *the linked list **sorted** as well*.

Example 1:



```
Input: head = [1,1,2]
Output: [1,2]
```

Example 2:



```
Input: head = [1,1,2,3,3]
Output: [1,2,3]
```

Constraints:

- The number of nodes in the list is in the range `[0, 300]`.
- `-100 <= Node.val <= 100`
- The list is guaranteed to be **sorted** in ascending order.

SOLUTION (PYTHON 3)

Solution 1: Single Pass

> **How to think about it**
>
> The first idea is dump values into a set and rebuild. Correct, and n ≤ 300 is tiny, but that ignores sorted adjacency and uses extra space. The bottleneck is not rewriting links in place. Duplicates sit next to each other, so skipping cur.next when values match is enough. Unlike the previous problem, we keep the first occurrence. A single pointer walk: drop the next node when equal, advance only when different. The head is always kept, so no dummy is needed.

We use a pointer cur to traverse the linked list. If the element corresponding to the current cur is the same as the element corresponding to cur.next, we set the next pointer of cur to point to the next node of cur.next. Otherwise, it means that the element corresponding to cur in the linked list is not duplicated, so we can move the cur pointer to the next node.

After the traversal ends, return the head node of the linked list.

The time complexity is O(n), where n is the length of the linked list. The space complexity is O(1).

Python 3

```
# Definition for singly-linked list.
# class ListNode:
#     def __init__(self, val=0, next=None):
#         self.val = val
#         self.next = next
class Solution:
    def deleteDuplicates(self, head: Optional[ListNode]) -> Optional[ListNode]:
        cur = head
        while cur and cur.next:
            if cur.val == cur.next.val:
                cur.next = cur.next.next
            else:
                cur = cur.next
        return head
```

    return head
```

142. Linked List Cycle II

Medium · Hash Table, Linked List, Two Pointers, Floyd Cycle Detection

leetcode.com/problems/linked-list-cycle-ii

★ **TOP 10 PROBLEM** in Fast & Slow Pointers (Linked List): master this one first

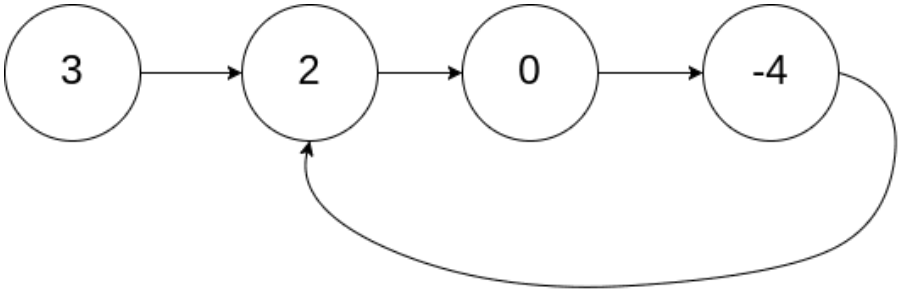
PROBLEM

Given the `head` of a linked list, return *the node where the cycle begins. If there is no cycle, return* `null`.

There is a cycle in a linked list if there is some node in the list that can be reached again by continuously following the `next` pointer. Internally, `pos` is used to denote the index of the node that tail's `next` pointer is connected to (**0-indexed**). It is `-1` if there is no cycle. **Note that** `pos` **is not passed as a parameter**.

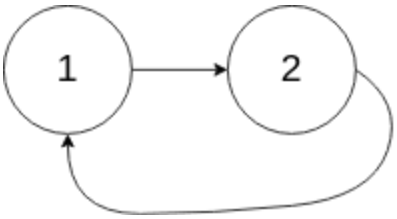
Do not modify the linked list.

Example 1:



```
Input: head = [3,2,0,-4], pos = 1
Output: tail connects to node index 1
Explanation: There is a cycle in the linked list, where tail connects to the second node.
```

Example 2:



```
Input: head = [1,2], pos = 0
Output: tail connects to node index 0
Explanation: There is a cycle in the linked list, where tail connects to the first node.
```

Example 3:

```
Input: head = [1], pos = -1
Output: no cycle
Explanation: There is no cycle in the linked list.
```

Constraints:

- The number of the nodes in the list is in the range `[0, 10^4]`.
- `-10^5 <= Node.val <= 10^5`

- `pos` is `-1` or a **valid index** in the linked-list.

Follow up: Can you solve it using `O(1)` (i.e. constant) memory?

SOLUTION (PYTHON 3)

Solution 1: Two Pointers

How to think about it

We must return the cycle entrance, not only detect it. A visited map works, but the follow-up wants O(1) space. n≤ 10^4. After the fast and slow pointers meet, send one pointer back to the head and walk both at the same speed; they meet at the entrance, because the head-to-entrance distance equals the meet-to-entrance distance around the cycle.

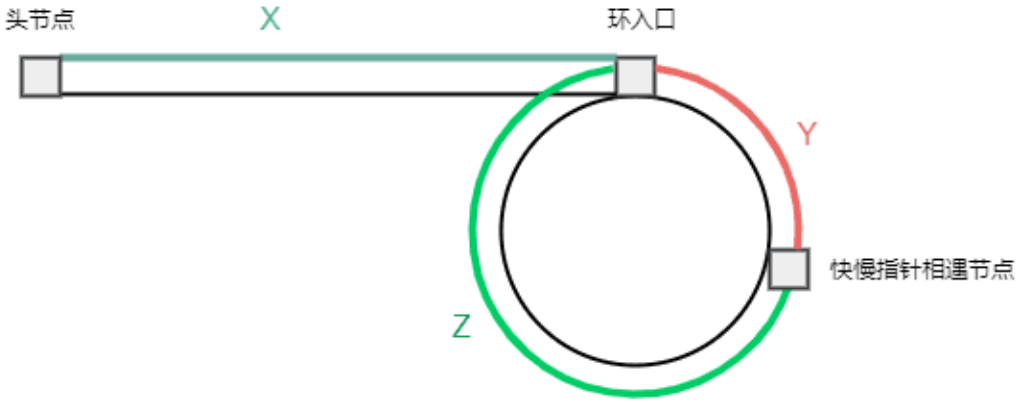
We first use the fast and slow pointers to judge whether the linked list has a ring. If there is a ring, the fast and slow pointers will definitely meet, and the meeting node must be in the ring.

If there is no ring, the fast pointer will reach the tail of the linked list first, and return `null` directly.

If there is a ring, we then define an answer pointer ans to point to the head of the linked list, and then let ans and the slow pointer move forward together, moving one step at a time, until ans and the slow pointer meet, and the meeting node is the ring entrance node.

Why can this find the entrance node of the ring?

Let's assume that the distance from the head node of the linked list to the entrance of the ring is x, the distance from the entrance of the ring to the meeting node is y, and the distance from the meeting node to the entrance of the ring is z. Then the distance traveled by the slow pointer is x + y, and the distance traveled by the fast pointer is x + y + k × (y + z), where k is the number of times the fast pointer goes around the ring.



Because the speed of the fast pointer is twice that of the slow pointer, it is 2 × (x + y) = x + y + k × (y + z), which can be deduced that x + y = k × (y + z), that is x = (k - 1) × (y + z) + z.

That is to say, if we define an answer pointer ans to point to the head of the linked list, and the ans and the slow pointer move forward together, they will definitely meet at the ring entrance.

The time complexity is O(n), where n is the number of nodes in the linked list. The space complexity is O(1).

Python 3

```
# Definition for singly-linked list.
# class ListNode:
#     def __init__(self, x):
#         self.val = x
#         self.next = None

class Solution:
    def detectCycle(self, head: Optional[ListNode]) -> Optional[ListNode]:
        fast = slow = head
        while fast and fast.next:
            slow = slow.next
            fast = fast.next.next
            if slow == fast:
                ans = head
                while ans != slow:
                    ans = ans.next
                    slow = slow.next
                return ans
```

```

19. Remove Nth Node From End of List

Medium · Linked List, Two Pointers

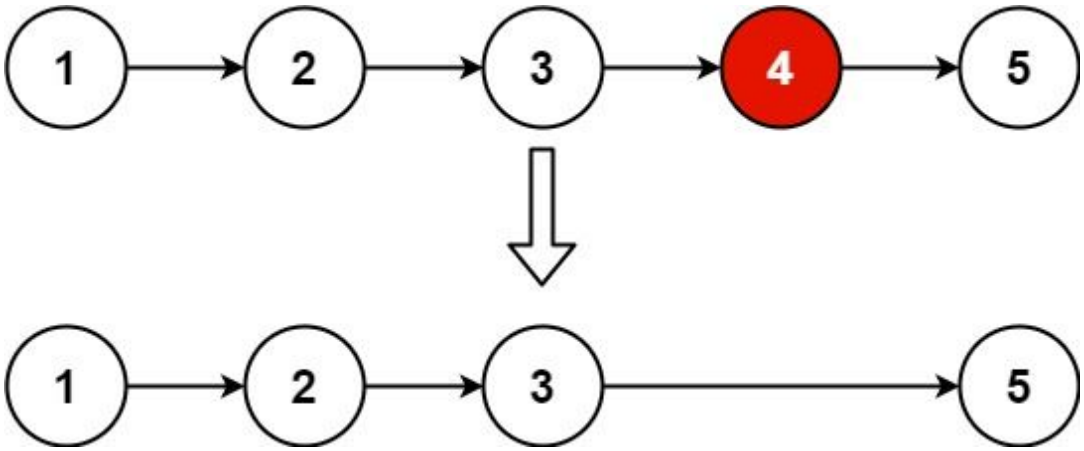
leetcode.com/problems/remove-nth-node-from-end-of-list

★ **TOP 10 PROBLEM** in Fast & Slow Pointers (Linked List): master this one first

PROBLEM

Given the `head` of a linked list, remove the n^{th} node from the end of the list and return its head.

Example 1:



```
Input: head = [1,2,3,4,5], n = 2
Output: [1,2,3,5]
```

Example 2:

```
Input: head = [1], n = 1
Output: []
```

Example 3:

```
Input: head = [1,2], n = 1
Output: [1]
```

Constraints:

- The number of nodes in the list is `sz`.
- `1 <= sz <= 30`
- `0 <= Node.val <= 100`
- `1 <= n <= sz`

Follow up: Could you do this in one pass?

SOLUTION (PYTHON 3)

Solution 1: Fast and Slow Pointers

How to think about it

The first idea is to count the length L, then walk L-n steps and delete. sz≤ 30 would pass, but the follow-up asks for one pass. Until we reach the end we do not know where the n-th node from the end is, and deletion still needs its predecessor. Give the fast pointer a head start of n steps, then move both; when fast hits the tail, slow sits on the predecessor. A dummy node makes deleting the head the same as deleting a middle node. So one walk with fast and slow locates and removes the node.

We define two pointers `fast` and `slow`, both initially pointing to the dummy head node of the linked list.

Next, the `fast` pointer moves forward n steps first, then `fast` and `slow` pointers move forward together until the `fast` pointer reaches the end of the linked list. At this point, the node pointed to by `slow.next` is the predecessor of the n-th node from the end, and we can delete it.

The time complexity is O(n), where n is the length of the linked list. The space complexity is O(1).

Python 3

```
# Definition for singly-linked list.
# class ListNode:
#     def __init__(self, val=0, next=None):
#         self.val = val
#         self.next = next

143. Reorder List

Medium · Stack, Recursion, Linked List, Two Pointers

leetcode.com/problems/reorder-list

★ **TOP 10 PROBLEM** in Fast & Slow Pointers (Linked List): master this one first

PROBLEM

You are given the head of a singly linked-list. The list can be represented as:

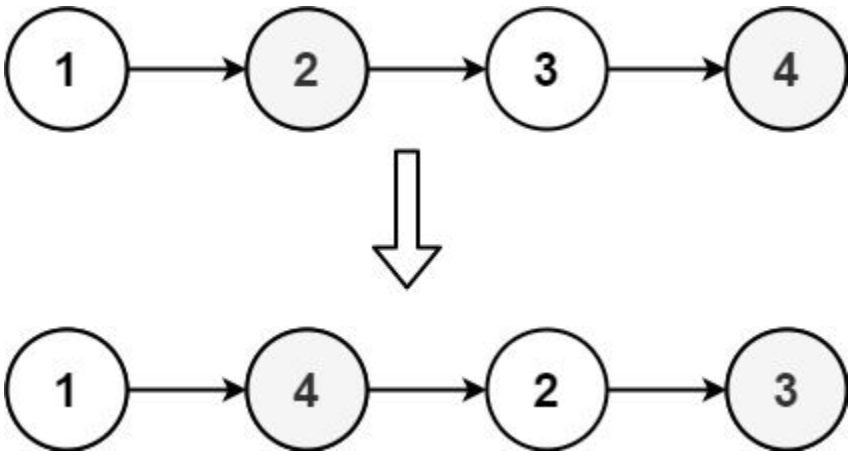
```
L0 → L1 → … → Ln - 1 → Ln
```

Reorder the list to be on the following form:

```
L0 → Ln → L1 → Ln - 1 → L2 → Ln - 2 → …
```

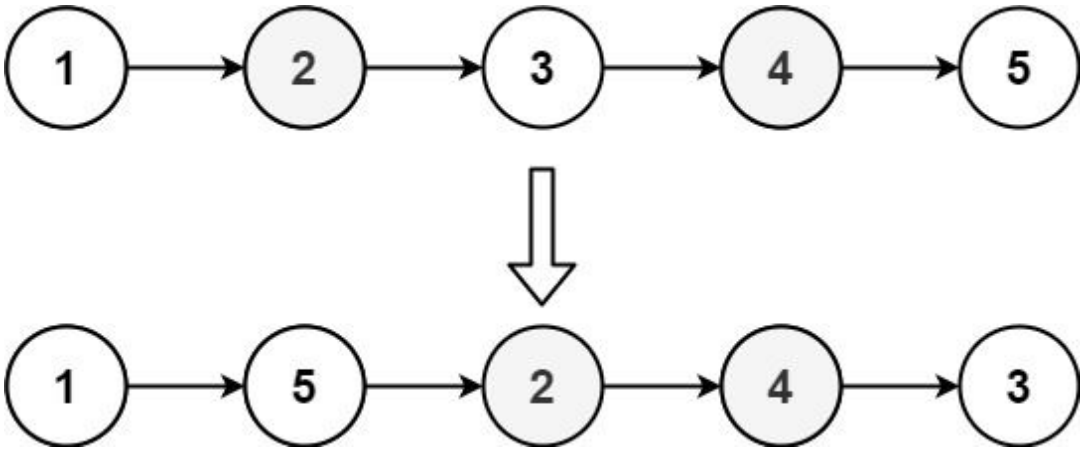
You may not modify the values in the list's nodes. Only nodes themselves may be changed.

Example 1:



```
Input: head = [1,2,3,4]
Output: [1,4,2,3]
```

Example 2:



```
Input: head = [1,2,3,4,5]
Output: [1,5,2,4,3]
```

Constraints:

- The number of nodes in the list is in the range `[1, 5 * 10^4]`.
- `1 <= Node.val <= 1000`

SOLUTION (PYTHON 3)

Solution 1: Fast and Slow Pointers + Reverse List + Merge Lists

How to think about it

Reorder as $L_0 \to L_n \to L_1 \to L_{n-1} \ldots$. An array of pointers is O(n) space. $n \leq 5 \times 10^4$. The second half must be reversed and woven into the first: find the midpoint with two pointers, cut, reverse the second half, and merge alternately. Three linear passes, in place.

We first use fast and slow pointers to find the midpoint of the linked list, then reverse the second half of the list, and finally merge the two halves.

The time complexity is O(n), where n is the length of the linked list. The space complexity is O(1).

Python 3

```
# Definition for singly-linked list.
# class ListNode:
#     def __init__(self, val=0, next=None):
#         self.val = val
#         self.next = next
class Solution:
    def reorderList(self, head: Optional[ListNode]) -> None:
        fast = slow = head
        while fast.next and fast.next.next:
            slow = slow.next
            fast = fast.next.next

        cur = slow.next
        slow.next = None

        pre = None
        while cur:
            t = cur.next
            cur.next = pre

2130. Maximum Twin Sum of a Linked List

Medium · Stack, Linked List, Two Pointers

leetcode.com/problems/maximum-twin-sum-of-a-linked-list

PROBLEM

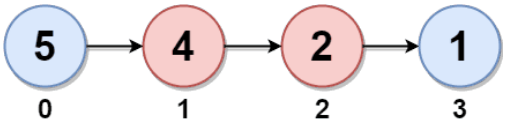
In a linked list of size `n`, where `n` is **even**, the i^{th} node (**0-indexed**) of the linked list is known as the **twin** of the $(n-1-i)^{th}$ node, if `0 <= i <= (n / 2) - 1`.

- For example, if `n = 4`, then node `0` is the twin of node `3`, and node `1` is the twin of node `2`. These are the only nodes with twins for `n = 4`.

The **twin sum** is defined as the sum of a node and its twin.

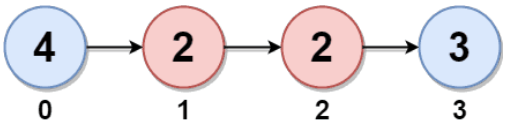
Given the `head` of a linked list with even length, return *the **maximum twin sum** of the linked list*.

Example 1:



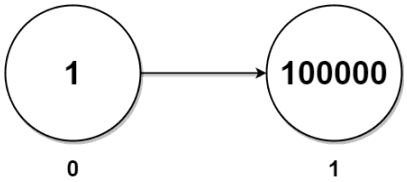
```
Input: head = [5,4,2,1]
Output: 6
Explanation:
Nodes 0 and 1 are the twins of nodes 3 and 2, respectively. All have twin sum = 6.
There are no other nodes with twins in the linked list.
Thus, the maximum twin sum of the linked list is 6.
```

Example 2:



```
Input: head = [4,2,2,3]
Output: 7
Explanation:
The nodes with twins present in this linked list are:
- Node 0 is the twin of node 3 having a twin sum of 4 + 3 = 7.
- Node 1 is the twin of node 2 having a twin sum of 2 + 2 = 4.
Thus, the maximum twin sum of the linked list is max(7, 4) = 7.
```

Example 3:



```
Input: head = [1,100000]
Output: 100001
Explanation:
There is only one node with a twin in the linked list having twin sum of 1 + 100000 = 100001.
```

Constraints:

- The number of nodes in the list is an **even** integer in the range `[2, 10^5]`.

- $1 <= Node.val <= 10^5$

SOLUTIONS (PYTHON 3)

Solution 1: Simulation

> **How to think about it**
>
> Twin nodes are values at symmetric indices; we need their maximum sum. A list does not support random access, and walking from the head for every pair would be quadratic. Copying values into an array makes index i pair with n-1-i. n is even and at most 10^5, so linear extra memory is acceptable. Store the values, then take the maximum of s[i]+s[-(i+1)] over the first half.

We can store the values of the nodes in the linked list into an array, then use two pointers pointing to the beginning and end of the array to calculate the twin sum for each pair of twin nodes. The maximum twin sum is the answer.

The time complexity is O(n) and the space complexity is O(n), where n is the number of nodes in the linked list.

Python 3

```
# Definition for singly-linked list.
# class ListNode:
#     def __init__(self, val=0, next=None):
#         self.val = val
#         self.next = next
class Solution:
    def pairSum(self, head: Optional[ListNode]) -> int:
        s = []
        while head:
            s.append(head.val)
            head = head.next
        n = len(s)
        return max(s[i] + s[-(i + 1)] for i in range(n >> 1))
```

Solution 2

> **How to think about it**
>
> Solution 1 uses an O(n) array. Constant extra memory requires pairing on the list itself. A fast/slow split finds the midpoint; reverse the second half and walk it against the first half, taking pairwise sums. The reversal is in place, so the extra space is O(1).

Python 3

```python
# Definition for singly-linked list.
# class ListNode:
#     def __init__(self, val=0, next=None):
#         self.val = val
#         self.next = next
class Solution:
    def pairSum(self, head: Optional[ListNode]) -> int:
        def reverse(head):
            dummy = ListNode()
            curr = head
            while curr:
                next = curr.next
                curr.next = dummy.next
                dummy.next = curr
                curr = next
            return dummy.next

        slow, fast = head, head.next
        while fast and fast.next:
            slow, fast = slow.next, fast.next.next
        pa = head
        q = slow.next
        slow.next = None
        pb = reverse(q)
        ans = 0
        while pa and pb:
            ans = max(ans, pa.val + pb.val)
            pa = pa.next
            pb = pb.next
        return ans
```

    return best
```

725. Split Linked List in Parts

Medium · Linked List

leetcode.com/problems/split-linked-list-in-parts

PROBLEM

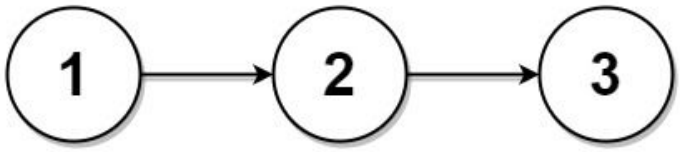
Given the `head` of a singly linked list and an integer `k`, split the linked list into `k` consecutive linked list parts.

The length of each part should be as equal as possible: no two parts should have a size differing by more than one. This may lead to some parts being null.

The parts should be in the order of occurrence in the input list, and parts occurring earlier should always have a size greater than or equal to parts occurring later.

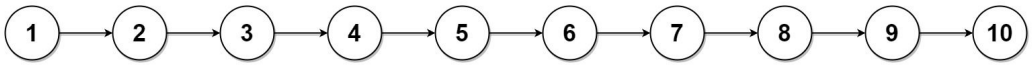
Return *an array of the* `k` *parts*.

Example 1:



```
Input: head = [1,2,3], k = 5
Output: [[1],[2],[3],[],[]]
Explanation:
The first element output[0] has output[0].val = 1, output[0].next = null.
The last element output[4] is null, but its string representation as a ListNode is [].
```

Example 2:



```
Input: head = [1,2,3,4,5,6,7,8,9,10], k = 3
Output: [[1,2,3,4],[5,6,7],[8,9,10]]
Explanation:
The input has been split into consecutive parts with size difference at most 1, and earlier parts are a
larger size than the later parts.
```

Constraints:

- The number of nodes in the list is in the range `[0, 1000]`.
- `0 <= Node.val <= 1000`
- `1 <= k <= 50`

SOLUTION (PYTHON 3)

Solution 1: Simulation

How to think about it

Split a list into k parts as evenly as possible, giving leftover nodes to the earlier parts. n≤ 1000, so count then cut. Each part gets floor(n/k) nodes, and the first n mod k parts get one extra. Unused slots stay null. A second walk advances the computed length, severs next, and records the next head. Two passes in all.

First, we traverse the linked list to obtain its length n, and then we calculate the average length cnt = floor(n/k) and the remainder mod = n mod k. For the first mod parts, each part has a length of cnt + 1, while the lengths of the remaining parts are cnt.

Next, we just need to traverse the linked list and split it into k parts.

The time complexity is O(n), and the space complexity is O(k). Here, n is the length of the linked list.

Python 3

```
# Definition for singly-linked list.
# class ListNode:
#     def __init__(self, val=0, next=None):
#         self.val = val
#         self.next = next
class Solution:
    def splitListToParts(
        self, head: Optional[ListNode], k: int
    ) -> List[Optional[ListNode]]:
        n = 0
        cur = head
        while cur:
            n += 1
            cur = cur.next
        cnt, mod = divmod(n, k)
        ans = [None] * k
        cur = head
        for i in range(k):
            if cur is None:
                break
            ans[i] = cur
            m = cnt + int(i < mod)
            for _ in range(1, m):
                cur = cur.next
            nxt = cur.next
            cur.next = None
            cur = nxt
        return ans
```

```

2095. Delete the Middle Node of a Linked List

Medium · Linked List, Two Pointers

leetcode.com/problems/delete-the-middle-node-of-a-linked-list

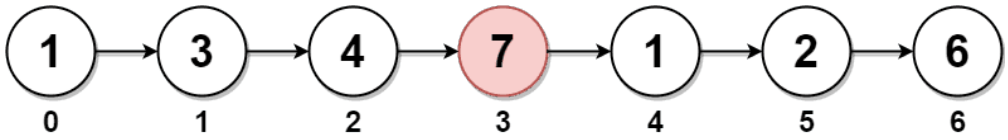
PROBLEM

You are given the `head` of a linked list. **Delete** the **middle node**, and return *the* `head` *of the modified linked list.*

The **middle node** of a linked list of size `n` is the $\lfloor n / 2 \rfloor^{th}$ node from the **start** using **0-based indexing**, where $\lfloor x \rfloor$ denotes the largest integer less than or equal to `x`.

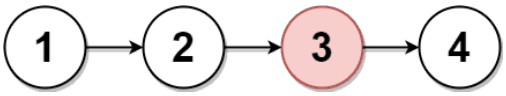
- For `n` = `1`, `2`, `3`, `4`, and `5`, the middle nodes are `0`, `1`, `1`, `2`, and `2`, respectively.

Example 1:



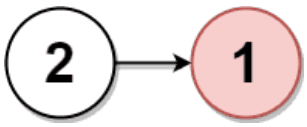
```
Input: head = [1,3,4,7,1,2,6]
Output: [1,3,4,1,2,6]
Explanation:
The above figure represents the given linked list. The indices of the nodes are written below.
Since n = 7, node 3 with value 7 is the middle node, which is marked in red.
We return the new list after removing this node.
```

Example 2:



```
Input: head = [1,2,3,4]
Output: [1,2,4]
Explanation:
The above figure represents the given linked list.
For n = 4, node 2 with value 3 is the middle node, which is marked in red.
```

Example 3:



```
Input: head = [2,1]
Output: [2]
Explanation:
The above figure represents the given linked list.
For n = 2, node 1 with value 1 is the middle node, which is marked in red.
Node 0 with value 2 is the only node remaining after removing node 1.
```

Constraints:

- The number of nodes in the list is in the range $[1, 10^5]$.
- $1 <= Node.val <= 10^5$

SOLUTION (PYTHON 3)

Solution 1: Fast and Slow Pointers

> **How to think about it**
>
> Delete the middle node (the later one if even length), which needs its predecessor. Slow starts at a dummy, fast at the head; two steps versus one leaves slow just before the middle. Rewire `slow.next`. Length 1 is handled because the dummy sits before the only node.

The fast and slow pointer technique is a common method used to solve problems related to linked lists. We can maintain two pointers, a slow pointer slow and a fast pointer fast. Initially, slow points to a dummy node, whose next pointer points to the head node head of the list, while fast points to the head node head.

Then, we move the slow pointer one position backward and the fast pointer two positions backward each time, until the fast pointer reaches the end of the list. At this point, the node next to the node pointed by the slow pointer is the middle node of the list. We can remove the middle node by setting the next pointer of the node pointed by the slow pointer to point to the next next node.

The time complexity is O(n), where n is the length of the list. The space complexity is O(1).

Python 3

```
# Definition for singly-linked list.
# class ListNode:
#     def __init__(self, val=0, next=None):
#         self.val = val
#         self.next = next
class Solution:
    def deleteMiddle(self, head: Optional[ListNode]) -> Optional[ListNode]:
        dummy = ListNode(next=head)
        slow, fast = dummy, head
        while fast and fast.next:
            slow = slow.next
            fast = fast.next.next
        slow.next = slow.next.next
        return dummy.next
```

    for i in range(target - 1):
        previous = previous.next
    previous.next = previous.next.next
    return head
```

61. Rotate List

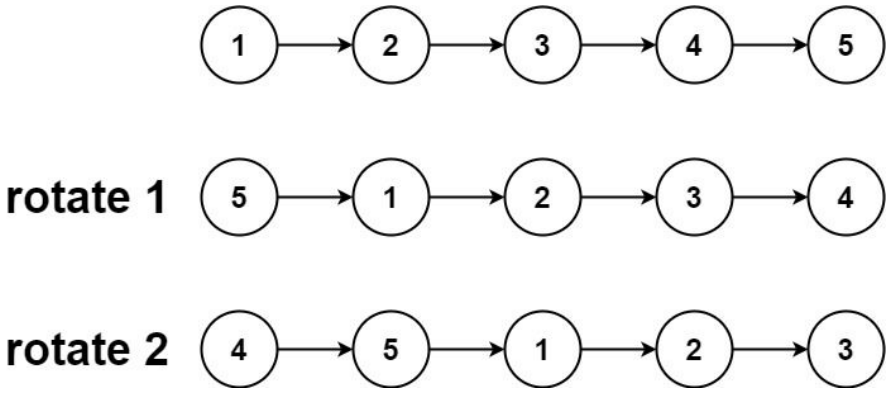
Medium · Linked List, Two Pointers

leetcode.com/problems/rotate-list

PROBLEM

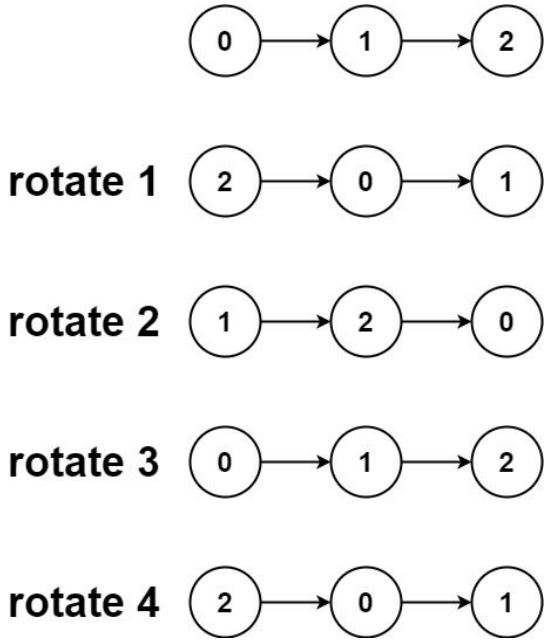
Given the `head` of a linked list, rotate the list to the right by `k` places.

Example 1:



```
Input: head = [1,2,3,4,5], k = 2
Output: [4,5,1,2,3]
```

Example 2:



```
Input: head = [0,1,2], k = 4
Output: [2,0,1]
```

Constraints:

- The number of nodes in the list is in the range `[0, 500]`.
- `-100 <= Node.val <= 100`
- `0 <= k <= 2 * 10^9`

SOLUTION (PYTHON 3)

Solution 1: Fast and Slow Pointers + Link List Concatenation

How to think about it

The first idea is to dump the list into an array, rotate, and rebuild. n ≤ 500 is fine, but k can be 2×10^9, so we cannot rotate one step at a time. The bottleneck is both the huge k and locating the new head without random access. Right-rotating k times equals rotating k mod n times; the new head is the k-th node from the tail. A gap of k between fast and slow pointers puts slow just before the new head when fast reaches the tail, so we never recount n-k. We only rewire a few pointers, in O(1) extra space.

First, we check whether the number of nodes in the linked list is less than 2. If so, we directly return head.

Otherwise, we first count the number of nodes n in the linked list, and then take the modulus of k by n to get the effective value of k.

If the effective value of k is 0, it means that the linked list does not need to be rotated, and we can directly return head.

Otherwise, we use fast and slow pointers, let the fast pointer move k steps first, and then let the fast and slow pointers move together until the fast pointer moves to the end of the linked list. At this time, the next node of the slow pointer is the new head node of the linked list.

Finally, we concatenate the linked list.

The time complexity is O(n), where n is the number of nodes in the linked list. The space complexity is O(1).

Python 3

```python
# Definition for singly-linked list.
# class ListNode:
#     def __init__(self, val=0, next=None):
#         self.val = val
#         self.next = next
class Solution:
    def rotateRight(self, head: Optional[ListNode], k: int) -> Optional[ListNode]:
        if head is None or head.next is None:
            return head
        cur, n = head, 0
        while cur:
            n += 1
            cur = cur.next
        k %= n
        if k == 0:
            return head
        fast = slow = head
        for _ in range(k):
            fast = fast.next
        while fast.next:
            fast, slow = fast.next, slow.next

        ans = slow.next
        slow.next = None
        fast.next = head
        return ans
```

109. Convert Sorted List to Binary Search Tree

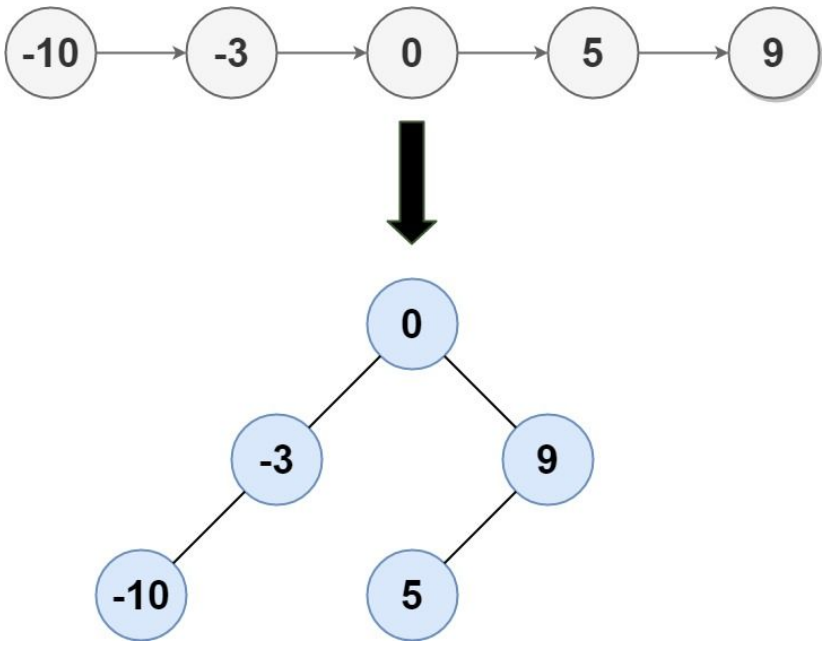
Medium · Tree, Binary Search Tree, Linked List, Divide and Conquer, Binary Tree

leetcode.com/problems/convert-sorted-list-to-binary-search-tree

PROBLEM

Given the `head` of a singly linked list where elements are sorted in **ascending order**, convert *it to a **height-balanced** binary search tree*.

Example 1:



```
Input: head = [-10,-3,0,5,9]
Output: [0,-3,9,-10,null,5]
Explanation: One possible answer is [0,-3,9,-10,null,5], which represents the shown height balanced BST.
```

Example 2:

```
Input: head = []
Output: []
```

Constraints:

- The number of nodes in `head` is in the range $[0, 2 * 10^4]$.
- -10^5 <= Node.val <= 10^5

SOLUTION (PYTHON 3)

Solution 1: DFS

How to think about it

A list cannot access the midpoint in O(1). Finding it with two pointers at every recursive step costs O(nlog n). There are up to 2× 10^4 nodes. A sorted list is still an inorder sequence. Flatten it into an array, then build a balanced BST as with a sorted array: midpoint as root, recurse on both sides. O(n) extra space buys O(1) midpoint access.

We first convert the linked list to an array nums, and then use depth-first search to construct the binary search tree.

We define a function dfs(i, j), where i and j represent the current interval [i, j]. Each time, we choose the number at the middle position mid of the interval as the root node, recursively construct the left subtree for the interval [i, mid - 1], and the right subtree for the interval [mid + 1, j]. Finally, we return the node corresponding to mid as the root node of the current subtree.

In the main function, we just need to call dfs(0, n - 1) and return the result.

The time complexity is O(n), and the space complexity is O(n). Here, n is the length of the linked list.

Python 3

```
# Definition for singly-linked list.
# class ListNode:
#     def __init__(self, val=0, next=None):
#         self.val = val
#         self.next = next
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def sortedListToBST(self, head: Optional[ListNode]) -> Optional[TreeNode]:
        def dfs(i: int, j: int) -> Optional[TreeNode]:
            if i > j:
                return None
            mid = (i + j) >> 1
            l, r = dfs(i, mid - 1), dfs(mid + 1, j)
            return TreeNode(nums[mid], l, r)

        nums = []
        while head:
            nums.append(head.val)
            head = head.next
        return dfs(0, len(nums) - 1)
```

        fast = fast.next.next
    previous.next = None
    root = TreeNode(slow.val)
    root.left = sorted_list_to_bst_middle(head)
    root.right = sorted_list_to_bst_middle(slow.next)
    return root
```

817. Linked List Components

Medium · Array, Hash Table, Linked List

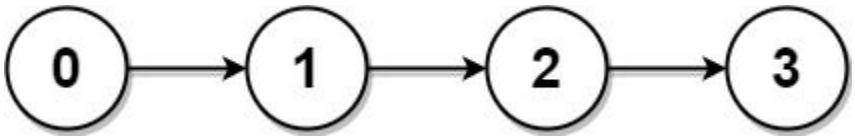
leetcode.com/problems/linked-list-components

PROBLEM

You are given the `head` of a linked list containing unique integer values and an integer array `nums` that is a subset of the linked list values.

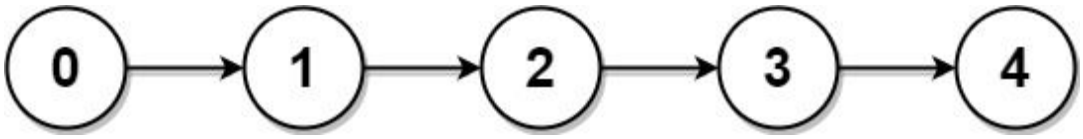
Return the number of **connected components** in `nums`. A connected component is a non-empty, maximal sequence of **consecutive** nodes in the linked list such that every node's value belongs to nums.

Example 1:



```
Input: head = [0,1,2,3], nums = [0,1,3]
Output: 2
Explanation: 0 and 1 are connected, so [0, 1] and [3] are the two connected components.
```

Example 2:



```
Input: head = [0,1,2,3,4], nums = [0,3,1,4]
Output: 2
Explanation: 0 and 1 are connected, 3 and 4 are connected, so [0, 1] and [3, 4] are the two connected
components.
```

Constraints:

- The number of nodes in the linked list is `n`.
- `1 <= n <= 10^4`
- `0 <= Node.val < n`
- All the values `Node.val` are **unique**.
- `1 <= nums.length <= n`
- `0 <= nums[i] < n`
- All the values of `nums` are **unique**.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

A component is a maximal run of nums values on the list. n≤ 10^4, so a set lookup plus one walk is enough; no graph is required. Skip nodes outside the set. Each time a run inside the set begins, count one component and advance past the whole run.

Python 3

```
# Definition for singly-linked list.
# class ListNode:
#     def __init__(self, val=0, next=None):
#         self.val = val
#         self.next = next
class Solution:
    def numComponents(self, head: Optional[ListNode], nums: List[int]) -> int:
        ans = 0
        s = set(nums)
        while head:
            while head and head.val not in s:
                head = head.next
            ans += head is not None
            while head and head.val in s:
                head = head.next
        return ans
```

Complexity. Time: O(n + m), m = len(nums). Space: O(m).

```

328. Odd Even Linked List

Medium · Linked List

leetcode.com/problems/odd-even-linked-list

★ **TOP 10 PROBLEM** in Fast & Slow Pointers (Linked List): master this one first

Also appears in pattern 25 Linked List Reversal / Manipulation

PROBLEM

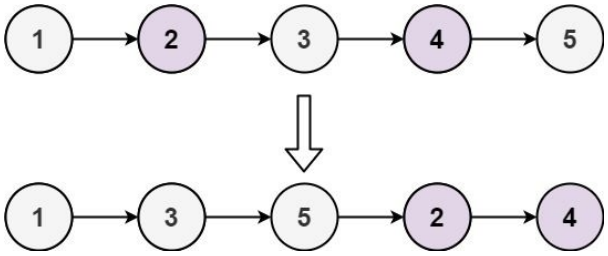
Given the `head` of a singly linked list, group all the nodes with odd indices together followed by the nodes with even indices, and return *the reordered list*.

The **first** node is considered **odd**, and the **second** node is **even**, and so on.

Note that the relative order inside both the even and odd groups should remain as it was in the input.

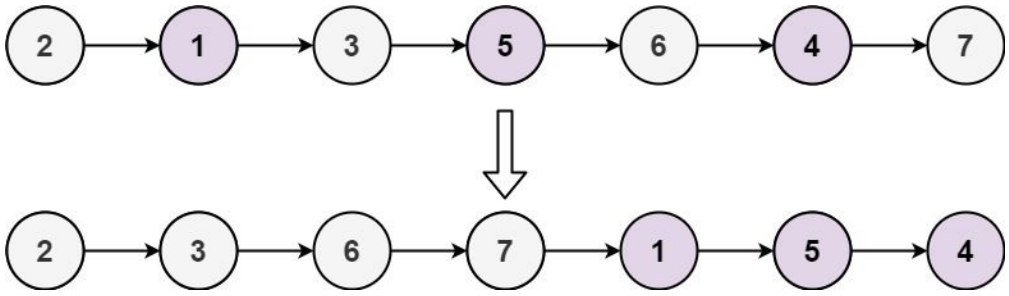
You must solve the problem in `O(1)` extra space complexity and `O(n)` time complexity.

Example 1:



```
Input: head = [1,2,3,4,5]
Output: [1,3,5,2,4]
```

Example 2:



```
Input: head = [2,1,3,5,6,4,7]
Output: [2,3,6,7,1,5,4]
```

Constraints:

- The number of nodes in the linked list is in the range `[0, 10^4]`.
- `-10^6 <= Node.val <= 10^6`

SOLUTION (PYTHON 3)

Solution 1: Single Pass

How to think about it

Keep odd-positioned nodes before even-positioned ones, preserving order. An extra list is easy; O(1) space is required. Let a and b trail the odd and even chains, and c remember the even head. Repeatedly splice b.next after a, then the new successor after b, until the even chain ends. Set a.next=c.

We can use two pointers a and b to represent the tail nodes of the odd and even nodes respectively. Initially, pointer a points to the head node head of the list, and pointer b points to the second node head.next of the list. In addition, we use a pointer c to point to the head node head.next of the even nodes, which is the initial position of pointer b.

We traverse the list, set pointer a to point to the next node of b, i.e., a.next = b.next, then move pointer a back by one position, i.e., a = a.next; set pointer b to point to the next node of a, i.e., b.next = a.next, then move pointer b back by one position, i.e., b = b.next. Continue to traverse until b reaches the end of the list.

Finally, we set the tail node a of the odd nodes to point to the head node c of the even nodes, i.e., a.next = c, then return the head node head of the list.

The time complexity is O(n), where n is the length of the list, and we need to traverse the list once. The space complexity is O(1). We only need to maintain a limited number of pointers.

Python 3

```
# Definition for singly-linked list.
# class ListNode:
#     def __init__(self, val=0, next=None):
#         self.val = val
#         self.next = next
class Solution:
    def oddEvenList(self, head: Optional[ListNode]) -> Optional[ListNode]:
        if head is None:
            return None
        a = head
        b = c = head.next
        while b and b.next:
            a.next = b.next
            a = a.next
            b.next = a.next
            b = b.next
        a.next = c
        return head
```

86. Partition List

Medium · Linked List, Two Pointers

leetcode.com/problems/partition-list

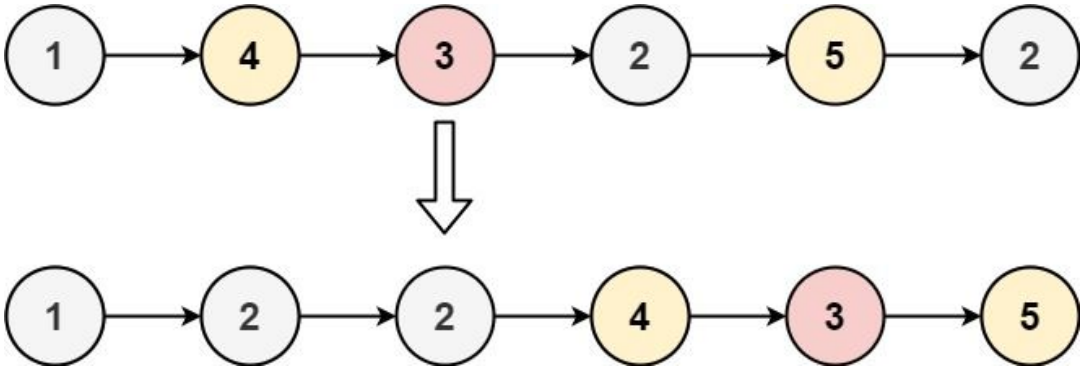
★ **TOP 10 PROBLEM** in Fast & Slow Pointers (Linked List): master this one first

PROBLEM

Given the `head` of a linked list and a value `x`, partition it such that all nodes **less than** `x` come before nodes **greater than or equal** to `x`.

You should **preserve** the original relative order of the nodes in each of the two partitions.

Example 1:



```
Input: head = [1,4,3,2,5,2], x = 3
Output: [1,2,2,4,3,5]
```

Example 2:

```
Input: head = [2,1], x = 2
Output: [1,2]
```

Constraints:

- The number of nodes in the list is in the range `[0, 200]`.
- `-100 <= Node.val <= 100`
- `-200 <= x <= 200`

SOLUTION (PYTHON 3)

Solution 1: Simulation

How to think about it

The first idea is two scans: collect nodes < x, then the rest, and rebuild. Correct, and n ≤ 200 is tiny, but that copies nodes or walks twice, and it is easy to scramble relative order. The bottleneck is splitting and reassembling instead of one pass. The problem only asks for a stable partition: order among the small nodes and among the large nodes both stay the same. So grow two lists in one walk and stitch the small tail to the large head. Tail pointers link original nodes — no copies; clear the large tail to avoid a cycle.

We create two linked lists l and r, one to store nodes less than x and the other to store nodes greater than or equal to x. Then we concatenate them.

The time complexity is O(n), where n is the length of the original linked list. The space complexity is O(1).

Python 3

```
# Definition for singly-linked list.
# class ListNode:
#     def __init__(self, val=0, next=None):
#         self.val = val
#         self.next = next
class Solution:
    def partition(self, head: Optional[ListNode], x: int) -> Optional[ListNode]:
        l = ListNode()
        r = ListNode()
        tl, tr = l, r
        while head:
            if head.val < x:
                tl.next = head
                tl = tl.next
            else:
                tr.next = head
                tr = tr.next
            head = head.next
        tr.next = None
        tl.next = r.next
        return l.next
```

148. Sort List

Medium · Linked List, Two Pointers, Divide and Conquer, Sorting, Merge Sort

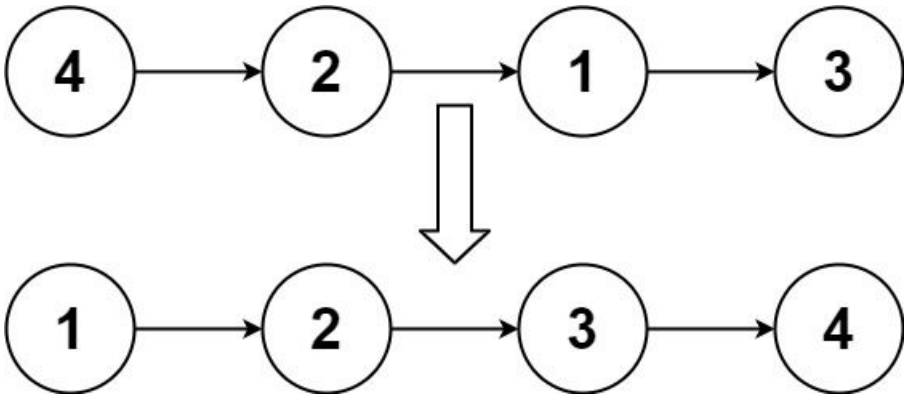
leetcode.com/problems/sort-list

★ **TOP 10 PROBLEM** in Fast & Slow Pointers (Linked List): master this one first

PROBLEM

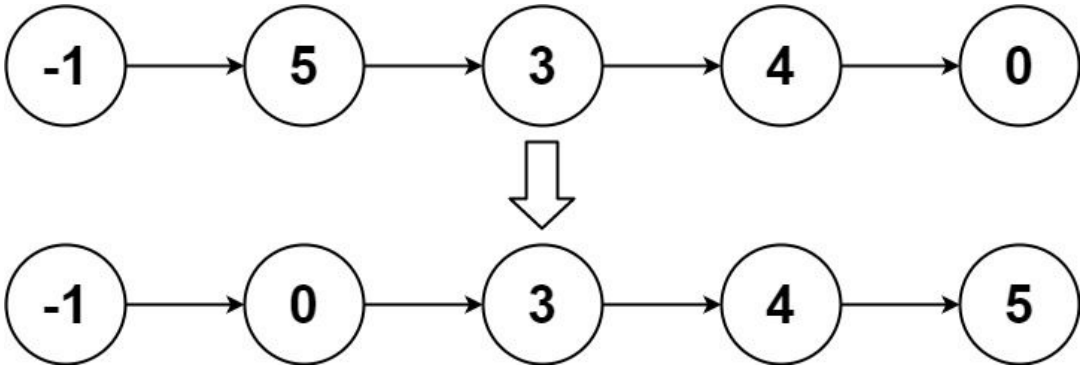
Given the `head` of a linked list, return *the list after sorting it in* ***ascending order***.

Example 1:



```
Input: head = [4,2,1,3]
Output: [1,2,3,4]
```

Example 2:



```
Input: head = [-1,5,3,4,0]
Output: [-1,0,3,4,5]
```

Example 3:

```
Input: head = []
Output: []
```

Constraints:

- The number of nodes in the list is in the range `[0, 5 * 10^4]`.
- `-10^5 <= Node.val <= 10^5`

Follow up: Can you sort the linked list in `O(n logn)` time and `O(1)` memory (i.e. constant space)?

SOLUTION (PYTHON 3)

Solution 1: Merge Sort

How to think about it

Sort a list; the follow-up wants O(nlog n) time and constant extra space. There is no random access, so quicksort swaps are awkward. n≤ 5× 10^4. Merge sort only needs sequential scans: split at the midpoint, sort both halves, merge. The recursion stack is O(log n).

We can use the merge sort approach to solve this problem.

First, we use the fast and slow pointers to find the middle of the linked list and break the list from the middle to form two separate sublists l1 and l2.

Then, we recursively sort l1 and l2, and finally merge l1 and l2 into a sorted linked list.

The time complexity is O(n × log n), and the space complexity is O(log n). Here, n is the length of the linked list.

Python 3

```
# Definition for singly-linked list.
# class ListNode:
#     def __init__(self, val=0, next=None):
#         self.val = val
#         self.next = next
class Solution:
    def sortList(self, head: Optional[ListNode]) -> Optional[ListNode]:
        if head is None or head.next is None:
            return head
        slow, fast = head, head.next
        while fast and fast.next:
            slow = slow.next
            fast = fast.next.next
        l1, l2 = head, slow.next
        slow.next = None
        l1, l2 = self.sortList(l1), self.sortList(l2)
        dummy = ListNode()
        tail = dummy
        while l1 and l2:
            if l1.val <= l2.val:
                tail.next = l1
                l1 = l1.next
            else:
                tail.next = l2
                l2 = l2.next
            tail = tail.next
        tail.next = l1 or l2
        return dummy.next
```

PATTERN 25 OF 41

Linked List Reversal / Manipulation

20 problems · 4 Easy · 14 Medium · 2 Hard

THE IDEA

Re-wire next pointers carefully: save the next node before you overwrite it. A dummy head removes the special case at the front.

Signals: reverse a list or part of it, reverse in groups of K, merge two lists, remove the nth node from the end, reorder list, add two numbers.

A TEMPLATE TO KEEP IN YOUR HANDS (PYTHON)

```
prev, cur = None, head
while cur:
    nxt = cur.next        # save it first
    cur.next = prev       # turn the arrow around
    prev, cur = cur, nxt
return prev
```

PATTERN 25 · LINKED LIST REVERSAL / MANIPULATION · PROBLEM 1 OF 20

206. Reverse Linked List

Easy · Recursion, Linked List

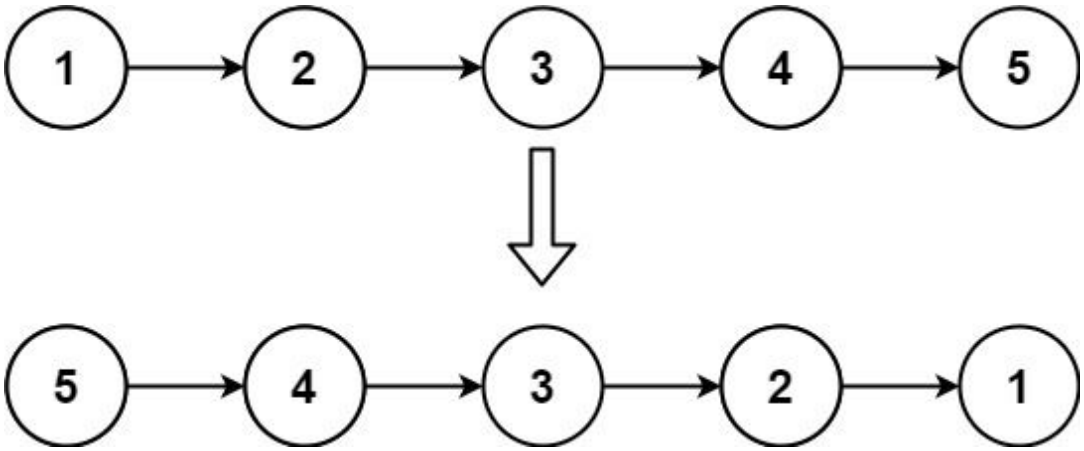
leetcode.com/problems/reverse-linked-list

★ **TOP 10 PROBLEM** in Linked List Reversal / Manipulation: master this one first

PROBLEM

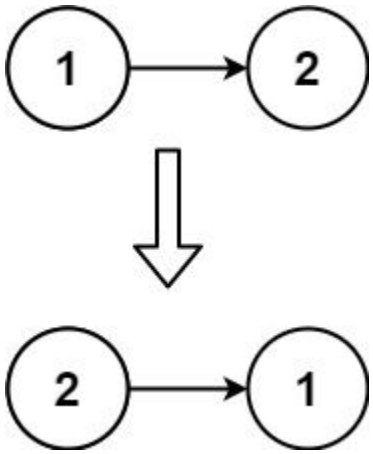
Given the `head` of a singly linked list, reverse the list, and return *the reversed list*.

Example 1:



```
Input: head = [1,2,3,4,5]
Output: [5,4,3,2,1]
```

Example 2:



```
Input: head = [1,2]
Output: [2,1]
```

Example 3:

```
Input: head = []
Output: []
```

Constraints:

- The number of nodes in the list is the range `[0, 5000]`.
- `-5000 <= Node.val <= 5000`

Follow up: A linked list can be reversed either iteratively or recursively. Could you implement both?

SOLUTIONS (PYTHON 3)

Solution 1: Head Insertion Method

> **How to think about it**
>
> Storing nodes in an array and rebuilding backwards works, but only pointer rewrites are needed. Head insertion reverses the list in one pass: each node is inserted immediately after a dummy. When the scan ends, dummy.next is the new head and extra space is constant.

We create a dummy node dummy, then traverse the linked list and insert each node after the dummy node. After traversal, return dummy.next.

The time complexity is O(n), where n is the length of the linked list. The space complexity is O(1).

Python 3

```python
# Definition for singly-linked list.
# class ListNode:
#     def __init__(self, val=0, next=None):
#         self.val = val
#         self.next = next
class Solution:
    def reverseList(self, head: ListNode) -> ListNode:
        dummy = ListNode()
        curr = head
        while curr:
            next = curr.next
            curr.next = dummy.next
            dummy.next = curr
            curr = next
        return dummy.next
```

Solution 2: Recursion

> **How to think about it**
>
> Head insertion is already linear. We can instead reverse the suffix recursively, then attach the current node behind the new tail. The pointer updates are shorter, at the cost of O(n) call-stack space.

We recursively reverse all nodes from the second node to the end of the list, then attach the head to the end of the reversed list.

The time complexity is O(n), and the space complexity is O(n). Where n is the length of the linked list.

Python 3

```python
# Definition for singly-linked list.
# class ListNode:
#     def __init__(self, val=0, next=None):
#         self.val = val
#         self.next = next
class Solution:
    def reverseList(self, head: ListNode) -> ListNode:
        if head is None or head.next is None:
            return head
        ans = self.reverseList(head.next)
        head.next.next = head
        head.next = None
        return ans
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

        node = following
    head.next = node
    return previous
```

21. Merge Two Sorted Lists

Easy · Recursion, Linked List

leetcode.com/problems/merge-two-sorted-lists

★ **TOP 10 PROBLEM** in Linked List Reversal / Manipulation, K-way Merge: master this one first

Also appears in pattern 38 K-way Merge

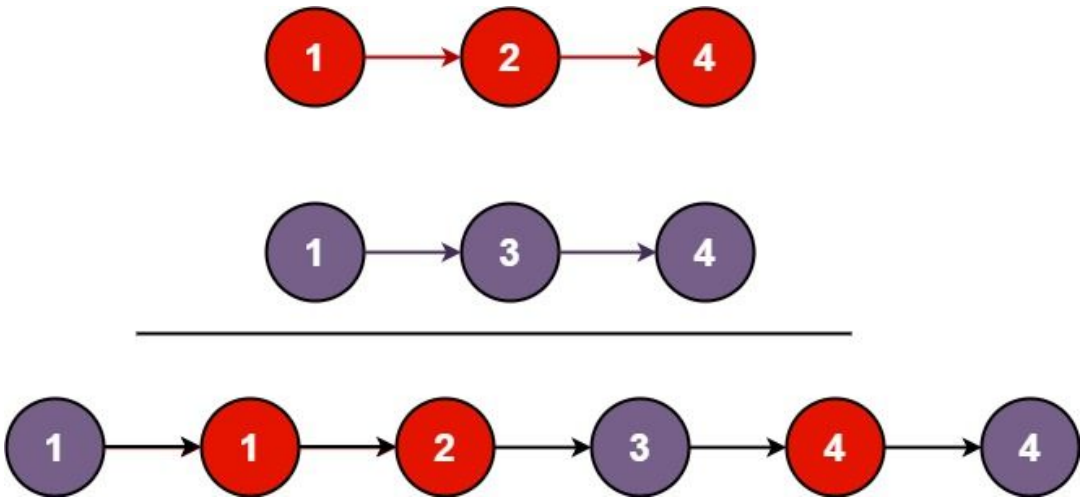
PROBLEM

You are given the heads of two sorted linked lists `list1` and `list2`.

Merge the two lists into one **sorted** list. The list should be made by splicing together the nodes of the first two lists.

Return *the head of the merged linked list*.

Example 1:



```
Input: list1 = [1,2,4], list2 = [1,3,4]
Output: [1,1,2,3,4,4]
```

Example 2:

```
Input: list1 = [], list2 = []
Output: []
```

Example 3:

```
Input: list1 = [], list2 = [0]
Output: [0]
```

Constraints:

- The number of nodes in both lists is in the range `[0, 50]`.
- `-100 <= Node.val <= 100`
- Both `list1` and `list2` are sorted in **non-decreasing** order.

SOLUTIONS (PYTHON 3)

Solution 1: Recursion

How to think about it

The first idea is to dump both lists into an array, sort, and rebuild. Total length is at most 100, so it would pass, but it throws away the fact that both lists are already sorted. The bottleneck is unnecessary reordering: each step only needs the smaller of the two heads. After taking it, what remains is still two sorted lists — the same problem, one node smaller. Compare the heads of l_1 and l_2; keep the smaller one and hang the merge of the rest on its next. When one list is empty, the other is the answer as-is. Recursion depth equals the number of nodes. Lengths here are tiny, so O(m+n) stack space is fine.

First, we judge whether the linked lists l_1 and l_2 are empty. If one of them is empty, we return the other linked list. Otherwise, we compare the head nodes of l_1 and l_2:

- If the value of the head node of l_1 is less than or equal to the value of the head node of l_2, we recursively call the function mergeTwoLists(l_1.next, l_2), and connect the head node of l_1 with the returned linked list head node, and return the head node of l_1.
- Otherwise, we recursively call the function mergeTwoLists(l_1, l_2.next), and connect the head node of l_2 with the returned linked list head node, and return the head node of l_2.

The time complexity is O(m + n), and the space complexity is O(m + n). Here, m and n are the lengths of the two linked lists respectively.

Python 3

```
# Definition for singly-linked list.
# class ListNode:
#     def __init__(self, val=0, next=None):
#         self.val = val
#         self.next = next
class Solution:
    def mergeTwoLists(
        self, list1: Optional[ListNode], list2: Optional[ListNode]
    ) -> Optional[ListNode]:
        if list1 is None or list2 is None:
            return list1 or list2
        if list1.val <= list2.val:
            list1.next = self.mergeTwoLists(list1.next, list2)
            return list1
        else:
            list2.next = self.mergeTwoLists(list1, list2.next)
            return list2
```

Solution 2: Iteration

How to think about it

Solution 1 is correct, but the recursion stack is linear in the number of nodes. The lists here are short, yet the same choice can be made with constant extra space. The observation is unchanged: each step still compares the two heads and appends the smaller. A dummy dummy plus a tail pointer curr do that in a loop; when one list runs out, splice the other on. Time matches the recursive version; extra space drops to O(1).

We can also use iteration to implement the merging of two sorted linked lists.

First, we define a dummy head node dummy, then loop through the two linked lists, compare the head nodes of the two linked lists, add the smaller node to the end of dummy, until one of the linked lists is empty, then add the remaining part of the other linked list to the end of dummy.

Finally, return dummy.next.

The time complexity is O(m + n), where m and n are the lengths of the two linked lists respectively. Ignoring the space consumption of the answer linked list, the space complexity is O(1).

Python 3

```
# Definition for singly-linked list.
# class ListNode:
#     def __init__(self, val=0, next=None):
#         self.val = val
#         self.next = next
class Solution:
    def mergeTwoLists(
        self, list1: Optional[ListNode], list2: Optional[ListNode]
    ) -> Optional[ListNode]:
        dummy = ListNode()
        curr = dummy
        while list1 and list2:
            if list1.val <= list2.val:
                curr.next = list1
                list1 = list1.next
            else:
                curr.next = list2
                list2 = list2.next
            curr = curr.next
        curr.next = list1 or list2
        return dummy.next
```

            tail = node
    tail.next = None
    return dummy.next
```

203. Remove Linked List Elements

Easy · Recursion, Linked List

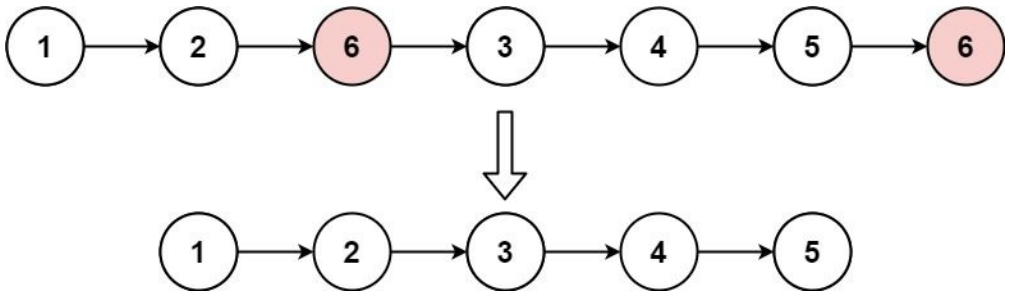
leetcode.com/problems/remove-linked-list-elements

★ **TOP 10 PROBLEM** in Linked List Reversal / Manipulation: master this one first

PROBLEM

Given the `head` of a linked list and an integer `val`, remove all the nodes of the linked list that has `Node.val == val`, and return *the new head*.

Example 1:



```
Input: head = [1,2,6,3,4,5,6], val = 6
Output: [1,2,3,4,5]
```

Example 2:

```
Input: head = [], val = 1
Output: []
```

Example 3:

```
Input: head = [7,7,7,7], val = 7
Output: []
```

Constraints:

- The number of nodes in the list is in the range `[0, 10^4]`.
- `1 <= Node.val <= 50`
- `0 <= val <= 50`

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Removing nodes with value val is a predecessor-pointer update, but the head itself may be deleted, so special-casing head is messy. A dummy node in front lets pre inspect its successor: skip it when the value matches, otherwise advance. Return dummy.next.

Python 3

```
# Definition for singly-linked list.
# class ListNode:
#     def __init__(self, val=0, next=None):
#         self.val = val
#         self.next = next
class Solution:
    def removeElements(self, head: ListNode, val: int) -> ListNode:
        dummy = ListNode(-1, head)
        pre = dummy
        while pre.next:
            if pre.next.val != val:
                pre = pre.next
            else:
                pre.next = pre.next.next
        return dummy.next
```

Complexity. Time: O(n). Space: O(1).

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

Built on the solutions above: helper functions, then the function for each follow-up. No tests and no restating of the question.

```
# FOLLOW-UPS (answered below, in this order):

```

1290. Convert Binary Number in a Linked List to Integer

Easy · Linked List, Math

leetcode.com/problems/convert-binary-number-in-a-linked-list-to-integer

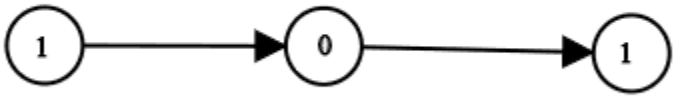
PROBLEM

Given `head` which is a reference node to a singly-linked list. The value of each node in the linked list is either `0` or `1`. The linked list holds the binary representation of a number.

Return the *decimal value* of the number in the linked list.

The **most significant bit** is at the head of the linked list.

Example 1:



```
Input: head = [1,0,1]
Output: 5
Explanation: (101) in base 2 = (5) in base 10
```

Example 2:

```
Input: head = [0]
Output: 0
```

Constraints:

- The Linked List is not empty.
- Number of nodes will not exceed `30`.
- Each node's value is either `0` or `1`.

SOLUTION (PYTHON 3)

Solution 1: Traverse the Linked List

> **How to think about it**
>
> The list is a binary number from high bit to low. Shifting the running value left and ORing the current bit accumulates the integer. Length is at most 30, so it fits. We need not collect bits first.

We use a variable ans to record the current decimal value, with an initial value of 0.

Traverse the linked list. For each node, left-shift ans by one bit, then perform a bitwise OR with the current node's value. After traversal, ans is the decimal value.

The time complexity is O(n), where n is the length of the linked list. The space complexity is O(1).

Python 3

```
# Definition for singly-linked list.
# class ListNode:
#     def __init__(self, val=0, next=None):
#         self.val = val
#         self.next = next
class Solution:
    def getDecimalValue(self, head: ListNode) -> int:
        ans = 0
        while head:
            ans = ans << 1 | head.val
            head = head.next
        return ans
```

    return dummy.next
```

PATTERN 25 · LINKED LIST REVERSAL / MANIPULATION · PROBLEM 5 OF 20

92. Reverse Linked List II

Medium · Linked List

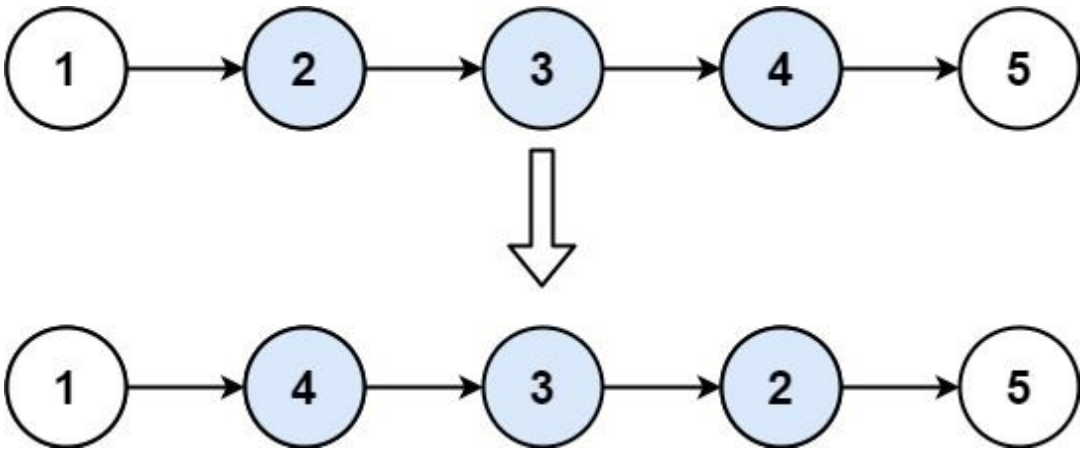
leetcode.com/problems/reverse-linked-list-ii

★ **TOP 10 PROBLEM** in Linked List Reversal / Manipulation: master this one first

PROBLEM

Given the `head` of a singly linked list and two integers `left` and `right` where `left <= right`, reverse the nodes of the list from position `left` to position `right`, and return *the reversed list*.

Example 1:



```
Input: head = [1,2,3,4,5], left = 2, right = 4
Output: [1,4,3,2,5]
```

Example 2:

```
Input: head = [5], left = 1, right = 1
Output: [5]
```

Constraints:

- The number of nodes in the list is `n`.
- `1 <= n <= 500`
- `-500 <= Node.val <= 500`
- `1 <= left <= right <= n`

Follow up:

Could you do it in one pass?

SOLUTION (PYTHON 3)

Solution 1: Simulation

How to think about it

We could cut out [left,right], reverse it, and splice it back, but left=1 replaces the head and we have to remember several cut points. The follow-up asks for one pass. The key: head-insert each node of the range right after the predecessor of left. That reverses in place. A dummy node covers left=1. Walk to left-1, then head-insert right-left+1 times.

Define a dummy head node `dummy`, pointing to the head node `head` of the linked list. Then define a pointer `pre` pointing to `dummy`. Start traversing the linked list from the dummy head node. When you traverse to the `left` node, point `pre` to this node. Then start traversing `right - left + 1` times from this node, and insert the nodes you traverse into the back of `pre`. Finally, return `dummy.next`.

The time complexity is O(n), and the space complexity is O(1). Here, n is the length of the linked list.

Python 3

```
# Definition for singly-linked list.
# class ListNode:
#     def __init__(self, val=0, next=None):
#         self.val = val
#         self.next = next
class Solution:
    def reverseBetween(

24. Swap Nodes in Pairs

Medium · Recursion, Linked List

leetcode.com/problems/swap-nodes-in-pairs

★ **TOP 10 PROBLEM** in Linked List Reversal / Manipulation: master this one first

PROBLEM

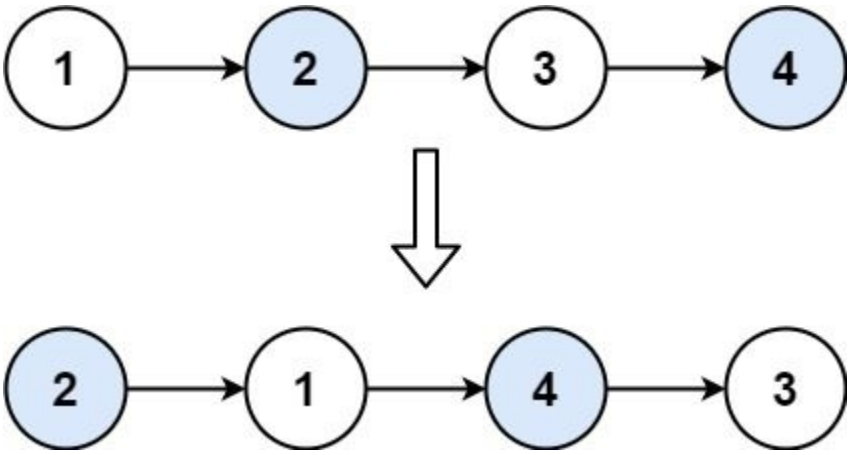
Given a linked list, swap every two adjacent nodes and return its head. You must solve the problem without modifying the values in the list's nodes (i.e., only nodes themselves may be changed.)

Example 1:

Input: head = [1,2,3,4]

Output: [2,1,4,3]

Explanation:



Example 2:

Input: head = []

Output: []

Example 3:

Input: head = [1]

Output: [1]

Example 4:

Input: head = [1,2,3]

Output: [2,1,3]

Constraints:

- The number of nodes in the list is in the range `[0, 100]`.
- `0 <= Node.val <= 100`

SOLUTIONS (PYTHON 3)

Solution 1: Recursion

How to think about it

The first idea is to swap values of adjacent nodes. The problem forbids changing values, so we must rewire pointers. At most 100 nodes, so any correct linking will pass. The bottleneck is the link order: flip the first pair and then the rest, and it is easy to lose a successor. After one pair is swapped, the suffix starting at the third node is the same problem. The new head is always the original second node. So recurse on head.next.next first, then reverse the current pair onto that result. An empty list or a single node cannot form a pair and is returned as-is.

We can implement swapping two nodes in the linked list through recursion.

The termination condition of recursion is that there are no nodes in the linked list, or there is only one node in the linked list. At this time, swapping cannot be performed, so we directly return this node.

Otherwise, we recursively swap the linked list head.next.next, and let the swapped head node be t. Then we let p be the next node of head, and let p point to head, and head point to t, finally return p.

The time complexity is O(n), and the space complexity is O(n). Here, n is the length of the linked list.

Python 3

```
# Definition for singly-linked list.
# class ListNode:
#     def __init__(self, val=0, next=None):
#         self.val = val
#         self.next = next
class Solution:
    def swapPairs(self, head: Optional[ListNode]) -> Optional[ListNode]:
        if head is None or head.next is None:
            return head
        t = self.swapPairs(head.next.next)
        p = head.next
        p.next = head
        head.next = t
        return p
```

Solution 2: Iteration

How to think about it

Solution 1 is correct, but recursion depth tracks the number of pairs, so extra space is O(n). The same three pointer writes inside a pair can run in a loop. A dummy pins the list head. Pointers pre and cur rewrite the two nodes after pre, then advance by one pair. Time stays O(n); extra space drops to O(1).

We set a dummy head node dummy, initially pointing to head, and then set two pointers pre and cur, initially pre points to dummy, and cur points to head.

Next, we traverse the linked list. Each time we need to swap the two nodes after pre, so we first judge whether cur and cur.next are empty. If they are not empty, we perform the swap, otherwise we terminate the loop.

The time complexity is O(n), and the space complexity is O(1). Here, n is the length of the linked list.

Python 3

```
# Definition for singly-linked list.
# class ListNode:
#     def __init__(self, val=0, next=None):
#         self.val = val
#         self.next = next
class Solution:
    def swapPairs(self, head: Optional[ListNode]) -> Optional[ListNode]:
        dummy = ListNode(next=head)
        pre, cur = dummy, head
        while cur and cur.next:
            t = cur.next
            cur.next = t.next
            t.next = cur
            pre.next = t
            pre, cur = cur, cur.next
        return dummy.next
```

2. Add Two Numbers

Medium · Recursion, Linked List, Math

leetcode.com/problems/add-two-numbers

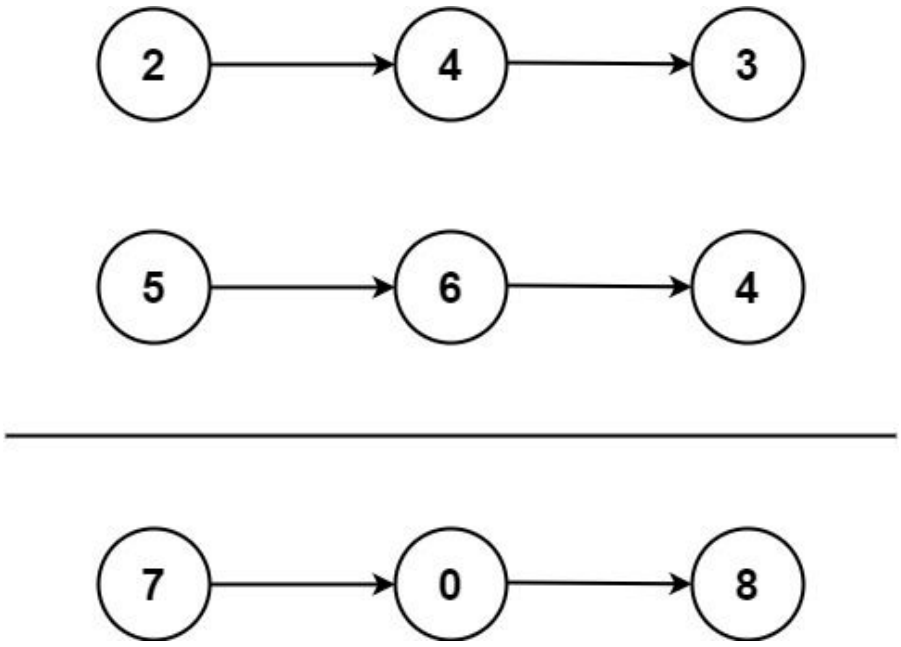
★ **TOP 10 PROBLEM** in Linked List Reversal / Manipulation: master this one first

PROBLEM

You are given two **non-empty** linked lists representing two non-negative integers. The digits are stored in **reverse order**, and each of their nodes contains a single digit. Add the two numbers and return the sum as a linked list.

You may assume the two numbers do not contain any leading zero, except the number 0 itself.

Example 1:



```
Input: l1 = [2,4,3], l2 = [5,6,4]
Output: [7,0,8]
Explanation: 342 + 465 = 807.
```

Example 2:

```
Input: l1 = [0], l2 = [0]
Output: [0]
```

Example 3:

```
Input: l1 = [9,9,9,9,9,9,9], l2 = [9,9,9,9]
Output: [8,9,9,9,0,0,0,1]
```

Constraints:

- The number of nodes in each linked list is in the range `[1, 100]`.
- `0 <= Node.val <= 9`
- It is guaranteed that the list represents a number that does not have leading zeros.

SOLUTION (PYTHON 3)

Solution 1: Simulation

How to think about it

The first idea is to convert both lists to integers and add. Length is at most 100, so big integers would pass, but the lists already store digits in reverse—this is column addition. Converting away from the list throws that structure away. The issue is not arithmetic volume: the lists may differ in length, and a final carry may remain. Each position is "the two digits (missing treated as 0) plus carry", then split into a new digit and a new carry. So we grow the answer from a dummy node and walk both lists together. The loop must continue while l_1, l_2, or carry remains; otherwise [9]+[1] drops the leading 1.

We traverse two linked lists l_1 and l_2 at the same time, and use the variable carry to indicate whether there is a carry.

Each time we traverse, we take out the current bit of the corresponding linked list, calculate the sum with the carry carry, and then update the value of the carry. Then we add the current bit to the answer linked list. If both linked lists are traversed, and the carry is 0, the traversal ends.

Finally, we return the head node of the answer linked list.

The time complexity is O(max (m, n)), where m and n are the lengths of the two linked lists. We need to traverse the entire position of the two linked lists, and each position only needs O(1) time. Ignoring the space consumption of the answer, the space complexity is O(1).

Python 3

```
# Definition for singly-linked list.
# class ListNode:
#     def __init__(self, val=0, next=None):
#         self.val = val
#         self.next = next
class Solution:
    def addTwoNumbers(
        self, l1: Optional[ListNode], l2: Optional[ListNode]
    ) -> Optional[ListNode]:
        dummy = ListNode()
        carry, curr = 0, dummy
        while l1 or l2 or carry:
            s = (l1.val if l1 else 0) + (l2.val if l2 else 0) + carry
            carry, val = divmod(s, 10)
            curr.next = ListNode(val)
            curr = curr.next
            l1 = l1.next if l1 else None
            l2 = l2.next if l2 else None
        return dummy.next
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

            total += head.val * digit
            head = head.next
        tail.next = ListNode(total % 10)
```

```
        tail = tail.next
        carry = total // 10
    return dummy.next
```

445. Add Two Numbers II

Medium · Stack, Linked List, Math

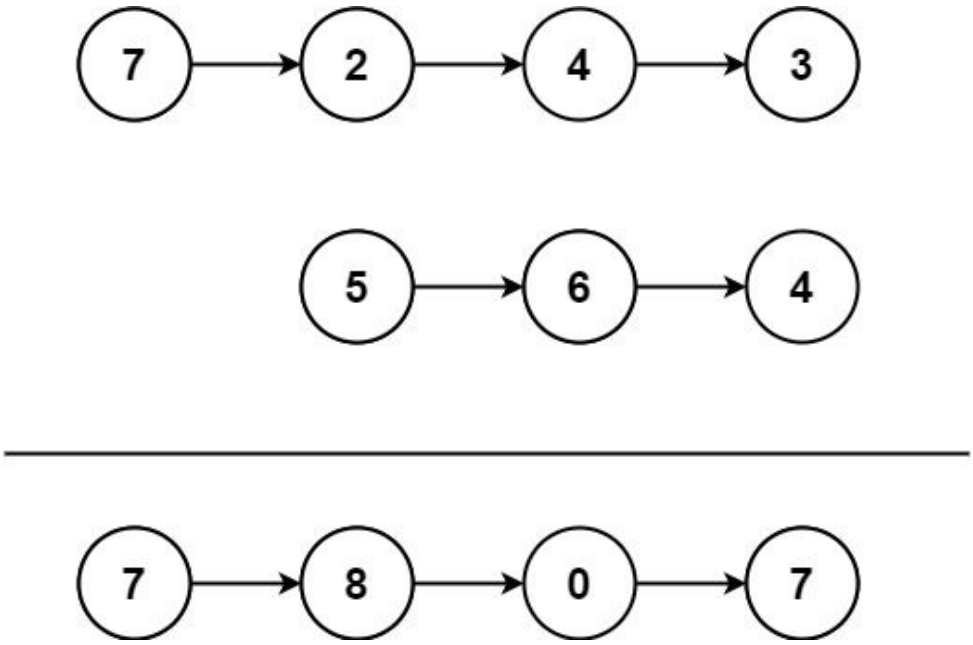
leetcode.com/problems/add-two-numbers-ii

PROBLEM

You are given two **non-empty** linked lists representing two non-negative integers. The most significant digit comes first and each of their nodes contains a single digit. Add the two numbers and return the sum as a linked list.

You may assume the two numbers do not contain any leading zero, except the number 0 itself.

Example 1:



```
Input: l1 = [7,2,4,3], l2 = [5,6,4]
Output: [7,8,0,7]
```

Example 2:

```
Input: l1 = [2,4,3], l2 = [5,6,4]
Output: [8,0,7]
```

Example 3:

```
Input: l1 = [0], l2 = [0]
Output: [0]
```

Constraints:

- The number of nodes in each linked list is in the range `[1, 100]`.
- `0 <= Node.val <= 9`
- It is guaranteed that the list represents a number that does not have leading zeros.

Follow up: Could you solve it without reversing the input lists?

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

The lists store the high digit first, so we cannot add from the heads as in Add Two Numbers. Reversing twice more is pointer-heavy. Push both lists onto stacks, pop the low digits, add with carry, and insert each new node at the front of the answer. A leftover carry becomes one more head insert. The stacks make the low end come out first; head insertion restores high-digit-first order without reversing the lists.

Python 3

```python
# Definition for singly-linked list.
# class ListNode:
#     def __init__(self, val=0, next=None):
#         self.val = val
#         self.next = next
class Solution:
    def addTwoNumbers(
        self, l1: Optional[ListNode], l2: Optional[ListNode]
    ) -> Optional[ListNode]:
        s1, s2 = [], []
        while l1:
            s1.append(l1.val)
            l1 = l1.next
        while l2:
            s2.append(l2.val)
            l2 = l2.next
        dummy = ListNode()
        carry = 0
        while s1 or s2 or carry:
            s = (0 if not s1 else s1.pop()) + (0 if not s2 else s2.pop()) + carry
            carry, val = divmod(s, 10)
            # node = ListNode(val, dummy.next)
            # dummy.next = node
            dummy.next = ListNode(val, dummy.next)
        return dummy.next
```

Complexity. Time: O(m + n). Space: O(m + n).

Solution 2

How to think about it

Solution 1 already adds via two stacks. Solution 2 is the same skeleton: pop, add, insert at the dummy head, until both stacks and the carry are gone.

Python 3 (written for this guide: the doocs page has no Python 3 version of this solution)

```python
class Solution:
    def addTwoNumbers(self, l1: Optional[ListNode], l2: Optional[ListNode]) -> Optional[ListNode]:
        def to_stack(head: Optional[ListNode]) -> List[int]:
            stack = []
            while head:
                stack.append(head.val)
                head = head.next
            return stack

        s1, s2 = to_stack(l1), to_stack(l2)
        dummy = ListNode()
        carry = 0
        while s1 or s2 or carry:
            if s1:
                carry += s1.pop()
            if s2:
                carry += s2.pop()
            dummy.next = ListNode(carry % 10, dummy.next)      # put the new digit in front
            carry //= 10
        return dummy.next
```

Complexity. Time: O(m + n). Space: O(m + n).

    while result.next and result.val == 0:
        result = result.next
    return result
```

138. Copy List with Random Pointer

Medium · Hash Table, Linked List

leetcode.com/problems/copy-list-with-random-pointer

★ **TOP 10 PROBLEM** in Linked List Reversal / Manipulation: master this one first

PROBLEM

A linked list of length `n` is given such that each node contains an additional random pointer, which could point to any node in the list, or `null`.

Construct a **deep copy** of the list. The deep copy should consist of exactly `n` **brand new** nodes, where each new node has its value set to the value of its corresponding original node. Both the `next` and `random` pointer of the new nodes should point to new nodes in the copied list such that the pointers in the original list and copied list represent the same list state. **None of the pointers in the new list should point to nodes in the original list**.

For example, if there are two nodes `X` and `Y` in the original list, where `X.random --> Y`, then for the corresponding two nodes `x` and `y` in the copied list, `x.random --> y`.

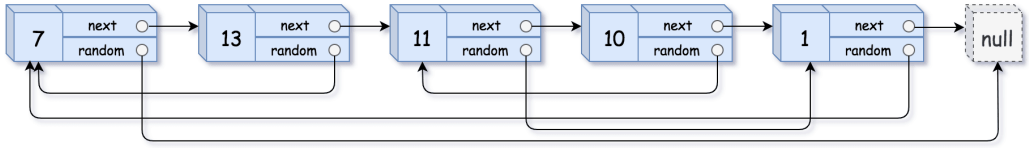
Return *the head of the copied linked list*.

The linked list is represented in the input/output as a list of `n` nodes. Each node is represented as a pair of `[val, random_index]` where:

- `val`: an integer representing `Node.val`
- `random_index`: the index of the node (range from `0` to `n-1`) that the `random` pointer points to, or `null` if it does not point to any node.

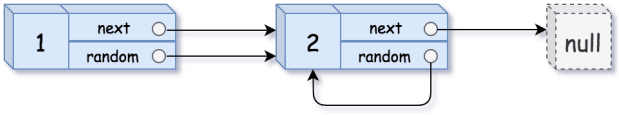
Your code will **only** be given the `head` of the original linked list.

Example 1:



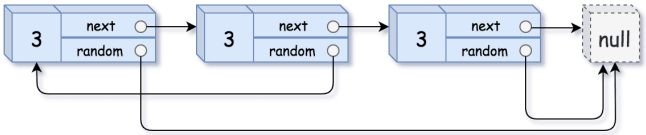
```
Input: head = [[7,null],[13,0],[11,4],[10,2],[1,0]]
Output: [[7,null],[13,0],[11,4],[10,2],[1,0]]
```

Example 2:



```
Input: head = [[1,1],[2,1]]
Output: [[1,1],[2,1]]
```

Example 3:



```
Input: head = [[3,null],[3,0],[3,null]]
Output: [[3,null],[3,0],[3,null]]
```

Constraints:

- `0 <= n <= 1000`
- -10^4 `<= Node.val <=` 10^4
- `Node.random` is `null` or is pointing to some node in the linked list.

SOLUTIONS (PYTHON 3)

Solution 1: Hash Table

> **How to think about it**
>
> Copy a list whose random pointer may refer to any node or null. If we copy next first, the random target may not exist yet. n≤ 1000. A first pass builds the new list along next and maps each original node to its copy; a second pass wires random through that map.

We can define a dummy head node dummy and use a pointer tail to point to the dummy head node. Then, we traverse the linked list, copying each node and storing the mapping between each node and its copy in a hash table d, while also connecting the next pointers of the copied nodes.

Next, we traverse the linked list again and use the mappings stored in the hash table to connect the random pointers of the copied nodes.

The time complexity is O(n), and the space complexity is O(n). Here, n is the length of the linked list.

Python 3

```python
"""
# Definition for a Node.
class Node:
    def __init__(self, x: int, next: 'Node' = None, random: 'Node' = None):
        self.val = int(x)
        self.next = next
        self.random = random
"""

class Solution:
    def copyRandomList(self, head: "Optional[Node]") -> "Optional[Node]":
        d = {}
        dummy = tail = Node(0)
        cur = head
        while cur:
            node = Node(cur.val)
            tail.next = node
            tail = tail.next
            d[cur] = node
            cur = cur.next
        cur = head
        while cur:
            d[cur].random = d[cur.random] if cur.random else None
            cur = cur.next
        return dummy.next
```

Solution 2: Simulation (Space Optimization)

How to think about it

Solution 1's map is O(n) space. Insert each copy after its original so the pair is adjacent; the matching random node is cur.random.next. Split the list afterwards. No hash table.

In Solution 1, we used an additional hash table to store the mapping between the original nodes and the copied nodes. We can also achieve this without using extra space, as follows:

1. Traverse the original linked list, and for each node, create a new node and insert it between the original node and the original node's next node.
2. Traverse the linked list again, and set the random pointer of the new node based on the random pointer of the original node.
3. Finally, split the linked list into the original linked list and the copied linked list.

The time complexity is O(n), where n is the length of the linked list. Ignoring the space occupied by the answer linked list, the space complexity is O(1).

Python 3

```
"""
# Definition for a Node.
class Node:
    def __init__(self, x: int, next: 'Node' = None, random: 'Node' = None):
        self.val = int(x)

430. Flatten a Multilevel Doubly Linked List

Medium · Depth-First Search, Linked List, Doubly-Linked List

leetcode.com/problems/flatten-a-multilevel-doubly-linked-list

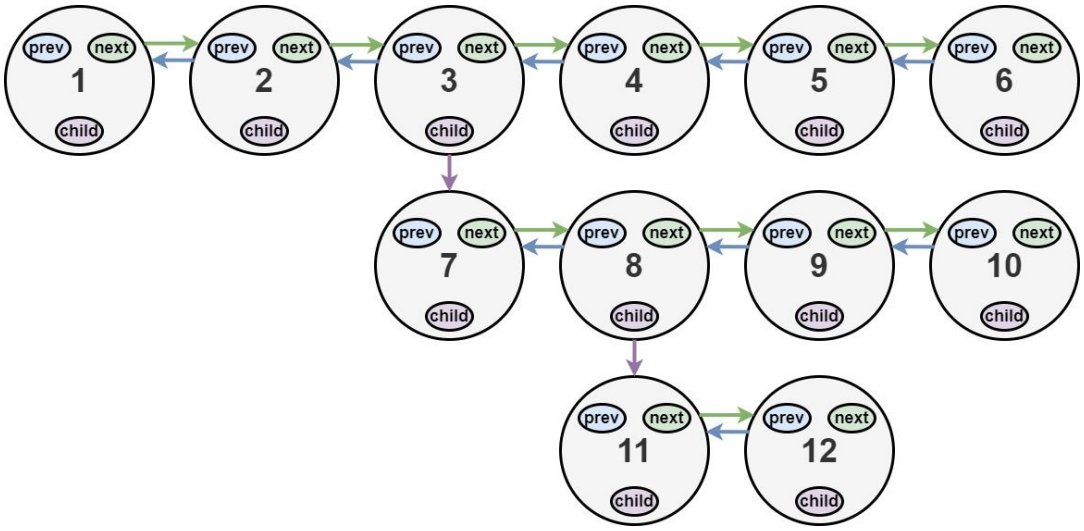
PROBLEM

You are given a doubly linked list, which contains nodes that have a next pointer, a previous pointer, and an additional **child pointer**. This child pointer may or may not point to a separate doubly linked list, also containing these special nodes. These child lists may have one or more children of their own, and so on, to produce a **multilevel data structure** as shown in the example below.

Given the `head` of the first level of the list, **flatten** the list so that all the nodes appear in a single-level, doubly linked list. Let `curr` be a node with a child list. The nodes in the child list should appear **after** `curr` and **before** `curr.next` in the flattened list.

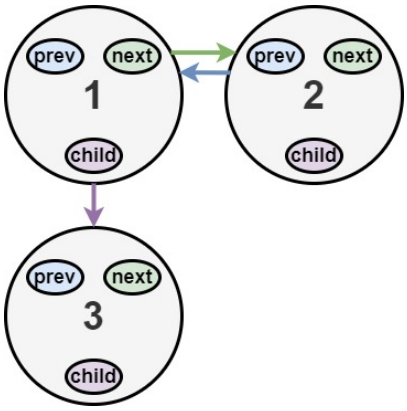
Return *the* `head` *of the flattened list. The nodes in the list must have* ***all*** *of their child pointers set to* `null`.

Example 1:



```
Input: head = [1,2,3,4,5,6,null,null,null,7,8,9,10,null,null,11,12]
Output: [1,2,3,7,8,11,12,9,10,4,5,6]
Explanation: The multilevel linked list in the input is shown.
After flattening the multilevel linked list it becomes:
```

Example 2:



```
Input: head = [1,2,null,3]
Output: [1,3,2]
Explanation: The multilevel linked list in the input is shown.
After flattening the multilevel linked list it becomes:
```

Example 3:

```
Input: head = []
Output: []
Explanation: There could be empty list in the input.
```

Constraints:

- The number of Nodes will not exceed `1000`.
- `1 <= Node.val <= 10^5`

How the multilevel linked list is represented in test cases:

We use the multilevel linked list from **Example 1** above:

```
 1---2---3---4---5---6--NULL
         |
         7---8---9---10--NULL
             |
             11--12--NULL
```

The serialization of each level is as follows:

```
[1,2,3,4,5,6,null]
[7,8,9,10,null]
[11,12,null]
```

To serialize all levels together, we will add nulls in each level to signify no node connects to the upper node of the previous level. The serialization becomes:

```
[1, 2, 3, 4, 5, 6, null]
             |
[null, null, 7, 8, 9, 10, null]
                   |
[ null, 11, 12, null]
```

Merging the serialization of each level and removing trailing nulls we obtain:

```
[1,2,3,4,5,6,null,null,null,7,8,9,10,null,null,11,12]
```

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Flattening a multilevel list is a preorder walk: child before the original next. Walking next first would append the child list at the very end. preorder(pre,cur) links the current node after its predecessor, saves the old next, flattens the child (the returned tail becomes the new predecessor), then flattens the saved next and clears child. A dummy node holds the head; afterwards the real head's prev is cleared. The original next must be saved before the child walk overwrites it.

Python 3

```
"""
# Definition for a Node.
class Node:
    def __init__(self, val, prev, next, child):
        self.val = val
        self.prev = prev
        self.next = next
        self.child = child
"""

class Solution:
    def flatten(self, head: 'Node') -> 'Node':
        def preorder(pre, cur):
            if cur is None:
                return pre
            cur.prev = pre
            pre.next = cur

            t = cur.next
            tail = preorder(cur, cur.child)
            cur.child = None
            return preorder(tail, t)

        if head is None:
            return None
        dummy = Node(0, None, head, None)
        preorder(dummy, head)
        dummy.next.prev = None
        return dummy.next
```

Complexity. Time: O(n). Space: O(d), d = deepest nesting level (O(n) in the worst case).

```

707. Design Linked List

Medium · Design, Linked List

leetcode.com/problems/design-linked-list

PROBLEM

Design your implementation of the linked list. You can choose to use a singly or doubly linked list.
A node in a singly linked list should have two attributes: `val` and `next`. `val` is the value of the current node, and `next` is a pointer/reference to the next node.
If you want to use the doubly linked list, you will need one more attribute `prev` to indicate the previous node in the linked list. Assume all nodes in the linked list are **0-indexed**.

Implement the `MyLinkedList` class:

- `MyLinkedList()` Initializes the `MyLinkedList` object.
- `int get(int index)` Get the value of the `index`th node in the linked list. If the index is invalid, return `-1`.
- `void addAtHead(int val)` Add a node of value `val` before the first element of the linked list. After the insertion, the new node will be the first node of the linked list.
- `void addAtTail(int val)` Append a node of value `val` as the last element of the linked list.
- `void addAtIndex(int index, int val)` Add a node of value `val` before the `index`th node in the linked list. If `index` equals the length of the linked list, the node will be appended to the end of the linked list. If `index` is greater than the length, the node **will not be inserted**.
- `void deleteAtIndex(int index)` Delete the `index`th node in the linked list, if the index is valid.

Example 1:

```
Input
["MyLinkedList", "addAtHead", "addAtTail", "addAtIndex", "get", "deleteAtIndex", "get"]
[[], [1], [3], [1, 2], [1], [1], [1]]
Output
[null, null, null, null, 2, null, 3]

Explanation
MyLinkedList myLinkedList = new MyLinkedList();
myLinkedList.addAtHead(1);
myLinkedList.addAtTail(3);
myLinkedList.addAtIndex(1, 2); // linked list becomes 1->2->3
myLinkedList.get(1); // return 2
myLinkedList.deleteAtIndex(1); // now the linked list is 1->3
myLinkedList.get(1); // return 3
```

Constraints:

- `0 <= index, val <= 1000`
- Please do not use the built-in LinkedList library.
- At most `2000` calls will be made to `get`, `addAtHead`, `addAtTail`, `addAtIndex` and `deleteAtIndex`.

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

We must implement index access, head/tail inserts, and indexed deletes without a library list. At most 2000 calls, so an O(n) walk from the head is fine. A singly linked list can reach index index only by walking predecessors. A dummy head unifies empty and non-empty updates; cnt makes bounds checks independent of the walk. Head and tail inserts reduce to addAtIndex: walk to the predecessor, then relink. Deletes do the same. Each operation is O(n).

Python 3

```python
class MyLinkedList:
    def __init__(self):
        self.dummy = ListNode()
        self.cnt = 0

    def get(self, index: int) -> int:
        if index < 0 or index >= self.cnt:
            return -1
        cur = self.dummy.next
        for _ in range(index):
            cur = cur.next
        return cur.val

    def addAtHead(self, val: int) -> None:
        self.addAtIndex(0, val)

    def addAtTail(self, val: int) -> None:
        self.addAtIndex(self.cnt, val)

    def addAtIndex(self, index: int, val: int) -> None:
        if index > self.cnt:
            return
        pre = self.dummy
        for _ in range(index):
            pre = pre.next
        pre.next = ListNode(val, pre.next)
        self.cnt += 1

    def deleteAtIndex(self, index: int) -> None:
        if index >= self.cnt:
            return
        pre = self.dummy
        for _ in range(index):
            pre = pre.next
        t = pre.next
        pre.next = t.next
        t.next = None
        self.cnt -= 1

# Your MyLinkedList object will be instantiated and called as such:
# obj = MyLinkedList()
# param_1 = obj.get(index)
# obj.addAtHead(val)
# obj.addAtTail(val)
# obj.addAtIndex(index,val)
# obj.deleteAtIndex(index)
```

Solution 2

How to think about it

Solution 1 allocates a node on every insert. The limit here is tiny, but repeated allocation dominates once the list grows large. Preallocate two arrays for values and successor indices, and treat an increasing idx as a node pool. Inserting claims the next slot and rewrites indices—the same linking as pointers. head stores the first index and cnt the length. Asymptotics match Solution 1 without per-operation allocation.

Python 3

```
class MyLinkedList:
    def __init__(self):
        self.e = [0] * 1010
        self.ne = [0] * 1010
        self.idx = 0
        self.head = -1
        self.cnt = 0

    def get(self, index: int) -> int:
        if index < 0 or index >= self.cnt:
            return -1
        i = self.head
        for _ in range(index):
            i = self.ne[i]
        return self.e[i]

    def addAtHead(self, val: int) -> None:
        self.e[self.idx] = val
        self.ne[self.idx] = self.head
        self.head = self.idx
        self.idx += 1
        self.cnt += 1

    def addAtTail(self, val: int) -> None:
        self.addAtIndex(self.cnt, val)

    def addAtIndex(self, index: int, val: int) -> None:
        if index > self.cnt:
            return
        if index <= 0:
            self.addAtHead(val)
            return
        i = self.head
        for _ in range(index - 1):
            i = self.ne[i]
        self.e[self.idx] = val
        self.ne[self.idx] = self.ne[i]
        self.ne[i] = self.idx
        self.idx += 1
        self.cnt += 1

    def deleteAtIndex(self, index: int) -> None:
        if index < 0 or index >= self.cnt:
            return -1
        self.cnt -= 1
        if index == 0:
            self.head = self.ne[self.head]
            return
        i = self.head
        for _ in range(index - 1):
            i = self.ne[i]
        self.ne[i] = self.ne[self.ne[i]]

# Your MyLinkedList object will be instantiated and called as such:
# obj = MyLinkedList()
# param_1 = obj.get(index)
# obj.addAtHead(val)
# obj.addAtTail(val)
# obj.addAtIndex(index,val)
```

```
# obj.deleteAtIndex(index)
```

Complexity. Time: get, addAtIndex, deleteAtIndex O(n); addAtHead O(1). Space: O(n).

```

PATTERN 25 · LINKED LIST REVERSAL / MANIPULATION · PROBLEM 12 OF 20

1721. Swapping Nodes in a Linked List

Medium · Linked List, Two Pointers

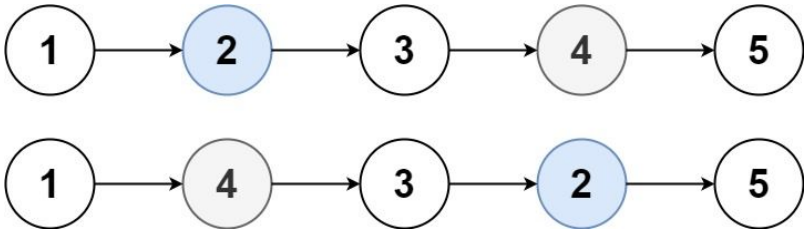
leetcode.com/problems/swapping-nodes-in-a-linked-list

PROBLEM

You are given the `head` of a linked list, and an integer `k`.

Return *the head of the linked list after **swapping** the values of the* k^{th} *node from the beginning and the* k^{th} *node from the end (the list is **1-indexed**).*

Example 1:



```
Input: head = [1,2,3,4,5], k = 2
Output: [1,4,3,2,5]
```

Example 2:

```
Input: head = [7,9,6,6,7,8,3,0,9,5], k = 5
Output: [7,9,6,6,8,7,3,0,9,5]
```

Constraints:

- The number of nodes in the list is `n`.
- `1 <= k <= n <=` 10^5
- `0 <= Node.val <= 100`

SOLUTION (PYTHON 3)

Solution 1: Two Pointers

> **How to think about it**
>
> We swap the values of the k-th node from the start and from the end. Measuring the length and walking twice works, but one pass is enough. Advance a fast pointer k-1 steps to the k-th node p, then move fast and slow together. When fast reaches the tail, slow is the k-th from the end. Swap the two values and return the head.

We can first use a fast pointer `fast` to find the kth node of the linked list, and use a pointer `p` to point to it. Then, we use a slow pointer `slow` to start from the head node of the linked list, and move both pointers forward at the same time. When the fast pointer reaches the last node of the linked list, the slow pointer `slow` points to the kth node from the end of the linked list, and we use a pointer `q` to point to it. At this point, we only need to swap the values of `p` and `q`.

The time complexity is O(n), where n is the length of the linked list. The space complexity is O(1).

Python 3

```
# Definition for singly-linked list.
# class ListNode:
#     def __init__(self, val=0, next=None):
#         self.val = val
#         self.next = next
class Solution:
    def swapNodes(self, head: Optional[ListNode], k: int) -> Optional[ListNode]:
        fast = slow = head
        for _ in range(k - 1):
            fast = fast.next
        p = fast
        while fast.next:
            fast, slow = fast.next, slow.next
        q = slow
        p.val, q.val = q.val, p.val
        return head

147. Insertion Sort List

Medium · Linked List, Sorting

leetcode.com/problems/insertion-sort-list

PROBLEM

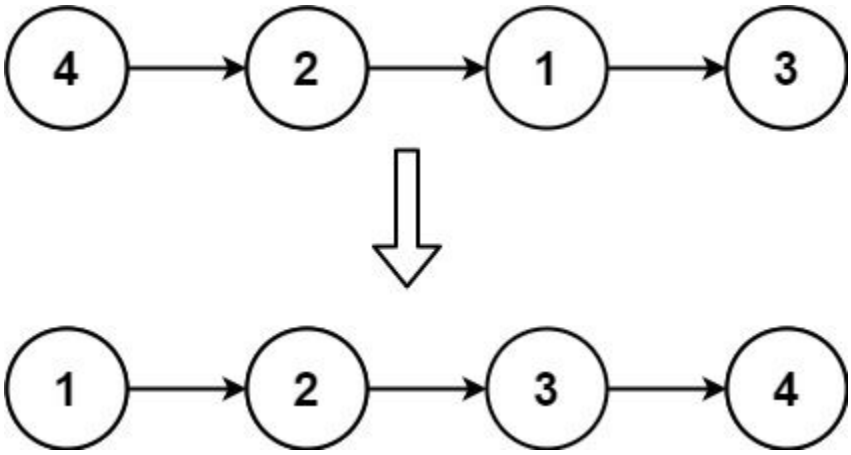
Given the `head` of a singly linked list, sort the list using **insertion sort**, and return *the sorted list's head*.

The steps of the **insertion sort** algorithm:

1. Insertion sort iterates, consuming one input element each repetition and growing a sorted output list.
2. At each iteration, insertion sort removes one element from the input data, finds the location it belongs within the sorted list and inserts it there.
3. It repeats until no input elements remain.

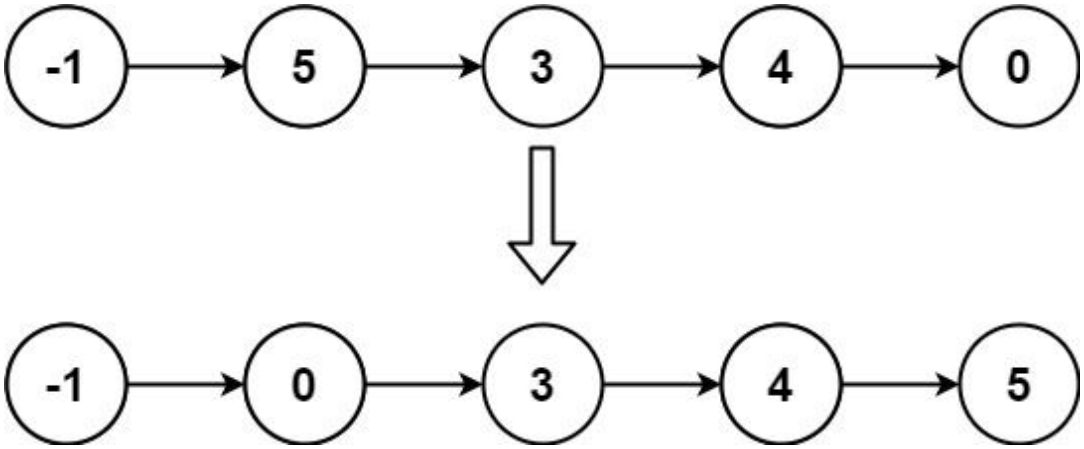
The following is a graphical example of the insertion sort algorithm. The partially sorted list (black) initially contains only the first element in the list. One element (red) is removed from the input data and inserted in-place into the sorted list with each iteration.

Example 1:



```
Input: head = [4,2,1,3]
Output: [1,2,3,4]
```

Example 2:



```
Input: head = [-1,5,3,4,0]
Output: [-1,0,3,4,5]
```

Constraints:

- The number of nodes in the list is in the range `[1, 5000]`.
- `-5000 <= Node.val <= 5000`

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Insertion-sort a list. n≤ 5000, so quadratic time is fine. Sorting an array and rebuilding the list is not insertion sort. pre marks the end of the sorted prefix. If the current value is larger, extend the prefix; otherwise walk from a dummy to the first larger node and splice it in. The dummy removes the head-insertion special case.

Python 3

```python
# Definition for singly-linked list.
# class ListNode:
#     def __init__(self, val=0, next=None):
#         self.val = val
#         self.next = next
class Solution:
    def insertionSortList(self, head: ListNode) -> ListNode:
        if head is None or head.next is None:
            return head
        dummy = ListNode(head.val, head)
        pre, cur = dummy, head
        while cur:
            if pre.val <= cur.val:
                pre, cur = cur, cur.next
                continue
            p = dummy
            while p.next.val <= cur.val:
                p = p.next
            t = cur.next
            cur.next = p.next
            p.next = cur
            pre.next = t
            cur = t
        return dummy.next
```

Complexity. Time: O(n^2). Space: O(1).

369. Plus One Linked List

Medium · Linked List, Math

leetcode.com/problems/plus-one-linked-list

PROBLEM

Given a non-negative integer represented as a linked list of digits, *plus one to the integer*.

The digits are stored such that the most significant digit is at the `head` of the list.

Example 1:

```
Input: head = [1,2,3]
Output: [1,2,4]
```

Example 2:

```
Input: head = [0]
Output: [1]
```

Constraints:

- The number of nodes in the linked list is in the range `[1, 100]`.
- `0 <= Node.val <= 9`
- The number represented by the linked list does not contain leading zeros except for the zero itself.

SOLUTION (PYTHON 3)

Solution 1: Linked List Traversal

How to think about it

Add one to a non-negative integer stored as a list. Materializing an array uses extra O(n) space. Carry only touches a trailing run of nines. A dummy head covers a new high digit. One scan remembers the last non-nine, increments it, and zeros the rest. If the dummy becomes 1, it is the new head.

We first set a dummy head node dummy, initially with a value of 0, and the successor node of dummy is the linked list head.

Next, we traverse the linked list starting from the dummy head node, find the last node that is not 9, increment its value by 1, and set the values of all nodes after this node to 0.

Finally, we check if the value of the dummy head node is 1. If it is 1, we return dummy; otherwise, we return the successor node of dummy.

The time complexity is O(n), where n is the length of the linked list. The space complexity is O(1).

Python 3

```python
# Definition for singly-linked list.
# class ListNode:
#     def __init__(self, val=0, next=None):
#         self.val = val
#         self.next = next
class Solution:
    def plusOne(self, head: Optional[ListNode]) -> Optional[ListNode]:
        dummy = ListNode(0, head)
        target = dummy
        while head:
            if head.val != 9:
                target = head
            head = head.next
        target.val += 1
        target = target.next
        while target:
            target.val = 0
            target = target.next
        return dummy if dummy.val else dummy.next
```

    if head.val == 0 and head.next:
        return head.next
    return head
```

1381. Design a Stack With Increment Operation

Medium · Stack, Design, Array

leetcode.com/problems/design-a-stack-with-increment-operation

Also appears in pattern 29 Design Problems

PROBLEM

Design a stack that supports increment operations on its elements.

Implement the `CustomStack` class:

- `CustomStack(int maxSize)` Initializes the object with `maxSize` which is the maximum number of elements in the stack.
- `void push(int x)` Adds `x` to the top of the stack if the stack has not reached the `maxSize`.
- `int pop()` Pops and returns the top of the stack or `-1` if the stack is empty.
- `void inc(int k, int val)` Increments the bottom `k` elements of the stack by `val`. If there are less than `k` elements in the stack, increment all the elements in the stack.

Example 1:

```
Input
["CustomStack","push","push","pop","push","push","push","increment","increment","pop","pop","pop","pop
"]
[[3],[1],[2],[],[2],[3],[4],[5,100],[2,100],[],[],[],[]]
Output
[null,null,null,2,null,null,null,null,null,103,202,201,-1]
Explanation
CustomStack stk = new CustomStack(3); // Stack is Empty []
stk.push(1); // stack becomes [1]
stk.push(2); // stack becomes [1, 2]
stk.pop(); // return 2 --> Return top of the stack 2, stack becomes [1]
stk.push(2); // stack becomes [1, 2]
stk.push(3); // stack becomes [1, 2, 3]
stk.push(4); // stack still [1, 2, 3], Do not add another elements as size is 4
stk.increment(5, 100); // stack becomes [101, 102, 103]
stk.increment(2, 100); // stack becomes [201, 202, 103]
stk.pop(); // return 103 --> Return top of the stack 103, stack becomes [201, 202]
stk.pop(); // return 202 --> Return top of the stack 202, stack becomes [201]
stk.pop(); // return 201 --> Return top of the stack 201, stack becomes []
stk.pop(); // return -1 --> Stack is empty return -1.
```

Constraints:

- `1 <= maxSize, x, k <= 1000`
- `0 <= val <= 100`
- At most `1000` calls will be made to each method of `increment`, `push` and `pop` each separately.

SOLUTION (PYTHON 3)

Solution 1: Array Simulation

How to think about it

increment adds val to the bottom k entries. Scanning the stack is fine for 10^3 calls, yet O(1) is possible: add[i] is a lazy increment for index i and below. The update lands on min(k,size)-1; a pop forwards that increment one slot down and clears it.

We can use an array stk to simulate the stack, and an integer i to represent the position of the next element to be pushed into the stack. In addition, we need another array add to record the cumulative increment value at each position.

When calling push(x), if i < maxSize, we put x into stk[i] and increment i by one.

When calling pop(), if i ≤ 0, it means the stack is empty, so we return -1. Otherwise, we decrement i by one, and the answer is stk[i] + add[i]. Then we add add[i] to add[i - 1], and set add[i] to zero. Finally, we return the answer.

When calling increment(k, val), if i > 0, we add val to add[min(i, k) - 1].

The time complexity is O(1), and the space complexity is O(n). Where n is the maximum capacity of the stack.

Python 3

```
class CustomStack:
    def __init__(self, maxSize: int):
        self.stk = [0] * maxSize
        self.add = [0] * maxSize
        self.i = 0

    def push(self, x: int) -> None:
        if self.i < len(self.stk):
            self.stk[self.i] = x
            self.i += 1

    def pop(self) -> int:
        if self.i <= 0:
            return -1
        self.i -= 1
        ans = self.stk[self.i] + self.add[self.i]
        if self.i > 0:
            self.add[self.i - 1] += self.add[self.i]
        self.add[self.i] = 0
        return ans

    def increment(self, k: int, val: int) -> None:
        i = min(k, self.i) - 1
        if i >= 0:
            self.add[i] += val

# Your CustomStack object will be instantiated and called as such:
# obj = CustomStack(maxSize)
# obj.push(x)
# param_2 = obj.pop()
# obj.increment(k,val)
```

            self.items[i] -= val
```

1669. Merge In Between Linked Lists

Medium · Linked List

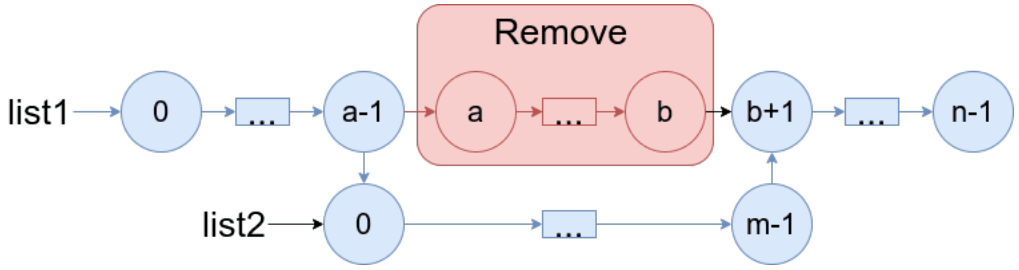
leetcode.com/problems/merge-in-between-linked-lists

PROBLEM

You are given two linked lists: `list1` and `list2` of sizes `n` and `m` respectively.

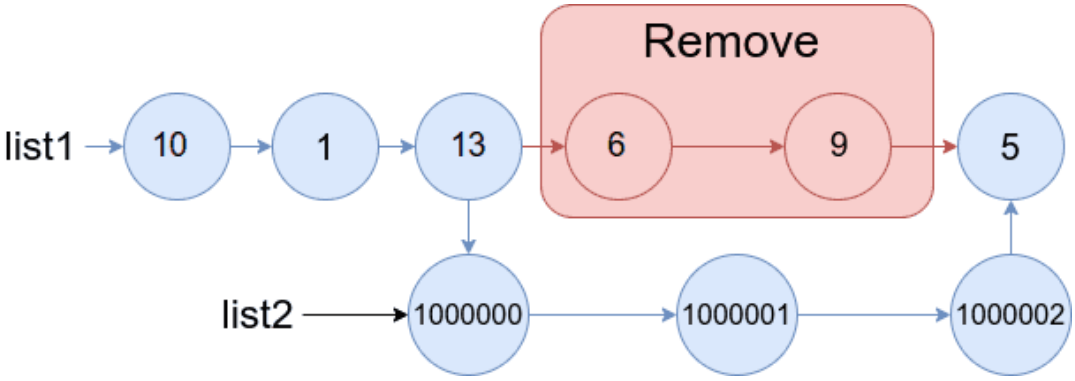
Remove `list1`'s nodes from the a^{th} node to the b^{th} node, and put `list2` in their place.

The blue edges and nodes in the following figure indicate the result:



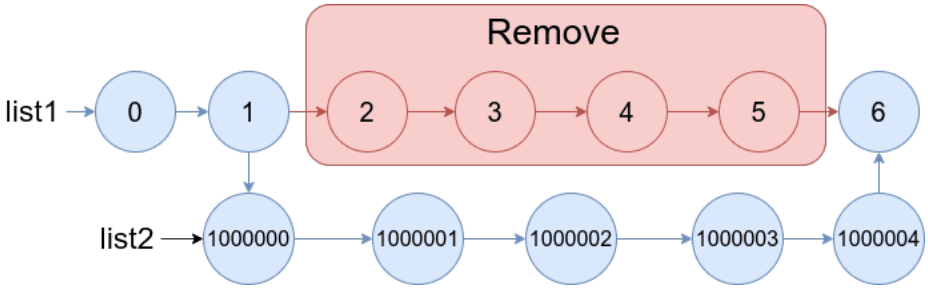
Build the result list and return its head.

Example 1:



```
Input: list1 = [10,1,13,6,9,5], a = 3, b = 4, list2 = [1000000,1000001,1000002]
Output: [10,1,13,1000000,1000001,1000002,5]
Explanation: We remove the nodes 3 and 4 and put the entire list2 in their place. The blue edges and
nodes in the above figure indicate the result.
```

Example 2:



```
Input: list1 = [0,1,2,3,4,5,6], a = 2, b = 5, list2 = [1000000,1000001,1000002,1000003,1000004]
Output: [0,1,1000000,1000001,1000002,1000003,1000004,6]
Explanation: The blue edges and nodes in the above figure indicate the result.
```

Constraints:

- `3 <= list1.length <= 10^4`

- `1 <= a <= b < list1.length - 1`
- `1 <= list2.length <= 10^4`

SOLUTION (PYTHON 3)

Solution 1: Simulation

> **How to think about it**
>
> Replace indices [a,b] of list1 with list2. Find the predecessor of a and node b, link the predecessor to list2's head, then list2's tail to b's successor. Two pointers walk the needed steps, a third scan finds list2's end, and b.next is cleared.

We can directly simulate the operations described in the problem.

In the implementation, we use two pointers p and q, both initially pointing to the head node of `list1`.

Then we move pointers p and q forward, until pointer p points to the node before the a-th node in `list1`, and pointer q points to the b-th node in `list1`. At this point, we set the `next` pointer of p to the head node of `list2`, and set the `next` pointer of the tail node of `list2` to the node pointed to by the `next` pointer of q. This completes the operation required by the problem.

The time complexity is O(m + n), and the space complexity is O(1). Where m and n are the lengths of `list1` and `list2` respectively.

Python 3

```
# Definition for singly-linked list.
# class ListNode:
#     def __init__(self, val=0, next=None):
#         self.val = val
#         self.next = next
class Solution:
    def mergeInBetween(
        self, list1: ListNode, a: int, b: int, list2: ListNode
    ) -> ListNode:
        p = q = list1
        for _ in range(a - 1):
            p = p.next
        for _ in range(b):
            q = q.next
        p.next = list2
        while p.next:
            p = p.next
        p.next = q.next
        q.next = None
        return list1
```

146. LRU Cache

Medium · Design, Hash Table, Linked List, Doubly-Linked List

leetcode.com/problems/lru-cache

★ **TOP 10 PROBLEM** in Linked List Reversal / Manipulation, Design Problems: master this one first

Also appears in pattern 29 Design Problems

PROBLEM

Design a data structure that follows the constraints of a **Least Recently Used (LRU) cache**.

Implement the `LRUCache` class:

- `LRUCache(int capacity)` Initialize the LRU cache with **positive** size `capacity`.
- `int get(int key)` Return the value of the `key` if the key exists, otherwise return `-1`.
- `void put(int key, int value)` Update the value of the `key` if the `key` exists. Otherwise, add the `key-value` pair to the cache. If the number of keys exceeds the `capacity` from this operation, **evict** the least recently used key.

The functions `get` and `put` must each run in `O(1)` average time complexity.

Example 1:

```
Input
["LRUCache", "put", "put", "get", "put", "get", "put", "get", "get", "get"]
[[2], [1, 1], [2, 2], [1], [3, 3], [2], [4, 4], [1], [3], [4]]
Output
[null, null, null, 1, null, -1, null, -1, 3, 4]

Explanation
LRUCache lRUCache = new LRUCache(2);
lRUCache.put(1, 1); // cache is {1=1}
lRUCache.put(2, 2); // cache is {1=1, 2=2}
lRUCache.get(1); // return 1
lRUCache.put(3, 3); // LRU key was 2, evicts key 2, cache is {1=1, 3=3}
lRUCache.get(2); // returns -1 (not found)
lRUCache.put(4, 4); // LRU key was 1, evicts key 1, cache is {4=4, 3=3}
lRUCache.get(1); // return -1 (not found)
lRUCache.get(3); // return 3
lRUCache.get(4); // return 4
```

Constraints:

- `1 <= capacity <= 3000`
- `0 <= key <=` 10^4
- `0 <= value <=` 10^5
- At most `2 * 10^5` calls will be made to `get` and `put`.

SOLUTION (PYTHON 3)

Solution 1: Hash Table + Doubly Linked List

How to think about it

get and put must be O(1), evicting the least recently used key. A hash map finds keys in O(1) but does not keep recency; moving nodes in an array or singly linked list is O(n). Up to 2× 10^5 calls. Map keys to nodes, and keep a doubly linked list with most-recent at the head. On access, detach the node and insert it at the head; when over capacity, drop the tail's predecessor. Lookup and pointer updates are O(1).

We can implement an LRU (Least Recently Used) cache using a "hash table" and a "doubly linked list".

- Hash Table: Used to store the key and its corresponding node location.
- Doubly Linked List: Used to store node data, sorted by access time.

When accessing a node, if the node exists, we delete it from its original position and reinsert it at the head of the list. This ensures that the node stored at the tail of the list is the least recently used node. When the number of nodes exceeds the maximum cache space, we eliminate the node at the tail of the list.

When inserting a node, if the node exists, we delete it from its original position and reinsert it at the head of the list. If it does not exist, we first check if the cache is full. If it is full, we delete the node at the tail of the list and insert the new node at the head of the list.

The time complexity is O(1), and the space complexity is O(capacity).

Python 3

```python
class Node:
    def __init__(self, key: int = 0, val: int = 0):
        self.key = key
        self.val = val
        self.prev = None
        self.next = None

class LRUCache:

    def __init__(self, capacity: int):
        self.size = 0
        self.capacity = capacity
        self.cache = {}
        self.head = Node()
        self.tail = Node()
        self.head.next = self.tail
        self.tail.prev = self.head

    def get(self, key: int) -> int:
        if key not in self.cache:
            return -1
        node = self.cache[key]
        self.remove_node(node)
        self.add_to_head(node)
        return node.val

    def put(self, key: int, value: int) -> None:
        if key in self.cache:
            node = self.cache[key]
            self.remove_node(node)
            node.val = value
            self.add_to_head(node)
        else:
            node = Node(key, value)
            self.cache[key] = node
            self.add_to_head(node)
            self.size += 1
            if self.size > self.capacity:
                node = self.tail.prev
                self.cache.pop(node.key)
                self.remove_node(node)
                self.size -= 1

    def remove_node(self, node):
        node.prev.next = node.next
        node.next.prev = node.prev

    def add_to_head(self, node):
        node.next = self.head.next
        node.prev = self.head
        self.head.next = node
        node.next.prev = node

# Your LRUCache object will be instantiated and called as such:
# obj = LRUCache(capacity)
# param_1 = obj.get(key)
# obj.put(key,value)
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

25. Reverse Nodes in k-Group

Hard · Recursion, Linked List

leetcode.com/problems/reverse-nodes-in-k-group

★ **TOP 10 PROBLEM** in Linked List Reversal / Manipulation: master this one first

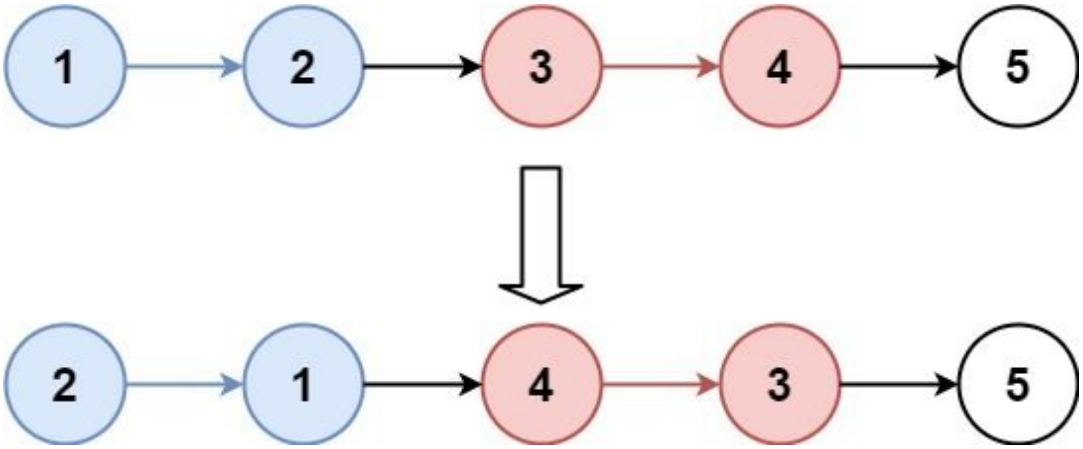
PROBLEM

Given the `head` of a linked list, reverse the nodes of the list `k` at a time, and return *the modified list*.

`k` is a positive integer and is less than or equal to the length of the linked list. If the number of nodes is not a multiple of `k` then left-out nodes, in the end, should remain as it is.

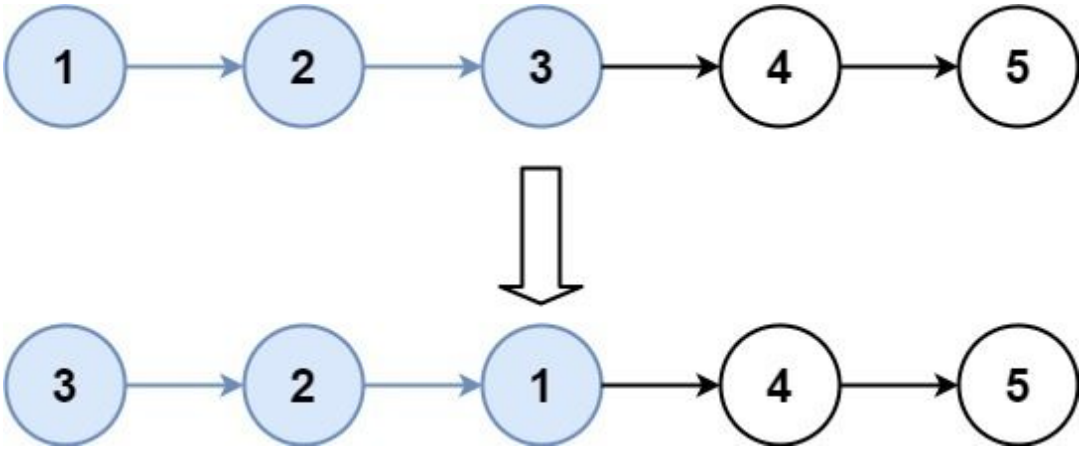
You may not alter the values in the list's nodes, only nodes themselves may be changed.

Example 1:



```
Input: head = [1,2,3,4,5], k = 2
Output: [2,1,4,3,5]
```

Example 2:



```
Input: head = [1,2,3,4,5], k = 3
Output: [3,2,1,4,5]
```

Constraints:

- The number of nodes in the list is `n`.
- `1 <= k <= n <= 5000`
- `0 <= Node.val <= 1000`

Follow-up: Can you solve the problem in `O(1)` extra memory space?

SOLUTION (PYTHON 3)

Solution 1: Simulation

How to think about it

The first idea is recursion by groups: reverse k nodes, then recurse on the rest. n ≤ 5000 would pass, but the follow-up asks for O(1) extra space, and a recursive stack grows with the number of groups. Two places are easy to get wrong: we must confirm a full group of k (otherwise leave the tail alone), and we must splice the reversed segment back without dropping a pointer. Inside a group the work is ordinary list reversal; between groups we only need the previous tail. Start from a dummy, walk k steps to probe, then detach, reverse, and reconnect; stop when a probe falls short. Probe, reverse, and relink are all pointer writes, so extra space is O(1).

We can simulate the entire reversal process according to the problem description.

First, we define a helper function reverse to reverse a linked list. Then, we define a dummy head node dummy and set its next pointer to head.

Next, we traverse the linked list, processing k nodes at a time. If the remaining nodes are fewer than k, we do not perform the reversal. Otherwise, we extract k nodes and call the reverse function to reverse these k nodes. Then, we connect the reversed linked list back to the original linked list. We continue to process the next k nodes until the entire linked list is traversed.

The time complexity is O(n), where n is the length of the linked list. The space complexity is O(1).

Python 3

```python
# Definition for singly-linked list.
# class ListNode:
#     def __init__(self, val=0, next=None):
#         self.val = val
#         self.next = next
class Solution:
    def reverseKGroup(self, head: Optional[ListNode], k: int) -> Optional[ListNode]:
        def reverse(head: Optional[ListNode]) -> Optional[ListNode]:
            dummy = ListNode()
            cur = head
            while cur:
                nxt = cur.next
                cur.next = dummy.next
                dummy.next = cur
                cur = nxt
            return dummy.next

        dummy = pre = ListNode(next=head)
        while pre:
            cur = pre
            for _ in range(k):
                cur = cur.next
                if cur is None:
                    return dummy.next
            node = pre.next
            nxt = cur.next
            cur.next = None
            pre.next = reverse(node)
            node.next = nxt
            pre = node
        return dummy.next
```

PATTERN 25 · LINKED LIST REVERSAL / MANIPULATION · PROBLEM 20 OF 20

23. Merge k Sorted Lists

Hard · Linked List, Divide and Conquer, Heap (Priority Queue), Merge Sort, Tournament Sort

leetcode.com/problems/merge-k-sorted-lists

★ **TOP 10 PROBLEM** in Linked List Reversal / Manipulation, K-way Merge: master this one first

Also appears in pattern 38 K-way Merge

PROBLEM

You are given an array of `k` linked-lists `lists`, each linked-list is sorted in ascending order.

Merge all the linked-lists into one sorted linked-list and return it.

Example 1:

```
Input: lists = [[1,4,5],[1,3,4],[2,6]]
Output: [1,1,2,3,4,4,5,6]
Explanation: The linked-lists are:
[
  1->4->5,
  1->3->4,
  2->6
]
merging them into one sorted linked list:
1->1->2->3->4->4->5->6
```

Example 2:

```
Input: lists = []
Output: []
```

Example 3:

```
Input: lists = [[]]
Output: []
```

Constraints:

- `k == lists.length`
- `0 <= k <= 10^4`
- `0 <= lists[i].length <= 500`
- `-10^4 <= lists[i][j] <= 10^4`
- `lists[i]` is sorted in **ascending order**.
- The sum of `lists[i].length` will not exceed `10^4`.

SOLUTION (PYTHON 3)

Solution 1: Priority Queue (Min Heap)

How to think about it

The first idea is pairwise merge: merge list 1 with 2, then fold in 3, and so on. With $N \le 10^4$ nodes and $k \le 10^4$ lists, the worst case is O(Nk) and can time out. Dumping every node into an array and sorting also works, but ignores that each list is already sorted. The bottleneck is finding the smallest among k heads at every step. A linear scan is O(k) per node and does not fit. At any moment the next node is just the minimum of the current heads. A min-heap of those k heads pops the smallest and pushes its successor. Each node enters and leaves the heap once, so the time is O(Nlog k) and the heap holds at most k pointers.

We can create a min heap pq to maintain the head nodes of all linked lists. Each time, we take out the node with the smallest value from the min heap, add it to the end of the result linked list, and then add the next node of this node to the heap. Repeat the above steps until the heap is empty.

The time complexity is O(n × log k), and the space complexity is O(k). Here, n is the total number of all linked list nodes, and k is the number of linked lists given in the problem.

Python 3

```python
# Definition for singly-linked list.
# class ListNode:
#     def __init__(self, val=0, next=None):
#         self.val = val
#         self.next = next
class Solution:
    def mergeKLists(self, lists: List[Optional[ListNode]]) -> Optional[ListNode]:
        setattr(ListNode, "__lt__", lambda a, b: a.val < b.val)
        pq = [head for head in lists if head]
        heapify(pq)
        dummy = cur = ListNode()
        while pq:
            node = heappop(pq)
            if node.next:
                heappush(pq, node.next)
            cur.next = node
            cur = cur.next
        return dummy.next
```

700. Search in a Binary Search Tree

Easy · Tree, Binary Search Tree, Binary Tree

leetcode.com/problems/search-in-a-binary-search-tree

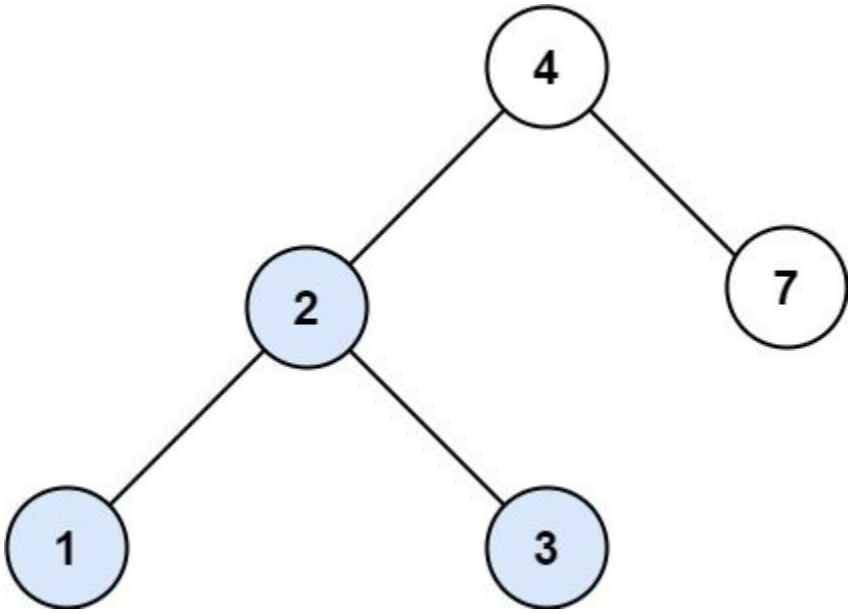
★ **TOP 10 PROBLEM** in Binary Search Tree (BST): master this one first

PROBLEM

You are given the `root` of a binary search tree (BST) and an integer `val`.

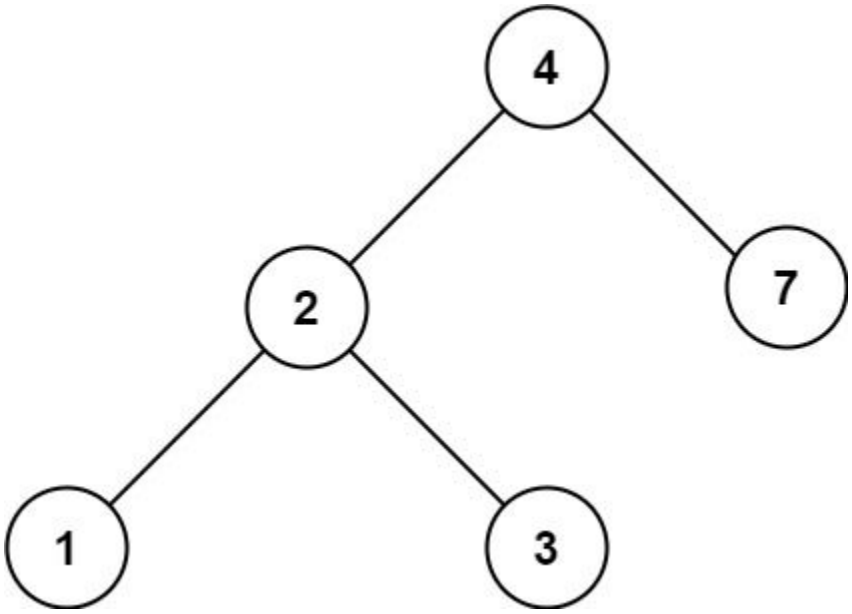
Find the node in the BST that the node's value equals `val` and return the subtree rooted with that node. If such a node does not exist, return `null`.

Example 1:



```
Input: root = [4,2,7,1,3], val = 2
Output: [2,1,3]
```

Example 2:



```
Input: root = [4,2,7,1,3], val = 5
Output: []
```

Constraints:

- The number of nodes in the tree is in the range `[1, 5000]`.
- `1 <= Node.val <= 10^7`
- `root` is a binary search tree.
- `1 <= val <= 10^7`

SOLUTION (PYTHON 3)

Solution 1: Recursion

How to think about it

We need the subtree rooted at the node whose value is val. n ≤ 5000 would allow a full scan, but that ignores the BST order. If the current value equals the target, that node is the answer; if it is larger, the target can only lie in the left subtree, otherwise only in the right. One comparison therefore discards an entire side. Recursion matches this walk: return the current node when it is empty or a hit, otherwise descend left or right. A degenerate chain still costs O(n) time and stack space.

We check if the current node is null or if the current node's value equals the target value. If so, we return the current node.

Otherwise, if the current node's value is greater than the target value, we recursively search the left subtree; otherwise, we recursively search the right subtree.

The time complexity is O(n), and the space complexity is O(n). Here, n is the number of nodes in the binary tree.

Python 3

```python
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def searchBST(self, root: Optional[TreeNode], val: int) -> Optional[TreeNode]:
        if root is None or root.val == val:
            return root
        return (
            self.searchBST(root.left, val)
            if root.val > val
            else self.searchBST(root.right, val)
        )
```

# path is empty if the value is missing.
# Time: O(h).  Space: O(h).
def path_to_value(root, val):
    path = []
    node = root
    while node:
        path.append(node.val)
        if node.val == val:
            return path
        node = node.left if val < node.val else node.right
    return []
```

235. Lowest Common Ancestor of a Binary Search Tree

Medium · Tree, Depth-First Search, Binary Search Tree, Binary Tree, Lowest Common Ancestor, Binary Lifting

leetcode.com/problems/lowest-common-ancestor-of-a-binary-search-tree

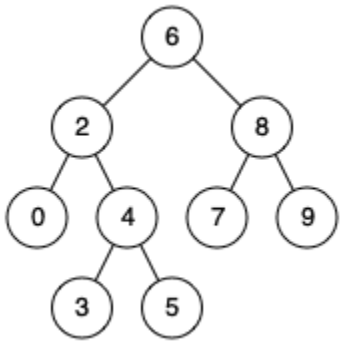
★ **TOP 10 PROBLEM** in Binary Search Tree (BST): master this one first

PROBLEM

Given a binary search tree (BST), find the lowest common ancestor (LCA) node of two given nodes in the BST.

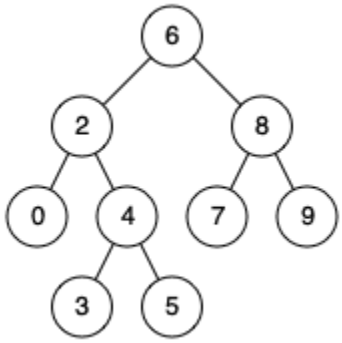
According to the definition of LCA on Wikipedia: "The lowest common ancestor is defined between two nodes `p` and `q` as the lowest node in `T` that has both `p` and `q` as descendants (where we allow **a node to be a descendant of itself**)."

Example 1:



```
Input: root = [6,2,8,0,4,7,9,null,null,3,5], p = 2, q = 8
Output: 6
Explanation: The LCA of nodes 2 and 8 is 6.
```

Example 2:



```
Input: root = [6,2,8,0,4,7,9,null,null,3,5], p = 2, q = 4
Output: 2
Explanation: The LCA of nodes 2 and 4 is 2, since a node can be a descendant of itself according to the
LCA definition.
```

Example 3:

```
Input: root = [2,1], p = 2, q = 1
Output: 2
```

Constraints:

- The number of nodes in the tree is in the range `[2, 10^5]`.

- -10^9 <= Node.val <= 10^9
- All Node.val are **unique**.
- p != q
- p and q will exist in the BST.

SOLUTIONS (PYTHON 3)

Solution 1: Iteration

> **How to think about it**
>
> In a BST the LCA of p and q is the fork between their values. Walk from the root: go left if both are smaller, right if both are larger, otherwise the current node is the fork. The walk is iterative and needs no call stack.

Starting from the root node, we traverse the tree. If the current node's value is less than both p and q values, it means that p and q should be in the right subtree of the current node, so we move to the right child. If the current node's value is greater than both p and q values, it means that p and q should be in the left subtree, so we move to the left child. Otherwise, it means the current node is the lowest common ancestor of p and q, so we return the current node.

The time complexity is O(n), where n is the number of nodes in the binary search tree. The space complexity is O(1).

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, x):
#         self.val = x
#         self.left = None
#         self.right = None

class Solution:
    def lowestCommonAncestor(
        self, root: 'TreeNode', p: 'TreeNode', q: 'TreeNode'
    ) -> 'TreeNode':
        while 1:
            if root.val < min(p.val, q.val):
                root = root.right
            elif root.val > max(p.val, q.val):
                root = root.left
            else:
                return root
```

Solution 2: Recursion

> **How to think about it**
>
> The same fork rule is a recursion: recurse into the side that contains both, otherwise return the current root. The idea matches the iteration with a shorter implementation.

We can also use a recursive approach to solve this problem.

We first check if the current node's value is less than both p and q values. If it is, we recursively traverse the right subtree. If the current node's value is greater than both p and q values, we recursively traverse the left subtree. Otherwise, it means the current node is the lowest common ancestor of p and q, so we return the current node.

The time complexity is O(n), and the space complexity is O(n). Where n is the number of nodes in the binary search tree.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, x):
#         self.val = x
#         self.left = None
#         self.right = None

class Solution:
    def lowestCommonAncestor(
        self, root: 'TreeNode', p: 'TreeNode', q: 'TreeNode'
    ) -> 'TreeNode':
        if root.val < min(p.val, q.val):
            return self.lowestCommonAncestor(root.right, p, q)
        if root.val > max(p.val, q.val):
            return self.lowestCommonAncestor(root.left, p, q)
        return root
```

530. Minimum Absolute Difference in BST

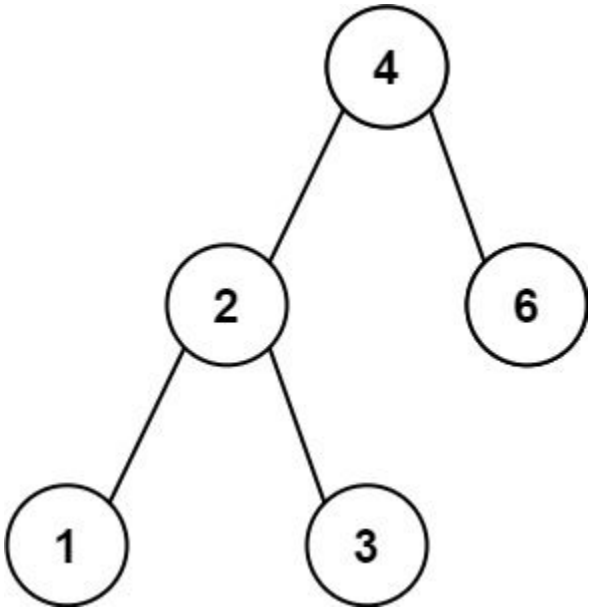
Easy · Tree, Depth-First Search, Breadth-First Search, Binary Search Tree, Binary Tree

leetcode.com/problems/minimum-absolute-difference-in-bst

PROBLEM

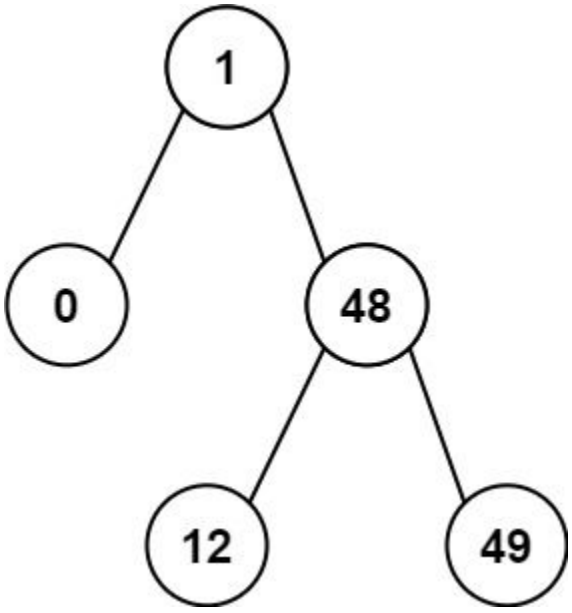
Given the `root` of a Binary Search Tree (BST), return *the minimum absolute difference between the values of any two different nodes in the tree*.

Example 1:



```
Input: root = [4,2,6,1,3]
Output: 1
```

Example 2:



```
Input: root = [1,0,48,null,null,12,49]
Output: 1
```

Constraints:

- The number of nodes in the tree is in the range `[2, 10^4]`.
- `0 <= Node.val <= 10^5`

Note: This question is the same as 783: https://leetcode.com/problems/minimum-distance-between-bst-nodes/

SOLUTIONS (PYTHON 3)

Solution 1: Inorder Traversal

How to think about it

The minimum pairwise difference on a general tree needs all pairs. In a BST, inorder is sorted, so the minimum lies between adjacent values. Walk inorder, keep the predecessor, and update with `val - pre`. Seed `pre` at -∞ so the first node is skipped. One inorder pass suffices.

The problem requires us to find the minimum difference between the values of any two nodes. Since the inorder traversal of a binary search tree is an increasing sequence, we only need to find the minimum difference between the values of two adjacent nodes in the inorder traversal.

We can use a recursive method to implement the inorder traversal. During the process, we use a variable pre to save the value of the previous node. This way, we can calculate the minimum difference between the values of two adjacent nodes during the traversal.

The time complexity is O(n), and the space complexity is O(n). Here, n is the number of nodes in the binary search tree.

Python 3

```python
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def getMinimumDifference(self, root: Optional[TreeNode]) -> int:
        def dfs(root: Optional[TreeNode]):
            if root is None:
                return
            dfs(root.left)
            nonlocal pre, ans
            ans = min(ans, root.val - pre)
            pre = root.val
            dfs(root.right)

        pre = -inf
        ans = inf
        dfs(root)
        return ans
```

Solution 2: Explicit-Stack Inorder

How to think about it

The minimum pairwise difference on a general tree needs all pairs. In a BST, inorder is sorted, so the minimum lies between adjacent values. Recursing inorder and subtracting the predecessor is correct on a short tree. The tree can contain 10^4 nodes. A left chain makes this walk recurse once per node and overflow the call stack. Each node only needs the previous value. The walk does not need a return value, as long as the left subtree is finished before the node and the right subtree comes after. An explicit stack performs that inorder walk. On entry it pushes an exit marker and the left child; on exit it updates the answer with the current value minus the predecessor and pushes the right child. The predecessor starts at -∞, so the first node does not become the answer.

The minimum difference between any two node values of a binary search tree is the minimum gap between adjacent values in its increasing inorder sequence.

An explicit stack walks the tree in that order, and pre stores the previous value, initially -∞. On entry we push an exit marker and the left child. On exit we update the answer with the current value minus pre, store the current value in pre, and push the right child.

The time complexity is O(n), and the space complexity is O(n). Here, n is the number of nodes in the binary search tree.

Python 3

```python
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def getMinimumDifference(self, root: Optional[TreeNode]) -> int:
        pre = -inf
        ans = inf
        stk = [(root, 0)]
        while stk:
            node, state = stk.pop()
            if node is None:
                continue
            if state == 0:
                stk.append((node, 1))
                stk.append((node.left, 0))
                continue
            ans = min(ans, node.val - pre)
            pre = node.val
            stk.append((node.right, 0))
        return ans
```

```

```
            best = difference
    return best
```

938. Range Sum of BST

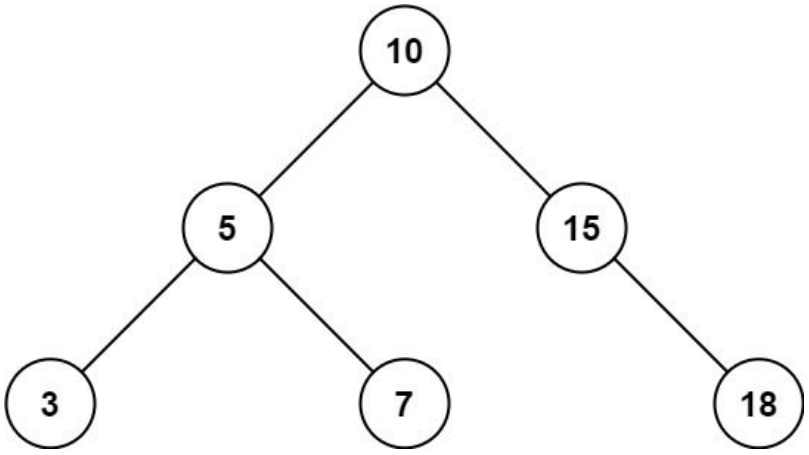
Easy · Tree, Depth-First Search, Binary Search Tree, Binary Tree

leetcode.com/problems/range-sum-of-bst

PROBLEM

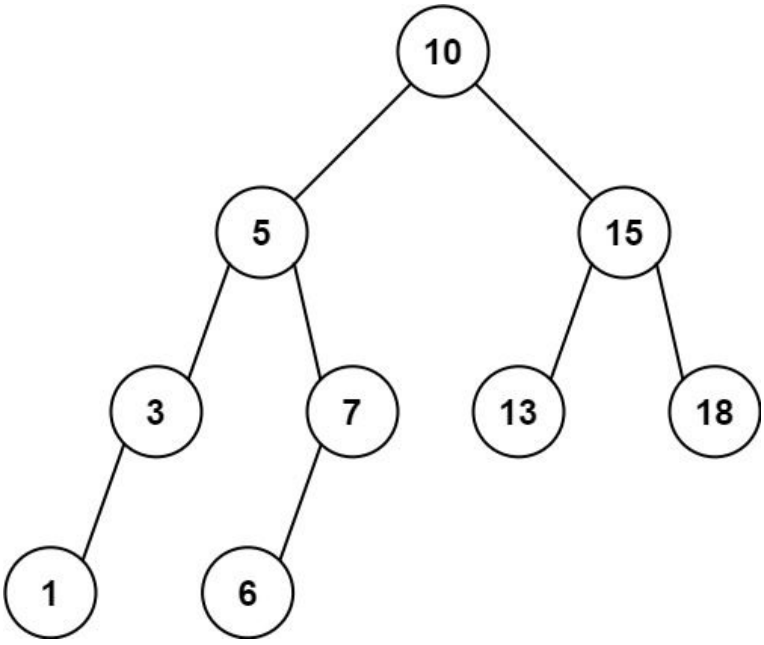
Given the `root` node of a binary search tree and two integers `low` and `high`, return *the sum of values of all nodes with a value in the* ***inclusive*** *range* `[low, high]`.

Example 1:



```
Input: root = [10,5,15,3,7,null,18], low = 7, high = 15
Output: 32
Explanation: Nodes 7, 10, and 15 are in the range [7, 15]. 7 + 10 + 15 = 32.
```

Example 2:



```
Input: root = [10,5,15,3,7,13,18,1,null,6], low = 6, high = 10
Output: 23
Explanation: Nodes 6, 7, and 10 are in the range [6, 10]. 6 + 7 + 10 = 23.
```

Constraints:

- The number of nodes in the tree is in the range `[1, 2 * 10^4]`.
- `1 <= Node.val <= 10^5`
- `1 <= low <= high <= 10^5`
- All `Node.val` are **unique**.

SOLUTION (PYTHON 3)

Solution 1: DFS

> **How to think about it**
>
> Sum BST nodes whose values lie in [low,high]. A full traversal works, but the search-tree order prunes: skip the left subtree when the current value is already ≤ low, and skip the right when it is already ≥ high. Recurse and add nodes that fall inside the interval.

We design a function dfs(root), which represents the sum of the values of all nodes in the subtree with root as the root, and the values are within the range [low, high]. The answer is dfs(root).

The execution logic of the function dfs(root) is as follows:

- If root is null, return 0.
- If the value x of root is within the range [low, high], then the initial answer of the function dfs(root) is x, otherwise it is 0.
- If x > low, it means that there may be nodes in the left subtree of root with values within the range [low, high], so we need to recursively call dfs(root.left) and add the result to the answer.
- If x < high, it means that there may be nodes in the right subtree of root with values within the range [low, high], so we need to recursively call dfs(root.right) and add the result to the answer.
- Finally, return the answer.

The time complexity is O(n), and the space complexity is O(n). Where n is the number of nodes in the binary search tree.

Python 3

```python
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def rangeSumBST(self, root: Optional[TreeNode], low: int, high: int) -> int:
        def dfs(root: Optional[TreeNode]) -> int:
            if root is None:
                return 0
            x = root.val
            ans = x if low <= x <= high else 0
            if x > low:
                ans += dfs(root.left)
            if x < high:
                ans += dfs(root.right)
            return ans

        return dfs(root)
```

    walk(root)
    return result
```

653. Two Sum IV - Input is a BST

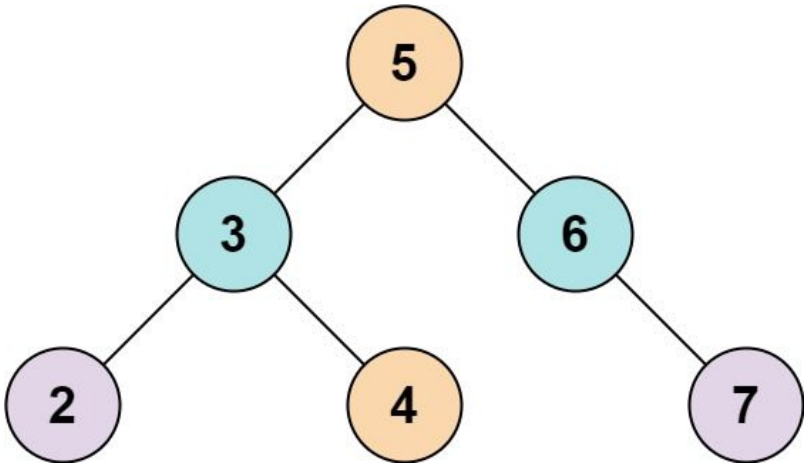
Easy · Tree, Depth-First Search, Breadth-First Search, Binary Search Tree, Hash Table, Two Pointers, Binary Tree

leetcode.com/problems/two-sum-iv-input-is-a-bst

PROBLEM

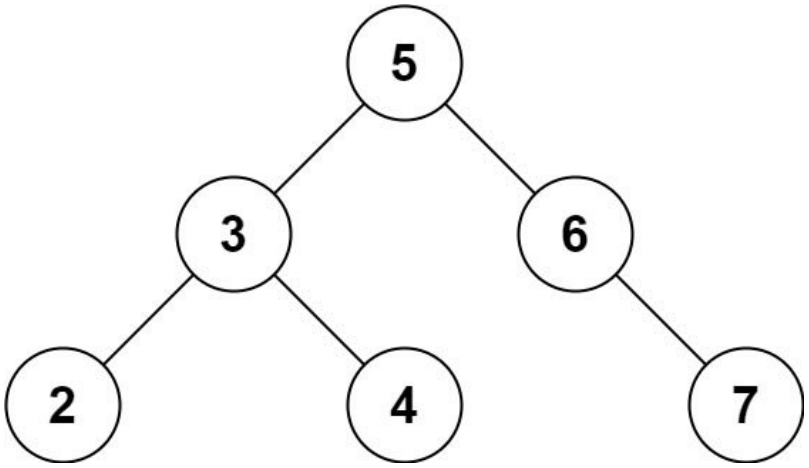
Given the `root` of a binary search tree and an integer `k`, return `true` *if there exist two elements in the BST such that their sum is equal to* `k`, *or* `false` *otherwise*.

Example 1:



```
Input: root = [5,3,6,2,4,null,7], k = 9
Output: true
```

Example 2:



```
Input: root = [5,3,6,2,4,null,7], k = 28
Output: false
```

Constraints:

- The number of nodes in the tree is in the range `[1, 10^4]`.
- `-10^4 <= Node.val <= 10^4`
- `root` is guaranteed to be a **valid** binary search tree.
- `-10^5 <= k <= 10^5`

SOLUTIONS (PYTHON 3)

Solution 1

> **How to think about it**
>
> Find two nodes summing to k. Inorder plus two pointers works after collecting values. A set of seen values during a walk is enough: if k-val is present, return true. The BST order is not required.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def findTarget(self, root: Optional[TreeNode], k: int) -> bool:
        def dfs(root):
            if root is None:
                return False
            if k - root.val in vis:
                return True
            vis.add(root.val)
            return dfs(root.left) or dfs(root.right)

        vis = set()
        return dfs(root)
```

Complexity. Time: O(n). Space: O(n).

Solution 2

> **How to think about it**
>
> DFS can be replaced by BFS with the same seen-set test; only the traversal order changes.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def findTarget(self, root: Optional[TreeNode], k: int) -> bool:
        q = deque([root])
        vis = set()
        while q:
            for _ in range(len(q)):
                node = q.popleft()
                if k - node.val in vis:
                    return True
                vis.add(node.val)
                if node.left:
                    q.append(node.left)
                if node.right:
                    q.append(node.right)
        return False
```

Complexity. Time: O(n). Space: O(n).

Solution 3: Hash Set and Explicit Stack

How to think about it

Find two nodes whose values sum to k. Inorder plus two pointers works after collecting every value. A set of values already seen is enough: if k minus the current value is present, return true. On a short tree one depth-first walk does this, and the BST order is not required. The tree can contain 10^4 nodes. A left chain makes this walk recurse once per node and overflow the call stack. Each node depends only on values already visited. The children do not need to return before the node is checked. An explicit stack keeps that depth-first order. Pop a node, test k minus its value, then store the value and push the right child and the left child. The set belongs to this call only.

A hash set stores values already visited, and an explicit stack walks the tree depth-first. When a node is popped, return true if k minus its value is already in the set. Otherwise store the value and push the non-null right child and left child.

The time complexity is O(n), and the space complexity is O(n). Here, n is the number of nodes in the binary search tree.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def findTarget(self, root: Optional[TreeNode], k: int) -> bool:
        vis = set()
        stk = []
        if root is not None:
            stk.append(root)
        while stk:
            node = stk.pop()
            if k - node.val in vis:
                return True
            vis.add(node.val)
            if node.right is not None:
                stk.append(node.right)
            if node.left is not None:
                stk.append(node.left)
        return False
```

501. Find Mode in Binary Search Tree

Easy · Tree, Depth-First Search, Binary Search Tree, Binary Tree

leetcode.com/problems/find-mode-in-binary-search-tree

PROBLEM

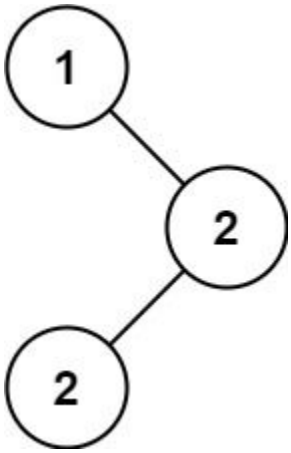
Given the `root` of a binary search tree (BST) with duplicates, return *all the mode(s) (i.e., the most frequently occurred element) in it*.

If the tree has more than one mode, return them in **any order**.

Assume a BST is defined as follows:

- The left subtree of a node contains only nodes with keys **less than or equal to** the node's key.
- The right subtree of a node contains only nodes with keys **greater than or equal to** the node's key.
- Both the left and right subtrees must also be binary search trees.

Example 1:



```
Input: root = [1,null,2,2]
Output: [2]
```

Example 2:

```
Input: root = [0]
Output: [0]
```

Constraints:

- The number of nodes in the tree is in the range `[1, 10^4]`.
- `-10^5 <= Node.val <= 10^5`

Follow up:

Could you do that without using any extra space? (Assume that the implicit stack space incurred due to recursion does not count).

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

The mode is the value with the highest frequency. Hashing every node is O(n) time and space and fits $n \le 10^4$, but ignores that the tree is a BST. Inorder yields a non-decreasing sequence, so equal values are adjacent. Track the predecessor, the current run length, and the best frequency: replace the answer when the run grows, append when it ties. One inorder pass collects every mode with O(h) extra space.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def findMode(self, root: TreeNode) -> List[int]:
        def dfs(root):
            if root is None:
                return
            nonlocal mx, prev, ans, cnt
            dfs(root.left)
            cnt = cnt + 1 if prev == root.val else 1
            if cnt > mx:
                ans = [root.val]
                mx = cnt
            elif cnt == mx:
                ans.append(root.val)
            prev = root.val
            dfs(root.right)

        prev = None
        mx = cnt = 0
        ans = []
        dfs(root)
        return ans
```

Solution 2: Explicit-Stack Inorder

How to think about it

The mode is the value with the highest frequency. Hashing every node fits $n \le 10^4$ in time, but ignores that the tree is a BST. Inorder visits the left child first. A chain of 10^4 nodes recurses once per node and overflows the call stack. Inorder is non-decreasing, so equal values are adjacent. The predecessor, the current run length, and the best frequency are enough; the walk does not need a return value. An explicit stack performs the inorder walk. On entry it pushes an exit marker and the left child; on exit the run length updates the answer, and then the right child is pushed. A longer run replaces the answer, and a tie appends the value.

An inorder walk of a binary search tree is non-decreasing, so equal values are adjacent. An explicit stack carries that walk together with the previous value, the current run length, and the best frequency. On entry we push an exit marker and the left child. On exit the run grows by one when the value matches its predecessor and otherwise restarts at 1. A longer run replaces the answer, a tie appends the value, and then the right child is pushed.

The time complexity is O(n) and the space complexity is O(n), where n is the number of nodes in the binary search tree.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def findMode(self, root: TreeNode) -> List[int]:
        prev = None
        mx = cnt = 0
        ans = []
        stk = [(root, 0)]
        while stk:
            node, state = stk.pop()
            if node is None:
                continue
            if state == 0:
                stk.append((node, 1))
                stk.append((node.left, 0))
                continue
            cnt = cnt + 1 if prev == node.val else 1
            if cnt > mx:
                ans = [node.val]
                mx = cnt
            elif cnt == mx:
                ans.append(node.val)
            prev = node.val
            stk.append((node.right, 0))
        return ans
```

270. Closest Binary Search Tree Value

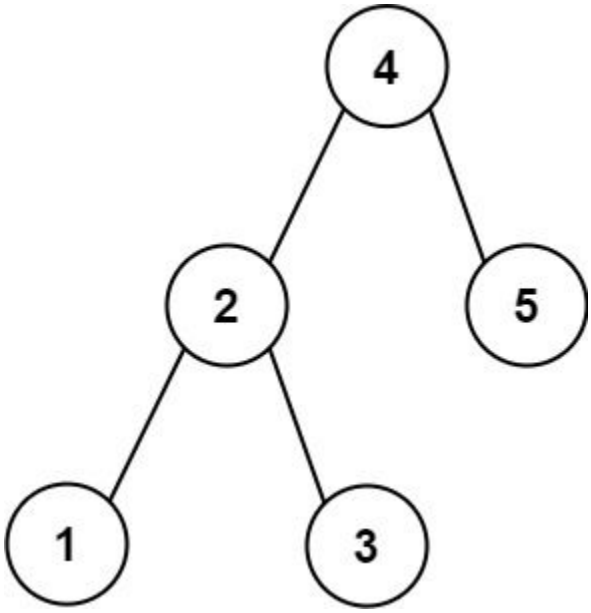
Easy · Tree, Depth-First Search, Binary Search Tree, Binary Search, Binary Tree

leetcode.com/problems/closest-binary-search-tree-value

PROBLEM

Given the `root` of a binary search tree and a `target` value, return *the value in the BST that is closest to the* `target`. If there are multiple answers, print the smallest.

Example 1:



```
Input: root = [4,2,5,1,3], target = 3.714286
Output: 4
```

Example 2:

```
Input: root = [1], target = 4.428571
Output: 1
```

Constraints:

- The number of nodes in the tree is in the range `[1, 10^4]`.
- `0 <= Node.val <= 10^9`
- `-10^9 <= target <= 10^9`

SOLUTIONS (PYTHON 3)

Solution 1: Recursion

How to think about it

We need not walk the whole BST: after comparing with target only one child can improve. Along the path we keep the closer value, breaking ties toward the smaller key. A recursion follows left or right accordingly.

We define a recursive function `dfs(node)`, which starts from the current node `node` and finds the node closest to the target value `target`. We can update the answer by comparing the absolute difference between the current node's value and the target value. If the target value is less than the current node's value, we recursively search the left subtree; otherwise, we recursively search the right subtree.

The time complexity is O(n), and the space complexity is O(n). Where n is the number of nodes in the binary search tree.

Python 3

```python
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def closestValue(self, root: Optional[TreeNode], target: float) -> int:
        def dfs(node: Optional[TreeNode]):
            if node is None:
                return
            nxt = abs(target - node.val)
            nonlocal ans, diff
            if nxt < diff or (nxt == diff and node.val < ans):
                diff = nxt
                ans = node.val
            node = node.left if target < node.val else node.right
            dfs(node)

        ans = 0
        diff = inf
        dfs(root)
        return ans
```

Solution 2: Iteration

> **How to think about it**
>
> The same walk is an iteration and needs no call stack.

We can rewrite the recursive function in an iterative form, using a loop to simulate the recursive process. We start from the root node and check whether the absolute difference between the current node's value and the target value is less than the current minimum difference. If it is, we update the answer. Then, based on the size relationship between the target value and the current node's value, we decide to move to the left subtree or the right subtree. The loop ends when we traverse to a null node.

The time complexity is O(n), where n is the number of nodes in the binary search tree. The space complexity is O(1).

Python 3

```python
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def closestValue(self, root: Optional[TreeNode], target: float) -> int:
        ans, diff = root.val, inf
        while root:
            nxt = abs(root.val - target)
            if nxt < diff or (nxt == diff and root.val < ans):
                diff = nxt
                ans = root.val
            root = root.left if target < root.val else root.right
        return ans
```

PATTERN 26 · BINARY SEARCH TREE (BST) · PROBLEM 9 OF 20

98. Validate Binary Search Tree

Medium · Tree, Depth-First Search, Binary Search Tree, Binary Tree

leetcode.com/problems/validate-binary-search-tree

★ **TOP 10 PROBLEM** in Binary Search Tree (BST): master this one first

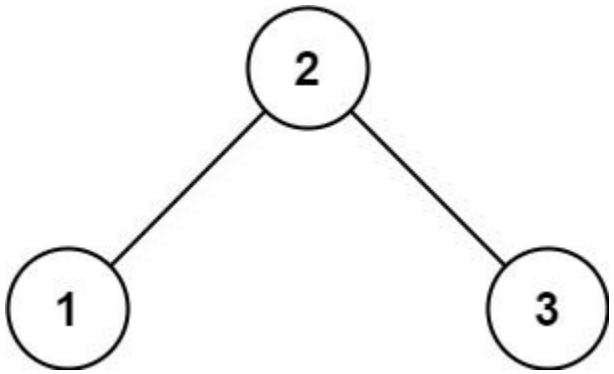
PROBLEM

Given the `root` of a binary tree, *determine if it is a valid binary search tree (BST)*.

A **valid BST** is defined as follows:

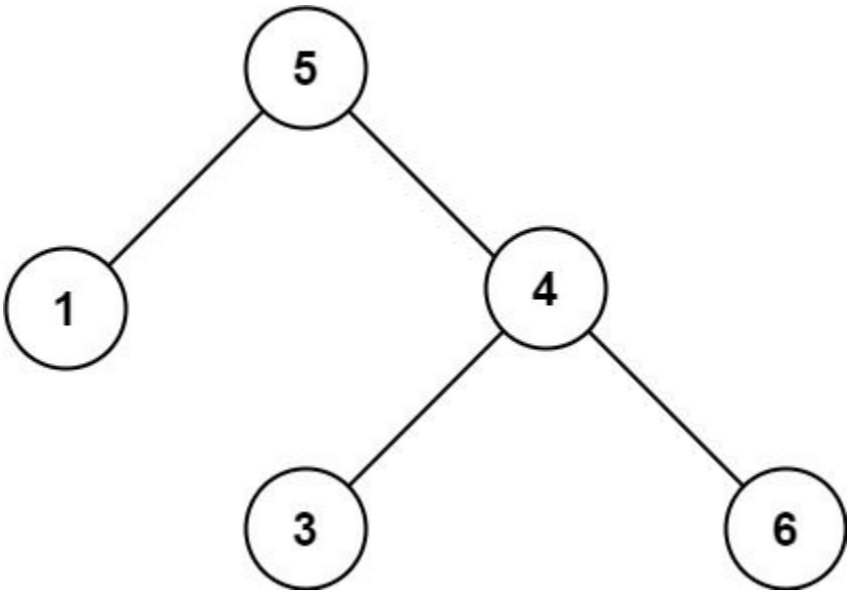
- The left subtree of a node contains only nodes with keys **strictly less than** the node's key.
- The right subtree of a node contains only nodes with keys **strictly greater than** the node's key.
- Both the left and right subtrees must also be binary search trees.

Example 1:



```
Input: root = [2,1,3]
Output: true
```

Example 2:



```
Input: root = [5,1,4,null,null,3,6]
Output: false
Explanation: The root node's value is 5 but its right child's value is 4.
```

Constraints:

- The number of nodes in the tree is in the range `[1, 10^4]`.
- `-2^31 <= Node.val <= 2^31 - 1`

SOLUTION (PYTHON 3)

Solution 1: Recursion

> **How to think about it**
>
> Checking only "left < root < right" is not enough: the maximum in the left subtree must also be less than the root. We can pass an allowed range, or use the BST fact that inorder is strictly increasing. During inorder, remember the previous value; the current one must be larger. Recurse left, compare, recurse right — one pass finds a violation. An empty tree is valid.

We can perform a recursive in-order traversal on the binary tree. If the result of the traversal is strictly ascending, then this tree is a binary search tree.

Therefore, we use a variable `prev` to save the last node we traversed. Initially, `prev = -∞`. Then we recursively traverse the left subtree. If the left subtree is not a binary search tree, we directly return `False`. Otherwise, we check whether the value of the current node is greater than `prev`. If not, we return `False`. Otherwise, we update `prev` to the value of the current node, and then recursively traverse the right subtree.

The time complexity is O(n), and the space complexity is O(n). Where n is the number of nodes in the binary tree.

Python 3

```python
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def isValidBST(self, root: Optional[TreeNode]) -> bool:
        def dfs(root: Optional[TreeNode]) -> bool:
            if root is None:
                return True
            if not dfs(root.left):
                return False
            nonlocal prev
            if prev >= root.val:
                return False
            prev = root.val
            return dfs(root.right)

        prev = -inf
        return dfs(root)
```

701. Insert into a Binary Search Tree

Medium · Tree, Binary Search Tree, Binary Tree

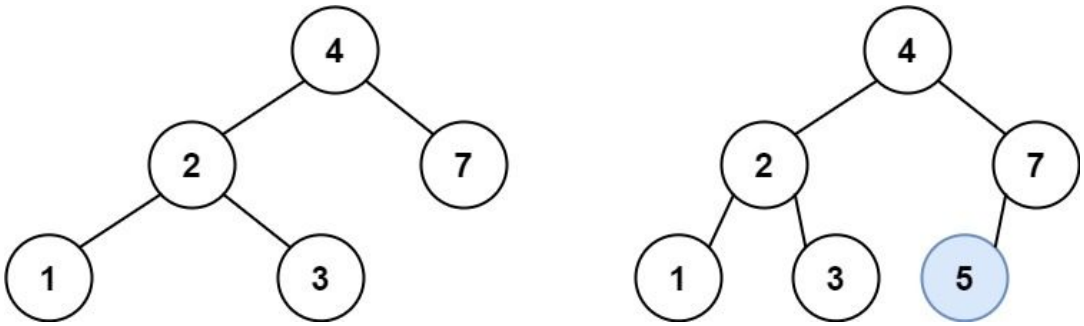
leetcode.com/problems/insert-into-a-binary-search-tree

PROBLEM

You are given the `root` node of a binary search tree (BST) and a `value` to insert into the tree. Return *the root node of the BST after the insertion*. It is **guaranteed** that the new value does not exist in the original BST.

Notice that there may exist multiple valid ways for the insertion, as long as the tree remains a BST after insertion. You can return **any of them**.

Example 1:



```
Input: root = [4,2,7,1,3], val = 5
Output: [4,2,7,1,3,5]
Explanation: Another accepted tree is:
```

Example 2:

```
Input: root = [40,20,60,10,30,50,70], val = 25
Output: [40,20,60,10,30,50,70,null,null,25]
```

Example 3:

```
Input: root = [4,2,7,1,3,null,null,null,null,null,null], val = 5
Output: [4,2,7,1,3,5]
```

Constraints:

- The number of nodes in the tree will be in the range `[0, 10^4]`.
- `-10^8 <= Node.val <= 10^8`
- All the values `Node.val` are **unique**.
- `-10^8 <= val <= 10^8`
- It's **guaranteed** that `val` does not exist in the original BST.

SOLUTION (PYTHON 3)

Solution 1: Recursion

How to think about it

Insert a fresh value into a BST and return the new root. n ≤ 10^4, so any correct insertion path is fine. BST order pins down a unique empty slot: walk by comparison and hang a new node there; no rotation is required. An empty tree becomes that single node. Recurse into the left or right child according to val, then attach the returned subtree. A chain still costs O(n) time and stack.

If the root node is null, we directly create a new node with the value val and return it.

If the root node's value is greater than val, we recursively insert val into the left subtree and update the root of the left subtree with the returned root node.

If the root node's value is less than val, we recursively insert val into the right subtree and update the root of the right subtree with the returned root node.

The time complexity is O(n), and the space complexity is O(n). Here, n is the number of nodes in the binary tree.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def insertIntoBST(self, root: Optional[TreeNode], val: int) -> Optional[TreeNode]:
        if root is None:
            return TreeNode(val)
        if root.val > val:
            root.left = self.insertIntoBST(root.left, val)
        else:
            root.right = self.insertIntoBST(root.right, val)
        return root
```

450. Delete Node in a BST

Medium · Tree, Binary Search Tree, Binary Tree

leetcode.com/problems/delete-node-in-a-bst

★ **TOP 10 PROBLEM** in Binary Search Tree (BST): master this one first

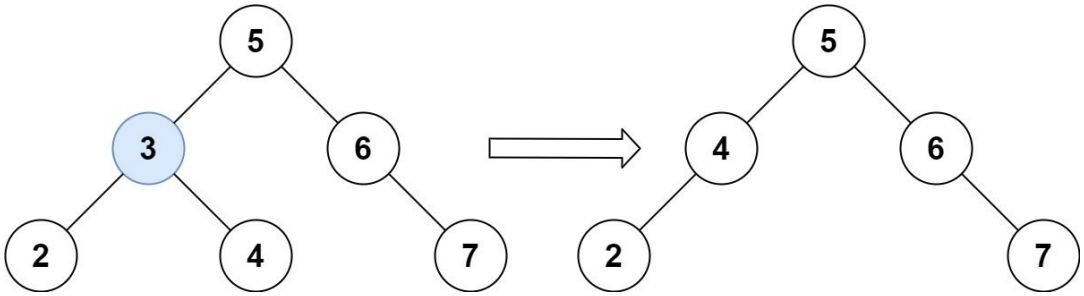
PROBLEM

Given a root node reference of a BST and a key, delete the node with the given key in the BST. Return *the **root node reference** (possibly updated) of the BST*.

Basically, the deletion can be divided into two stages:

1. Search for a node to remove.
2. If the node is found, delete the node.

Example 1:



```
Input: root = [5,3,6,2,4,null,7], key = 3
Output: [5,4,6,2,null,null,7]
Explanation: Given key to delete is 3. So we find the node with value 3 and delete it.
One valid answer is [5,4,6,2,null,null,7], shown in the above BST.
Please notice that another valid answer is [5,2,6,null,4,null,7] and it's also accepted.
```

Example 2:

```
Input: root = [5,3,6,2,4,null,7], key = 0
Output: [5,3,6,2,4,null,7]
Explanation: The tree does not contain a node with value = 0.
```

Example 3:

```
Input: root = [], key = 0
Output: []
```

Constraints:

- The number of nodes in the tree is in the range `[0, 10^4]`.
- `-10^5 <= Node.val <= 10^5`
- Each node has a **unique** value.
- `root` is a valid binary search tree.
- `-10^5 <= key <= 10^5`

Follow up: Could you solve it with time complexity `O(height of tree)`?

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Deletion must keep the BST ordered. A node with one child is replaced by that child; a node with two children needs a successor or predecessor. Recurse left or right by comparison. On a hit: return the right child if there is no left, the left child if there is no right; otherwise hang the whole left subtree off the leftmost node of the right subtree and return the right subtree. That leftmost node is the in-order successor and has no left child, so the in-order sequence stays sorted after one descent.

Python 3

```python
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def deleteNode(self, root: Optional[TreeNode], key: int) -> Optional[TreeNode]:
        if root is None:
            return None
        if root.val > key:
            root.left = self.deleteNode(root.left, key)
            return root
        if root.val < key:
            root.right = self.deleteNode(root.right, key)
            return root
        if root.left is None:
            return root.right
        if root.right is None:
            return root.left
        node = root.right
        while node.left:
            node = node.left
        node.left = root.left
        root = root.right
        return root
```

Complexity. Time: O(h), h = height of the tree. Space: O(h).

    else:
        parent.right = child
    return root
```

230. Kth Smallest Element in a BST

Medium · Tree, Depth-First Search, Binary Search Tree, Binary Tree

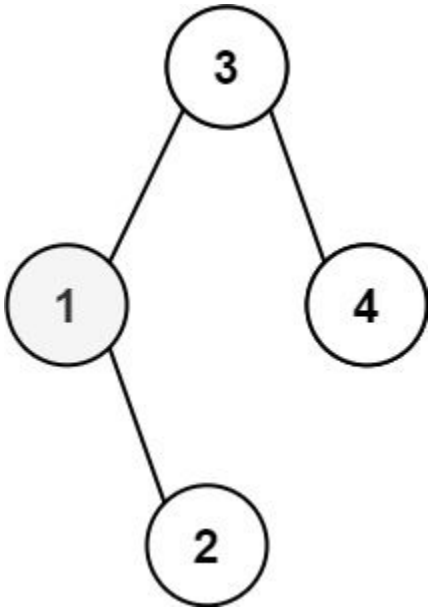
leetcode.com/problems/kth-smallest-element-in-a-bst

★ **TOP 10 PROBLEM** in Binary Search Tree (BST): master this one first

PROBLEM

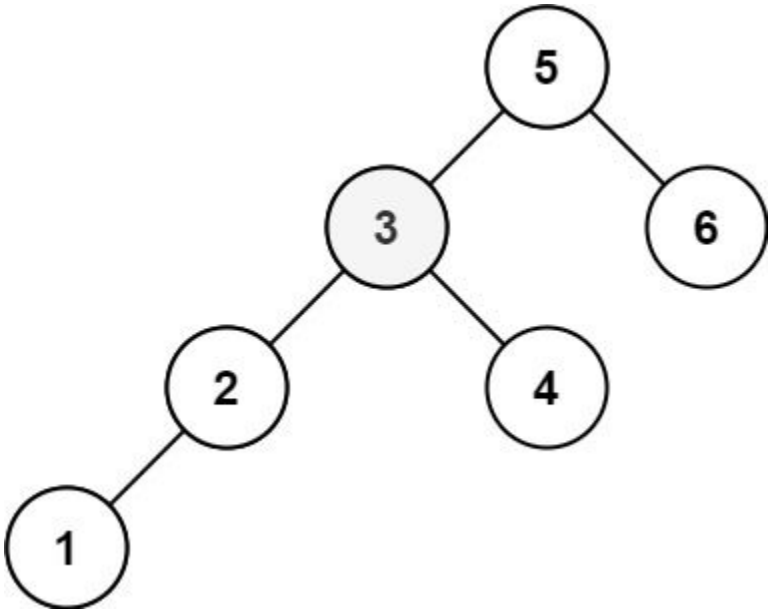
Given the `root` of a binary search tree, and an integer `k`, return *the* k^{th} *smallest value (**1-indexed**) of all the values of the nodes in the tree*.

Example 1:



```
Input: root = [3,1,4,null,2], k = 1
Output: 1
```

Example 2:



```
Input: root = [5,3,6,2,4,null,null,1], k = 3
Output: 3
```

Constraints:

- The number of nodes in the tree is `n`.
- `1 <= k <= n <= 10^4`
- `0 <= Node.val <= 10^4`

Follow up: If the BST is modified often (i.e., we can do insert and delete operations) and you need to find the kth smallest frequently, how would you optimize?

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

Inorder on a BST is sorted order. We only need the k-th visited node, not the full list. An explicit stack walks left, and each pop decrements k; when k hits 0 we have the answer.

Python 3

```python
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def kthSmallest(self, root: Optional[TreeNode], k: int) -> int:
        stk = []
        while root or stk:
            if root:
                stk.append(root)
                root = root.left
            else:
                root = stk.pop()
                k -= 1
                if k == 0:
                    return root.val
                root = root.right
```

Complexity. Time: O(h + k). Space: O(h).

Solution 2

How to think about it

One inorder pass is enough, but repeated queries on a static tree redo the left spine. After storing each subtree size, we compare the left size with k and walk left or right. Each query then follows a root-to-leaf path.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right

class BST:
    def __init__(self, root):
        self.cnt = Counter()
        self.root = root
        self.count(root)

    def kthSmallest(self, k):
        node = self.root
        while node:
            if self.cnt[node.left] == k - 1:
                return node.val
            if self.cnt[node.left] < k - 1:
                k -= self.cnt[node.left] + 1
                node = node.right
            else:
                node = node.left
        return 0

    def count(self, root):
        if root is None:
            return 0
        n = 1 + self.count(root.left) + self.count(root.right)
        self.cnt[root] = n
        return n

class Solution:
    def kthSmallest(self, root: Optional[TreeNode], k: int) -> int:
        bst = BST(root)
        return bst.kthSmallest(k)
```

Complexity. Time: build O(n), each query O(h). Space: O(n).

        else:
            k -= left_size + 1
            node = node.right
    return None
```

538. Convert BST to Greater Tree

Medium · Tree, Depth-First Search, Binary Search Tree, Binary Tree

leetcode.com/problems/convert-bst-to-greater-tree

★ **TOP 10 PROBLEM** in Binary Search Tree (BST): master this one first

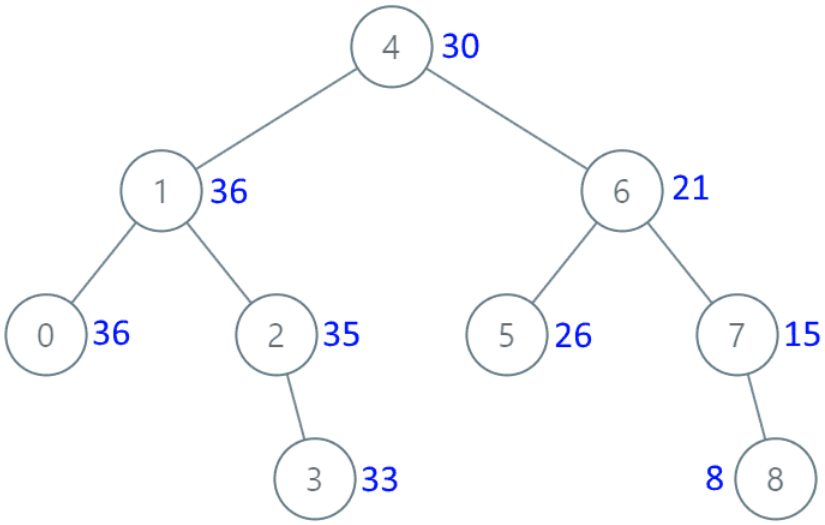
PROBLEM

Given the `root` of a Binary Search Tree (BST), convert it to a Greater Tree such that every key of the original BST is changed to the original key plus the sum of all keys greater than the original key in BST.

As a reminder, a *binary search tree* is a tree that satisfies these constraints:

- The left subtree of a node contains only nodes with keys **less than** the node's key.
- The right subtree of a node contains only nodes with keys **greater than** the node's key.
- Both the left and right subtrees must also be binary search trees.

Example 1:



```
Input: root = [4,1,6,0,2,5,7,null,null,null,3,null,null,null,8]
Output: [30,36,21,36,35,26,15,null,null,null,33,null,null,null,8]
```

Example 2:

```
Input: root = [0,null,1]
Output: [1,null,1]
```

Constraints:

- The number of nodes in the tree is in the range `[0, 10^4]`.
- `-10^4 <= Node.val <= 10^4`
- All the values in the tree are **unique**.
- `root` is guaranteed to be a valid binary search tree.

Note: This question is the same as 1038: https://leetcode.com/problems/binary-search-tree-to-greater-sum-tree/

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

Each node should become the sum of all keys not smaller than itself. In a BST those keys are exactly the nodes already seen in reverse inorder. Walk right-root-left, accumulate into s, and write s back. The right subtree is processed first, so larger keys are already included. One traversal.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def convertBST(self, root: TreeNode) -> TreeNode:
        def dfs(root):
            nonlocal s
            if root is None:
                return
            dfs(root.right)
            s += root.val
            root.val = s
            dfs(root.left)

        s = 0
        dfs(root)
        return root
```

Complexity. Time: O(n). Space: O(h).

Solution 2

How to think about it

Recursive reverse inorder uses an O(h) stack. Morris temporarily links a node's inorder predecessor (leftmost of the right subtree) to recover the parent without a stack. Thread when going right, accumulate and write on the return visit, then unthread and go left. The order is still right-root-left, with constant extra space.

Python 3

```python
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def convertBST(self, root: TreeNode) -> TreeNode:
        s = 0
        node = root
        while root:
            if root.right is None:
                s += root.val
                root.val = s
                root = root.left
            else:
                next = root.right
                while next.left and next.left != root:
                    next = next.left
                if next.left is None:
                    next.left = root
                    root = root.right
                else:
                    s += root.val
                    root.val = s
                    next.left = None
                    root = root.left
        return node
```

Solution 3: Explicit Stack

How to think about it

Each node should become the sum of every key not smaller than itself. In a BST those keys are exactly the nodes already seen in reverse inorder. Recursing down the right child and writing the sum back is correct on a short tree. The tree can contain 10^4 nodes. A right chain makes this walk recurse once per node and overflow the call stack. The running sum depends only on the greater keys already visited. A node does not need a value returned from its children, as long as the right child is finished before the node and the left child comes after. An explicit stack performs that reverse inorder. On entry it pushes an exit marker and the right child; on exit it adds the node value into s, writes s back, and pushes the left child.

An explicit stack walks the binary search tree in the order right, root, left. On entry we push an exit marker and the right child. On exit we add the node value into s, write s back to the node, and push the left child.

The time complexity is O(n) and the space complexity is O(n), where n is the number of nodes in the binary search tree.

Python 3

```python
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def convertBST(self, root: TreeNode) -> TreeNode:
        s = 0
        stk = [(root, 0)]
        while stk:
            node, state = stk.pop()
            if node is None:
                continue
            if state == 0:
                stk.append((node, 1))
                stk.append((node.right, 0))
                continue
            s += node.val
            node.val = s
            stk.append((node.left, 0))
        return root
```

                node.val = total
```

```
                node = node.left
    return root
```

1382. Balance a Binary Search Tree

Medium · Greedy, Tree, Depth-First Search, Binary Search Tree, Divide and Conquer, Binary Tree

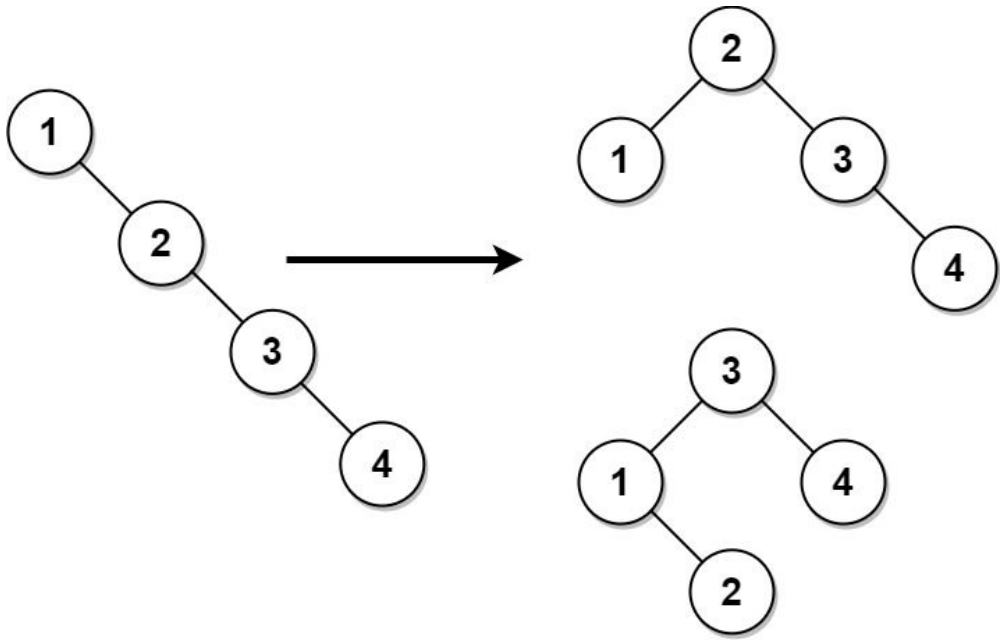
leetcode.com/problems/balance-a-binary-search-tree

PROBLEM

Given the `root` of a binary search tree, return *a **balanced** binary search tree with the same node values*. If there is more than one answer, return **any of them**.

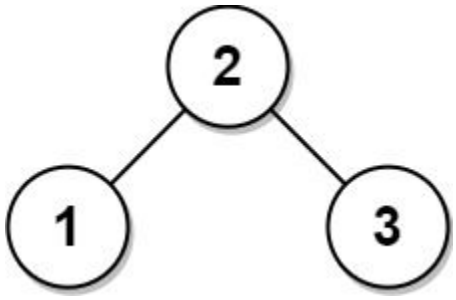
A binary search tree is **balanced** if the depth of the two subtrees of every node never differs by more than `1`.

Example 1:



```
Input: root = [1,null,2,null,3,null,4,null,null]
Output: [2,1,3,null,null,null,4]
Explanation: This is not the only correct answer, [3,1,4,null,2] is also correct.
```

Example 2:



```
Input: root = [2,1,3]
Output: [2,1,3]
```

Constraints:

- The number of nodes in the tree is in the range `[1, 10^4]`.
- `1 <= Node.val <= 10^5`

SOLUTION (PYTHON 3)

Solution 1: In-order Traversal + Construct Balanced Binary Search Tree

> **How to think about it**
>
> Rebalance a BST without changing the inorder sequence. An inorder walk yields a sorted array; recursively taking the midpoint as the root builds a tree of height log n that is still a BST.

Since the original tree is a binary search tree, we can save the result of the in-order traversal in an array nums. Then we design a function build(i, j), which is used to construct a balanced binary search tree within the index range [i, j] in nums. The answer is build(0, |nums| - 1).

The execution logic of the function build(i, j) is as follows:

- If i > j, then the balanced binary search tree is empty, return an empty node;
- Otherwise, we take mid = (i + j) / 2 as the root node, then recursively build the left and right subtrees, and return the root node.

The time complexity is O(n), and the space complexity is O(n). Where n is the number of nodes in the binary search tree.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def balanceBST(self, root: TreeNode) -> TreeNode:
        def dfs(root: TreeNode):
            if root is None:
                return
            dfs(root.left)
            nums.append(root.val)
            dfs(root.right)

        def build(i: int, j: int) -> TreeNode:
            if i > j:
                return None
            mid = (i + j) >> 1
            left = build(i, mid - 1)
            right = build(mid + 1, j)
            return TreeNode(nums[mid], left, right)

        nums = []
        dfs(root)
        return build(0, len(nums) - 1)
```

    return root
```

669. Trim a Binary Search Tree

Medium · Tree, Depth-First Search, Binary Search Tree, Binary Tree

leetcode.com/problems/trim-a-binary-search-tree

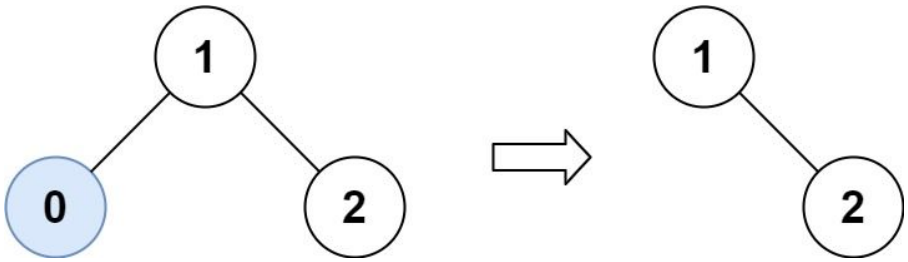
★ **TOP 10 PROBLEM** in Binary Search Tree (BST): master this one first

PROBLEM

Given the `root` of a binary search tree and the lowest and highest boundaries as `low` and `high`, trim the tree so that all its elements lies in `[low, high]`. Trimming the tree should **not** change the relative structure of the elements that will remain in the tree (i.e., any node's descendant should remain a descendant). It can be proven that there is a **unique answer**.

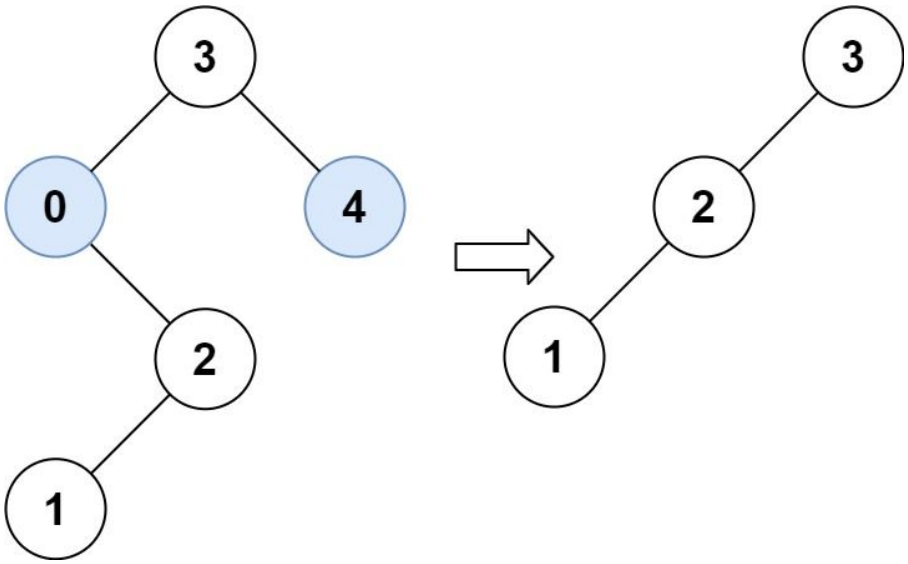
Return *the root of the trimmed binary search tree*. Note that the root may change depending on the given bounds.

Example 1:



```
Input: root = [1,0,2], low = 1, high = 2
Output: [1,null,2]
```

Example 2:



```
Input: root = [3,0,4,null,2,null,null,1], low = 1, high = 3
Output: [3,2,null,1]
```

Constraints:

- The number of nodes in the tree is in the range `[1, 10^4]`.
- `0 <= Node.val <= 10^4`
- The value of each node in the tree is **unique**.
- `root` is guaranteed to be a valid binary search tree.
- `0 <= low <= high <= 10^4`

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

Drop BST nodes outside [low,high]. Order lets us discard a whole left or right subtree at once. If the root is too large, recurse only left; if too small, only right; otherwise trim both children and keep the root.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def trimBST(
        self, root: Optional[TreeNode], low: int, high: int
    ) -> Optional[TreeNode]:
        def dfs(root):
            if root is None:
                return root
            if root.val > high:
                return dfs(root.left)
            if root.val < low:
                return dfs(root.right)
            root.left = dfs(root.left)
            root.right = dfs(root.right)
            return root

        return dfs(root)
```

Complexity. Time: O(n). Space: O(h).

Solution 2

How to think about it

Recursion uses linear stack. Slide the root into range, then walk each side: replace an undersized left child by its right, an oversized right child by its left. Extra memory is constant.

Python 3

```python
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def trimBST(
        self, root: Optional[TreeNode], low: int, high: int
    ) -> Optional[TreeNode]:
        while root and (root.val < low or root.val > high):
            root = root.left if root.val > high else root.right
        if root is None:
            return None
        node = root
        while node.left:
            if node.left.val < low:
                node.left = node.left.right
            else:
                node = node.left
        node = root
        while node.right:
            if node.right.val > high:
                node.right = node.right.left
            else:
                node = node.right
        return root
```

Complexity. Time: O(h). Space: O(1).

            node.right = node.right.left
        node = node.right
    return root
```

99. Recover Binary Search Tree

Medium · Tree, Depth-First Search, Binary Search Tree, Binary Tree

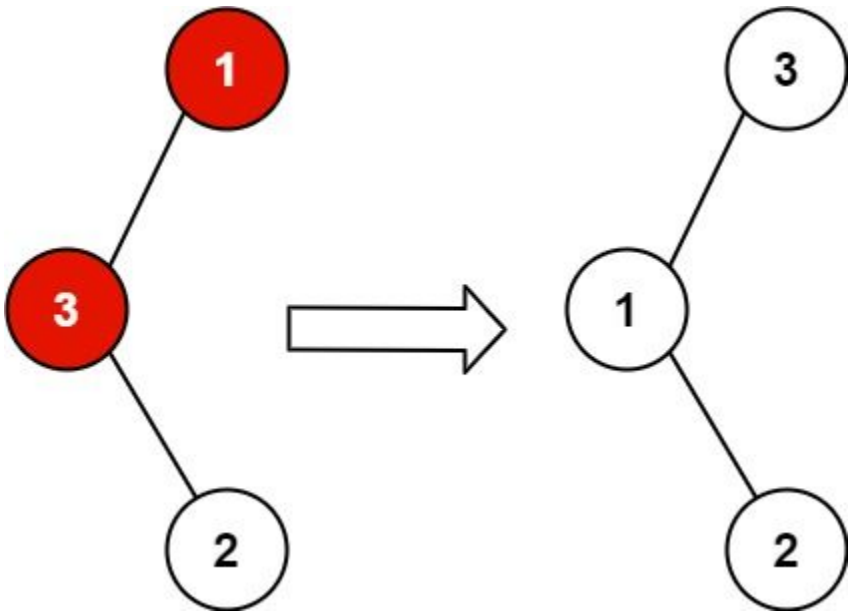
leetcode.com/problems/recover-binary-search-tree

★ **TOP 10 PROBLEM** in Binary Search Tree (BST): master this one first

PROBLEM

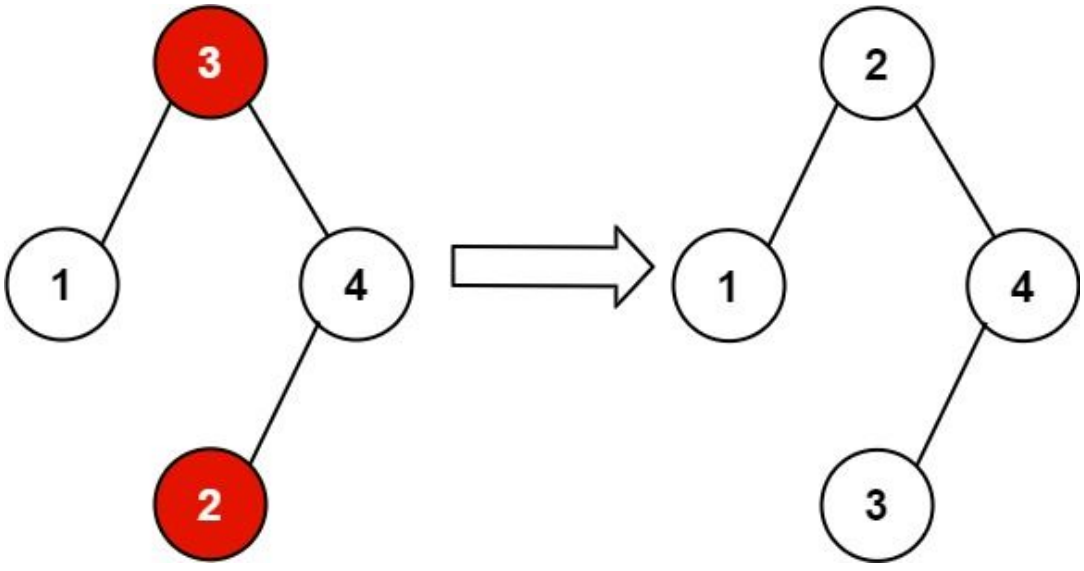
You are given the `root` of a binary search tree (BST), where the values of **exactly** two nodes of the tree were swapped by mistake. *Recover the tree without changing its structure*.

Example 1:



```
Input: root = [1,3,null,null,2]
Output: [3,1,null,null,2]
Explanation: 3 cannot be a left child of 1 because 3 > 1. Swapping 1 and 3 makes the BST valid.
```

Example 2:



```
Input: root = [3,1,4,null,null,2]
Output: [2,1,4,null,null,3]
Explanation: 2 cannot be in the right subtree of 3 because 2 < 3. Swapping 2 and 3 makes the BST valid.
```

Constraints:

- The number of nodes in the tree is in the range `[2, 1000]`.
- -2^{31} <= Node.val <= $2^{31} - 1$

Follow up:

A solution using

`O(n)`

space is pretty straight-forward. Could you devise a constant

`O(1)`

space solution?

SOLUTION (PYTHON 3)

Solution 1: In-order Traversal

How to think about it

Inorder of a BST is strictly increasing. After swapping two nodes, the sequence has one or two inversions: adjacent swap yields one; non-adjacent yields two (the earlier node of the first inversion and the later node of the second). Walk inorder, record those two nodes, and swap their values. No need to rebuild the tree. This solution uses recursive inorder (O(n) stack); Morris would meet the O(1) follow-up. The point of this method is to identify the swapped pair.

In-order traversal of a binary search tree results in an increasing sequence. If two nodes' values are mistakenly swapped, there will definitely be two reverse pairs in the sequence obtained from the in-order traversal. We use `first` and `second` to record the smaller and larger values of these two reverse pairs, respectively. Finally, swapping the values of these two nodes will correct the mistake.

The time complexity is O(n), and the space complexity is O(n). Here, n is the number of nodes in the binary search tree.

Python 3

```python
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def recoverTree(self, root: Optional[TreeNode]) -> None:
        """
        Do not return anything, modify root in-place instead.
        """

        def dfs(root):
            if root is None:
                return
            nonlocal prev, first, second
            dfs(root.left)
            if prev and prev.val > root.val:
                if first is None:
                    first = prev
                second = root
            prev = root
            dfs(root.right)

        prev = first = second = None
        dfs(root)
        first.val, second.val = second.val, first.val
```

```

96. Unique Binary Search Trees

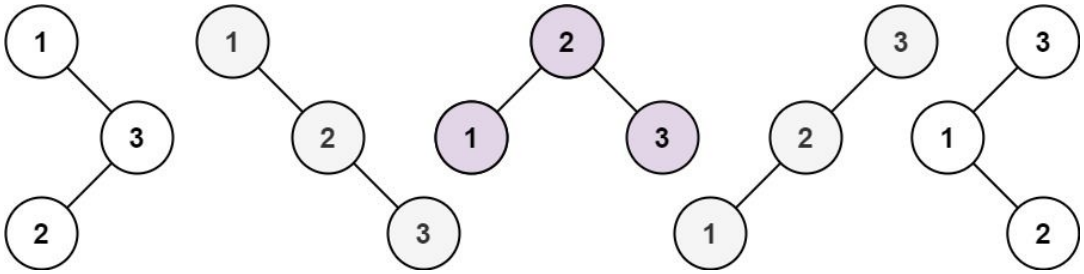
Medium · Tree, Binary Search Tree, Math, Dynamic Programming, Binary Tree

leetcode.com/problems/unique-binary-search-trees

PROBLEM

Given an integer `n`, return *the number of structurally unique **BST's** (binary search trees) which has exactly* `n` *nodes of unique values from* `1` *to* `n`.

Example 1:



```
Input: n = 3
Output: 5
```

Example 2:

```
Input: n = 1
Output: 1
```

Constraints:

- `1 <= n <= 19`

SOLUTION (PYTHON 3)

Solution 1: Dynamic Programming

> **How to think about it**
>
> The previous problem lists every tree; here we only need the count. The structure is the same: pick a root, multiply left and right counts, sum over roots. Shapes collapse to “how many nodes”: any i consecutive integers yield the same number of BSTs. Let f[i] be the number of trees with i nodes, f[0]=1, and build from small i so each size is computed once.

We define f[i] to represent the number of binary search trees that can be generated from [1, i]. Initially, f[0] = 1, and the answer is f[n].

We can enumerate the number of nodes i, then the number of nodes in the left subtree $j \in [0, i - 1]$, and the number of nodes in the right subtree k = i - j - 1. The number of combinations of the number of nodes in the left subtree and the right subtree is f[j] × f[k], so $f[i] = \sum_{j=0}^{i-1} f[j] \times f[i - j - 1]$.

Finally, return f[n].

The time complexity is O(n), and the space complexity is O(n). Here, n is the number of nodes.

Python 3

```
class Solution:
    def numTrees(self, n: int) -> int:
        f = [1] + [0] * n
        for i in range(n + 1):
            for j in range(i):
                f[i] += f[j] * f[i - j - 1]
        return f[n]
```

```

173. Binary Search Tree Iterator

Medium · Stack, Tree, Design, Binary Search Tree, Binary Tree, Iterator

leetcode.com/problems/binary-search-tree-iterator

★ **TOP 10 PROBLEM** in Binary Search Tree (BST): master this one first

PROBLEM

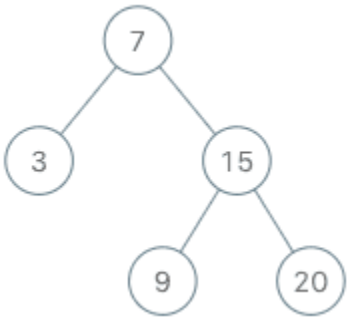
Implement the `BSTIterator` class that represents an iterator over the **in-order traversal** of a binary search tree (BST):

- `BSTIterator(TreeNode root)` Initializes an object of the `BSTIterator` class. The `root` of the BST is given as part of the constructor. The pointer should be initialized to a non-existent number smaller than any element in the BST.
- `boolean hasNext()` Returns `true` if there exists a number in the traversal to the right of the pointer, otherwise returns `false`.
- `int next()` Moves the pointer to the right, then returns the number at the pointer.

Notice that by initializing the pointer to a non-existent smallest number, the first call to `next()` will return the smallest element in the BST.

You may assume that `next()` calls will always be valid. That is, there will be at least a next number in the in-order traversal when `next()` is called.

Example 1:



```
Input
["BSTIterator", "next", "next", "hasNext", "next", "hasNext", "next", "hasNext", "next", "hasNext"]
[[[7, 3, 15, null, null, 9, 20]], [], [], [], [], [], [], [], [], []]
Output
[null, 3, 7, true, 9, true, 15, true, 20, false]

Explanation
BSTIterator bSTIterator = new BSTIterator([7, 3, 15, null, null, 9, 20]);
bSTIterator.next(); // return 3
bSTIterator.next(); // return 7
bSTIterator.hasNext(); // return True
bSTIterator.next(); // return 9
bSTIterator.hasNext(); // return True
bSTIterator.next(); // return 15
bSTIterator.hasNext(); // return True
bSTIterator.next(); // return 20
bSTIterator.hasNext(); // return False
```

Constraints:

- The number of nodes in the tree is in the range $[1, 10^5]$.
- $0 <= Node.val <= 10^6$
- At most 10^5 calls will be made to `hasNext`, and `next`.

Follow up:

- Could you implement `next()` and `hasNext()` to run in average `O(1)` time and use `O(h)` memory, where `h` is the height of the tree?

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

Inorder on a BST is sorted. Up to 10^5 nodes and as many calls. A full inorder into an array makes next/hasNext a cursor move — amortized O(1) — but O(n) space. The follow-up wants O(h) memory.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class BSTIterator:
    def __init__(self, root: TreeNode):
        def inorder(root):
            if root:
                inorder(root.left)
                self.vals.append(root.val)
                inorder(root.right)

        self.cur = 0
        self.vals = []
        inorder(root)

    def next(self) -> int:
        res = self.vals[self.cur]
        self.cur += 1
        return res

    def hasNext(self) -> bool:
        return self.cur < len(self.vals)

# Your BSTIterator object will be instantiated and called as such:
# obj = BSTIterator(root)
# param_1 = obj.next()
# param_2 = obj.hasNext()
```

Solution 2

How to think about it

Solution 1 flattens the whole tree. An explicit stack simulates inorder: push the left spine at init; next pops, then pushes the left spine of the right child. At most h nodes sit on the stack, and each node is pushed and popped once.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class BSTIterator:
    def __init__(self, root: TreeNode):
        self.stack = []
        while root:
            self.stack.append(root)
            root = root.left

    def next(self) -> int:
        cur = self.stack.pop()
        node = cur.right
        while node:
            self.stack.append(node)
            node = node.left
        return cur.val

    def hasNext(self) -> bool:
        return len(self.stack) > 0

# Your BSTIterator object will be instantiated and called as such:
# obj = BSTIterator(root)
# param_1 = obj.next()
# param_2 = obj.hasNext()
```

Complexity. Time: next O(1) amortised, hasNext O(1). Space: O(h), h = height of the tree.

```

1008. Construct Binary Search Tree from Preorder Traversal

Medium · Stack, Tree, Binary Search Tree, Array, Binary Tree, Monotonic Stack

leetcode.com/problems/construct-binary-search-tree-from-preorder-traversal

PROBLEM

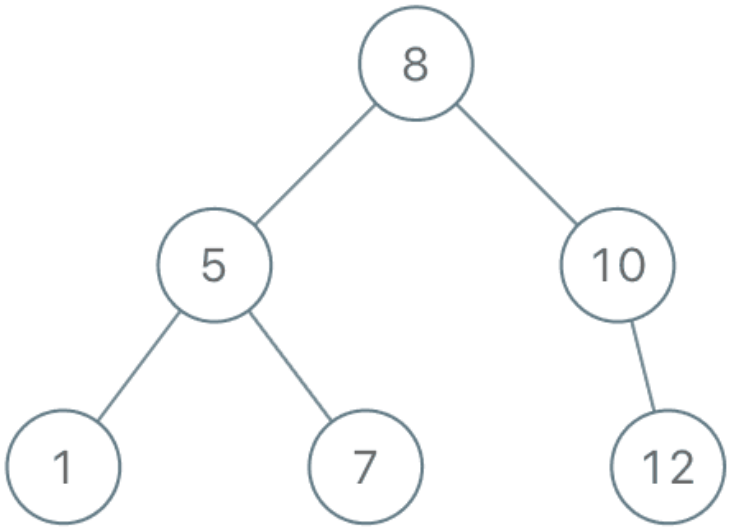
Given an array of integers preorder, which represents the **preorder traversal** of a BST (i.e., **binary search tree**), construct the tree and return *its root*.

It is **guaranteed** that there is always possible to find a binary search tree with the given requirements for the given test cases.

A **binary search tree** is a binary tree where for every node, any descendant of `Node.left` has a value **strictly less than** `Node.val`, and any descendant of `Node.right` has a value **strictly greater than** `Node.val`.

A **preorder traversal** of a binary tree displays the value of the node first, then traverses `Node.left`, then traverses `Node.right`.

Example 1:



```
Input: preorder = [8,5,1,7,10,12]
Output: [8,5,10,1,7,null,12]
```

Example 2:

```
Input: preorder = [1,3]
Output: [1,null,3]
```

Constraints:

- `1 <= preorder.length <= 100`
- `1 <= preorder[i] <= 1000`
- All the values of `preorder` are **unique**.

SOLUTION (PYTHON 3)

Solution 1: DFS + Binary Search

How to think about it

The first preorder value is the root; a linear scan finds the first larger key and splits the left and right subtrees. n≤ 100 makes $O(n^2)$ acceptable, yet each split walks the same ranges again. A BST preorder segment still has every left-subtree key below the root and every right-subtree key above it, so the first index greater than the root can be found by binary search. dfs(i,j) builds a node from preorder[i], bisects to the right-subtree start, and recurses on both sides in O(nlog n).

We design a function dfs(i, j) to construct a binary search tree from the nodes preorder[i] to preorder[j]. The answer is dfs(0, n - 1).

In dfs(i, j), we first construct the root node, which is preorder[i]. Then, we use binary search to find the first node greater than preorder[i] and get its index mid. We set dfs(i + 1, mid - 1) as the left subtree of the root node and dfs(mid, j) as the right subtree of the root node.

Finally, we return the root node.

The time complexity is O(n × log n), and the space complexity is O(n). Here, n is the length of the array preorder.

Python 3

```python
class Solution:
    def bstFromPreorder(self, preorder: List[int]) -> Optional[TreeNode]:
        def dfs(i: int, j: int) -> Optional[TreeNode]:
            if i > j:
                return None
            root = TreeNode(preorder[i])
            l, r = i + 1, j + 1
            while l < r:
                mid = (l + r) >> 1
                if preorder[mid] > preorder[i]:
                    r = mid
                else:
                    l = mid + 1
            root.left = dfs(i + 1, l - 1)
            root.right = dfs(l, j)
            return root

        return dfs(0, len(preorder) - 1)
```

136. Single Number

Easy · Bit Manipulation, Array

leetcode.com/problems/single-number

★ **TOP 10 PROBLEM** in Bit Manipulation: master this one first

Also appears in pattern 33 Cyclic Sort

PROBLEM

Given a **non-empty** array of integers `nums`, every element appears *twice* except for one. Find that single one.

You must implement a solution with a linear runtime complexity and use only constant extra space.

Example 1:

Input: nums = [2,2,1]

Output: 1

Example 2:

Input: nums = [4,1,2,1,2]

Output: 4

Example 3:

Input: nums = [1]

Output: 1

Constraints:

- `1 <= nums.length <= 3 * 10^4`
- `-3 * 10^4 <= nums[i] <= 3 * 10^4`
- Each element in the array appears twice except for one element which appears only once.

SOLUTIONS (PYTHON 3)

Solution 1: Bitwise Operation

How to think about it

Every number appears twice except one; we need linear time and constant space. A frequency map uses O(n) space. XOR has xxor x=0, xxor 0=x, and is commutative, so pairing cancels and the leftover is the unique number.

The XOR operation has the following properties:

- Any number XOR 0 is still the original number, i.e., x xor 0 = x;
- Any number XOR itself is 0, i.e., x xor x = 0;

Performing XOR operation on all elements in the array will result in the number that only appears once.

The time complexity is O(n), where n is the length of the array. The space complexity is O(1).

Python 3

```
class Solution:
    def singleNumber(self, nums: List[int]) -> int:
        return reduce(xor, nums)
```

Solution 2

> **How to think about it**
>
> Solution 1 is already an XOR fold. This variant uses the language's reduction to do the same operation.

Python 3 (written for this guide: the doocs page has no Python 3 version of this solution)

```
class Solution:
    def singleNumber(self, nums: List[int]) -> int:
        answer = 0
        for x in nums:
            answer ^= x
        return answer
```

PATTERN 27 · BIT MANIPULATION · PROBLEM 2 OF 20

191. Number of 1 Bits

Easy · Bit Manipulation, Divide and Conquer

leetcode.com/problems/number-of-1-bits

★ **TOP 10 PROBLEM** in Bit Manipulation: master this one first

PROBLEM

Given a positive integer `n`, write a function that returns the number of set bits in its binary representation (also known as the Hamming weight).

Example 1:

Input: n = 11

Output: 3

Explanation:

The input binary string **1011** has a total of three set bits.

Example 2:

Input: n = 128

Output: 1

Explanation:

The input binary string **10000000** has a total of one set bit.

Example 3:

Input: n = 2147483645

Output: 30

Explanation:

The input binary string **11111111111111111111111111111101** has a total of thirty set bits.

Constraints:

- `1 <= n <= 2^31 - 1`

Follow up:

If this function is called many times, how would you optimize it?

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

Count set bits. Checking every bit always looks at 32 positions. n&(n-1) clears the lowest 1, so the loop runs once per set bit.

Python 3

```python
class Solution:
    def hammingWeight(self, n: int) -> int:
        ans = 0
        while n:
            n &= n - 1
            ans += 1
        return ans
```

Complexity. Time: O(k), k = number of one bits (at most 32). Space: O(1).

Solution 2

> **How to think about it**
>
> Solution 1 uses n&(n-1). lowbit=n&-n isolates the lowest 1; subtract and repeat. Same idea, the form used in Fenwick trees.

Python 3

```
class Solution:
    def hammingWeight(self, n: int) -> int:
        ans = 0
        while n:
            n -= n & -n
            ans += 1
        return ans
```

Complexity. Time: O(k), k = number of one bits (at most 32). Space: O(1).

PATTERN 27 · BIT MANIPULATION · PROBLEM 3 OF 20

338. Counting Bits

Easy · Bit Manipulation, Dynamic Programming

leetcode.com/problems/counting-bits

★ **TOP 10 PROBLEM** in Bit Manipulation: master this one first

PROBLEM

Given an integer `n`, return *an array* `ans` *of length* `n + 1` *such that for each* `i` (`0 <= i <= n`), `ans[i]` *is the* ***number of*** `1`***'s*** *in the binary representation of* `i`.

Do not solve it with built-in functions (i.e., like

`__builtin_popcount`

in C++).

Example 1:

```
Input: n = 2
Output: [0,1,1]
Explanation:
0 --> 0
1 --> 1
2 --> 10
```

Example 2:

```
Input: n = 5
Output: [0,1,1,2,1,2]
Explanation:
0 --> 0
1 --> 1
2 --> 10
3 --> 11
4 --> 100
5 --> 101
```

Constraints:

- `0 <= n <=` 10^5

Follow up:

- It is very easy to come up with a solution with a runtime of `O(n log n)`. Can you do it in linear time `O(n)` and possibly in a single pass?

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

Count set bits of every integer in 0… n. Per-number bit scans cost O(log i). n≤ 10^5 still allows that, but we can do better later. Call `bit_count` (or repeated `lowbit`) on each i to fill the array.

Python 3

```python
class Solution:
    def countBits(self, n: int) -> List[int]:
        return [i.bit_count() for i in range(n + 1)]
```

Solution 2

How to think about it

Method 1 counts each integer from scratch. Clearing the lowest set bit yields i&(i-1), whose answer is already known, so ans[i]=ans[i&(i-1)]+1. Fill upward in O(n).

Python 3

```python
class Solution:
    def countBits(self, n: int) -> List[int]:
        ans = [0] * (n + 1)
        for i in range(1, n + 1):
            ans[i] = ans[i & (i - 1)] + 1
        return ans
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

PATTERN 27 · BIT MANIPULATION · PROBLEM 4 OF 20

268. Missing Number

Easy · Bit Manipulation, Array, Hash Table, Math, Binary Search, Sorting

leetcode.com/problems/missing-number

★ **TOP 10 PROBLEM** in Cyclic Sort: master this one first

Also appears in pattern 33 Cyclic Sort

PROBLEM

Given an array `nums` containing `n` distinct numbers in the range `[0, n]`, return *the only number in the range that is missing from the array.*

Example 1:

Input: nums = [3,0,1]

Output: 2

Explanation:

`n = 3` since there are 3 numbers, so all numbers are in the range `[0,3]`. 2 is the missing number in the range since it does not appear in `nums`.

Example 2:

Input: nums = [0,1]

Output: 2

Explanation:

`n = 2` since there are 2 numbers, so all numbers are in the range `[0,2]`. 2 is the missing number in the range since it does not appear in `nums`.

Example 3:

Input: nums = [9,6,4,2,3,5,7,0,1]

Output: 8

Explanation:

`n = 9` since there are 9 numbers, so all numbers are in the range `[0,9]`. 8 is the missing number in the range since it does not appear in `nums`.

Constraints:

- `n == nums.length`
- `1 <= n <= 10^4`
- `0 <= nums[i] <= n`
- All the numbers of `nums` are **unique**.

Follow up: Could you implement a solution using only `O(1)` extra space complexity and `O(n)` runtime complexity?

SOLUTIONS (PYTHON 3)

Solution 1: Bitwise Operation

How to think about it

One value from [0,n] is missing. XOR the indices 1..n with the array entries; pairs cancel and the missing number remains.

The XOR operation has the following properties:

- Any number XOR 0 is still the original number, i.e., x xor 0 = x;

- Any number XOR itself is 0, i.e., x xor x = 0;

Therefore, we can traverse the array, perform XOR operation between each element and the numbers [0,..n], and the final result will be the missing number.

The time complexity is O(n), where n is the length of the array. The space complexity is O(1).

Python 3

```
class Solution:
    def missingNumber(self, nums: List[int]) -> int:
        return reduce(xor, (i ^ v for i, v in enumerate(nums, 1)))
```

Solution 2: Mathematics

> **How to think about it**
>
> XOR avoids addition. Gauss's formula also works: n(n+1)/2 minus the array sum is the missing value.

We can also solve this problem using mathematics. By calculating the sum of [0,..n], subtracting the sum of all numbers in the array, we can obtain the missing number.

The time complexity is O(n), where n is the length of the array. The space complexity is O(1).

Python 3

```
class Solution:
    def missingNumber(self, nums: List[int]) -> int:
        n = len(nums)
        return (1 + n) * n // 2 - sum(nums)
```

```

190. Reverse Bits

Easy · Bit Manipulation, Divide and Conquer

leetcode.com/problems/reverse-bits

PROBLEM

Reverse bits of a given 32 bits signed integer.

Example 1:

Input: n = 43261596

Output: 964176192

Explanation:

Integer	Binary
43261596	00000010100101000001111010011100
964176192	00111001011110000010100101000000

Example 2:

Input: n = 2147483644

Output: 1073741822

Explanation:

Integer	Binary
2147483644	01111111111111111111111111111100
1073741822	00111111111111111111111111111110

Constraints:

- `0 <= n <= 2^31 - 2`
- `n` is even.

Follow up: If this function is called many times, how would you optimize it?

SOLUTION (PYTHON 3)

Solution 1: Bit Manipulation

> **How to think about it**
>
> Reverse the 32 bits of an unsigned integer. Pull each bit and write it to the mirrored index. Scan 32 times from the low end: take n's lowest bit, write it at position 31-i, then shift n right. The width is fixed.

We can extract each bit of n from the lowest bit to the highest bit, and then place it at the corresponding position of ans.

For example, for the i-th bit, we can extract the i-th bit of n and place it at the (31 - i)-th bit of ans by (n & 1) ≪ (31 - i), and then right shift n by one bit.

The time complexity is O(log n), and the space complexity is O(1).

Python 3

```python
class Solution:
    def reverseBits(self, n: int) -> int:
        ans = 0
        for i in range(32):
            ans |= (n & 1) << (31 - i)
            n >>= 1
        return ans
```

        table.append(reversed_value)
    return table

BYTE_TABLE = build_byte_table()

def reverse_bits_cached(x):
    return (BYTE_TABLE[x & 0xFF] << 24) | (BYTE_TABLE[(x >> 8) & 0xFF] << 16) | (BYTE_TABLE[(x >> 16) &
0xFF] << 8) | BYTE_TABLE[(x >> 24) & 0xFF]
```

389. Find the Difference

Easy · Bit Manipulation, Hash Table, String, Sorting

leetcode.com/problems/find-the-difference

Also appears in pattern 33 Cyclic Sort

PROBLEM

You are given two strings `s` and `t`.

String `t` is generated by random shuffling string `s` and then add one more letter at a random position.

Return the letter that was added to `t`.

Example 1:

```
Input: s = "abcd", t = "abcde"
Output: "e"
Explanation: 'e' is the letter that was added.
```

Example 2:

```
Input: s = "", t = "y"
Output: "y"
```

Constraints:

- `0 <= s.length <= 1000`
- `t.length == s.length + 1`
- `s` and `t` consist of lowercase English letters.

SOLUTIONS (PYTHON 3)

Solution 1: Counting

How to think about it

t is s shuffled plus one letter. A count difference finds it. Count s, decrement along t; the first negative frequency is the extra letter.

We can use a hash table or array cnt to count the occurrence of each character in string s, then traverse string t. For each character, we subtract its occurrence in cnt. If the corresponding count is negative, it means that the occurrence of this character in t is greater than in s, so this character is the added character.

The time complexity is O(n), and the space complexity is O(|Σ|), where n is the length of the string, and Σ represents the character set. Here the character set is all lowercase letters, so |Σ|=26.

Python 3

```python
class Solution:
    def findTheDifference(self, s: str, t: str) -> str:
        cnt = Counter(s)
        for c in t:
            cnt[c] -= 1
            if cnt[c] < 0:
                return c
```

Solution 2: Summation

> **How to think about it**
>
> Counting uses O(Σ) space. The difference of ASCII sums is the extra code point, in O(1) space.

We can sum the ASCII values of each character in string t, then subtract the sum of the ASCII values of each character in string s. The final result is the ASCII value of the added character.

The time complexity is O(n), where n is the length of the string. The space complexity is O(1).

Python 3

```
class Solution:
    def findTheDifference(self, s: str, t: str) -> str:
        a = sum(ord(c) for c in s)
        b = sum(ord(c) for c in t)
        return chr(b - a)
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

Built on the solutions above: helper functions, then the function for each follow-up. No tests and no restating of the question.

```
# FOLLOW-UPS (answered below, in this order):
# 1. A letter was REMOVED (not added): which one?
# 2. Which letter appears an ODD number of times in a
# string?

# ============================================================
# FOLLOW-UP 1: A letter was REMOVED (not added): which
# one?
# ============================================================

# ---- follow-up 1: function ----
# Answer: XOR the letters of both strings; the letter left
# is the removed one.
# Time: O(n).  Space: O(1).
def removed_letter(original, shorter):
    result = 0
    for ch in original:
        result ^= ord(ch)
    for ch in shorter:
        result ^= ord(ch)
    return chr(result)

# ============================================================
# FOLLOW-UP 2: Which letter appears an ODD number of times
# in a string?
# ============================================================

# ---- follow-up 2: function ----
# Answer: XOR all the letters: letters that appear an even

    result = 0
    for ch in text:
        result ^= ord(ch)
    return chr(result)
```

693. Binary Number with Alternating Bits

Easy · Bit Manipulation

leetcode.com/problems/binary-number-with-alternating-bits

PROBLEM

Given a positive integer, check whether it has alternating bits: namely, if two adjacent bits will always have different values.

Example 1:

```
Input: n = 5
Output: true
Explanation: The binary representation of 5 is: 101
```

Example 2:

```
Input: n = 7
Output: false
Explanation: The binary representation of 7 is: 111.
```

Example 3:

```
Input: n = 11
Output: false
Explanation: The binary representation of 11 is: 1011.
```

Constraints:

- $1 <= n <= 2^{31} - 1$

SOLUTIONS (PYTHON 3)

Solution 1: Simulation

How to think about it

Check that neighboring bits strictly alternate. A bit-by-bit scan is enough. Read the lowest bit, shift, and fail if it equals the previous bit.

We cyclically right-shift n until it becomes 0, checking whether the binary bits of n appear alternately. If during the loop we find that 0 and 1 do not appear alternately, we directly return false. Otherwise, when the loop ends, we return true.

The time complexity is O(log n), and the space complexity is O(1).

Python 3

```python
class Solution:
    def hasAlternatingBits(self, n: int) -> bool:
        prev = -1
        while n:
            curr = n & 1
            if prev == curr:
                return False
            prev = curr
            n >>= 1
        return True
```

Solution 2: Bit Manipulation

> **How to think about it**
> The scan is O(log n). nxor(n≫ 1) becomes a run of ones iff bits alternate; then n&(n+1)=0 confirms it in constant time.

Assuming 01 appears alternately, we can convert all trailing bits to 1 through misaligned XOR. Adding 1 gives us a power of 2, which is a number n (where n has only one bit that is 1). Then, using n & (n + 1) can eliminate the last 1 bit.

At this point, check if it equals 0. If so, the assumption holds, and it is an alternating 01 sequence.

The time complexity is O(1), and the space complexity is O(1).

Python 3

```python
class Solution:
    def hasAlternatingBits(self, n: int) -> bool:
        n ^= n >> 1
        return (n & (n + 1)) == 0
```

PATTERN 27 · BIT MANIPULATION · PROBLEM 8 OF 20

1486. XOR Operation in an Array

Easy · Bit Manipulation, Math

leetcode.com/problems/xor-operation-in-an-array

PROBLEM

You are given an integer `n` and an integer `start`.

Define an array `nums` where `nums[i] = start + 2 * i` (**0-indexed**) and `n == nums.length`.

Return *the bitwise XOR of all elements of* `nums`.

Example 1:

```
Input: n = 5, start = 0
Output: 8
Explanation: Array nums is equal to [0, 2, 4, 6, 8] where (0 ^ 2 ^ 4 ^ 6 ^ 8) = 8.
Where "^" corresponds to bitwise XOR operator.
```

Example 2:

```
Input: n = 4, start = 3
Output: 8
Explanation: Array nums is equal to [3, 5, 7, 9] where (3 ^ 5 ^ 7 ^ 9) = 8.
```

Constraints:

- `1 <= n <= 1000`
- `0 <= start <= 1000`
- `n == nums.length`

SOLUTION (PYTHON 3)

Solution 1: Simulation

> **How to think about it**
>
> n≤ 1000. Emit start+2i and XOR the values together.

We can directly simulate to calculate the XOR result of all elements in the array.

The time complexity is O(n), where n is the length of the array. The space complexity is O(1).

Python 3

```python
class Solution:
    def xorOperation(self, n: int, start: int) -> int:
        return reduce(xor, ((start + 2 * i) for i in range(n)))
```

137. Single Number II

Medium · Bit Manipulation, Array

leetcode.com/problems/single-number-ii

★ **TOP 10 PROBLEM** in Bit Manipulation: master this one first

PROBLEM

Given an integer array `nums` where every element appears **three times** except for one, which appears **exactly once**. *Find the single element and return it*.

You must implement a solution with a linear runtime complexity and use only constant extra space.

Example 1:

```
Input: nums = [2,2,3,2]
Output: 3
```

Example 2:

```
Input: nums = [0,1,0,1,0,1,99]
Output: 99
```

Constraints:

- `1 <= nums.length <= 3 * 10^4`
- `-2^31 <= nums[i] <= 2^31 - 1`
- Each element in `nums` appears exactly **three times** except for one element which appears **once**.

SOLUTIONS (PYTHON 3)

Solution 1: Bitwise Operation

How to think about it

Numbers appear three times except one; XOR is no longer enough because xxor xxor x=x. The follow-up still wants constant space. Count 1s per bit modulo 3: bits from the triples vanish, and the remainder is the answer. The sign bit is handled separately to avoid overflow.

We can enumerate each binary bit i, and for each binary bit, we calculate the sum of all numbers on that bit. If the sum of the numbers on that bit can be divided by 3, then the number that only appears once on that bit is 0, otherwise it is 1.

The time complexity is O(n × log M), where n and M are the length of the array and the range of elements in the array, respectively. The space complexity is O(1).

The C++ implementation adds INT_MIN for the sign bit instead of left-shifting a signed integer into overflow.

Python 3

```python
class Solution:
    def singleNumber(self, nums: List[int]) -> int:
        ans = 0
        for i in range(32):
            cnt = sum(num >> i & 1 for num in nums)
            if cnt % 3:
                if i == 31:
                    ans -= 1 << i
                else:
                    ans |= 1 << i
        return ans
```

Solution 2: Digital Circuit

> **How to think about it**
>
> Solution 1 rescans the array for every bit. Two integers a,b store each bit's count modulo 3; a truth table updates them as each number arrives, so one pass does the same counting.

We can use a more efficient method that uses digital circuits to simulate the above bitwise operation.

Each binary bit of an integer can only represent 2 states, 0 or 1. However, we need to represent the sum of the i-th bit of all integers traversed so far modulo 3. Therefore, we can use two integers a and b to represent it. There are three possible cases:

1. The i-th bit of integer a is 0 and the i-th bit of integer b is 0, which means the modulo 3 result is 0;
2. The i-th bit of integer a is 0 and the i-th bit of integer b is 1, which means the modulo 3 result is 1;
3. The i-th bit of integer a is 1 and the i-th bit of integer b is 0, which means the modulo 3 result is 2.

We use integer c to represent the number to be read in, and the truth table is as follows:

a_i	b_i	c_i	New a_i	New b_i
0	0	0	0	0
0	0	1	0	1
0	1	0	0	1
0	1	1	1	0
1	0	0	1	0
1	0	1	0	0

Based on the truth table, we can write the logical expression:

$$a_i = a_i' \, b_i \, c_i + a_i \, b_i' \, c_i'$$

and:

$$b_i = a_i' \, b_i' \, c_i + a_i' \, b_i \, c_i' = a_i' \, (b_i \text{ xor } c_i)$$

The final result is b, because when the binary bit of b is 1, it means that the number appears only once.

The time complexity is O(n), where n is the length of the array. The space complexity is O(1).

Python 3

```
class Solution:
    def singleNumber(self, nums: List[int]) -> int:
        a = b = 0
        for c in nums:
            aa = (~a & b & c) | (a & ~b & ~c)
            bb = ~a & (b ^ c)
            a, b = aa, bb
        return b
```

Solution 3: Set + Math

> **How to think about it**
>
> If extra space is allowed, the unique value is $(3\sum_{unique}-\sum_{all})/2$. Deduplicate, sum twice, and divide. Direct, but O(n) space.

Python 3 (written for this guide: the doocs page has no Python 3 version of this solution)

```
class Solution:
    def singleNumber(self, nums: List[int]) -> int:
        return (3 * sum(set(nums)) - sum(nums)) // 2
```

Solution 4: Bit Manipulation

How to think about it

The Solution 2 state machine collapses to two masks: ans and acc hold bits seen once and twice. They stay disjoint as x arrives; ans is the number that appeared once. Shorter code.

Python 3 (written for this guide: the doocs page has no Python 3 version of this solution)

```
class Solution:
    def singleNumber(self, nums: List[int]) -> int:
        ones = twos = 0
        for x in nums:
            ones ^= x & ~twos
            twos ^= x & ~ones
        return ones
```

```

```
    return ones
```

260. Single Number III

Medium · Bit Manipulation, Array

leetcode.com/problems/single-number-iii

★ **TOP 10 PROBLEM** in Bit Manipulation: master this one first

PROBLEM

Given an integer array `nums`, in which exactly two elements appear only once and all the other elements appear exactly twice. Find the two elements that appear only once. You can return the answer in **any order**.

You must write an algorithm that runs in linear runtime complexity and uses only constant extra space.

Example 1:

```
Input: nums = [1,2,1,3,2,5]
Output: [3,5]
Explanation: [5, 3] is also a valid answer.
```

Example 2:

```
Input: nums = [-1,0]
Output: [-1,0]
```

Example 3:

```
Input: nums = [0,1]
Output: [1,0]
```

Constraints:

- `2 <= nums.length <= 3 * 10^4`
- `-2^31 <= nums[i] <= 2^31 - 1`
- Each integer in `nums` will appear twice, only two integers will appear once.

SOLUTIONS (PYTHON 3)

Solution 1: Bitwise Operation

How to think about it

All but two values appear twice, so the XOR of the array is the XOR xs of those two. They differ, so xs has a 1 bit. Group by the lowbit of xs; the two targets land in different groups. XOR the group that has that bit to get a, then b=xsxor a.

The XOR operation has the following properties:

- Any number XOR 0 is still the original number, i.e., x xor 0 = x;
- Any number XOR itself is 0, i.e., x xor x = 0;

Since all numbers in the array appear twice except for two numbers, we can perform XOR operation on all numbers in the array to get the XOR result of the two numbers that only appear once.

Since these two numbers are not equal, there is at least one bit that is 1 in the XOR result. We can use the `lowbit` operation to find the lowest bit of 1 in the XOR result, and divide all numbers in the array into two groups based on whether this bit is 1 or not. This way, the two numbers that only appear once are separated into different groups.

Perform XOR operation on each group separately to obtain the two numbers a and b that only appear once.

The time complexity is O(n), where n is the length of the array. The space complexity is O(1).

Python 3

```
class Solution:
    def singleNumber(self, nums: List[int]) -> List[int]:
        xs = reduce(xor, nums)
        a = 0
        lb = xs & -xs
        for x in nums:
            if x & lb:
                a ^= x
        b = xs ^ a
        return [a, b]
```

Solution 2: Hash Table

> **How to think about it**
>
> The bit method is constant-space. With linear extra memory, a set toggles membership: insert on the first sighting, delete on the second. The remainder is the pair of unique numbers.

Python 3 (written for this guide: the doocs page has no Python 3 version of this solution)

```
class Solution:
    def singleNumber(self, nums: List[int]) -> List[int]:
        seen = set()
        for x in nums:
            if x in seen:
                seen.remove(x)
            else:
                seen.add(x)
        return list(seen)
```

leetcode.com/problems/sum-of-two-integers

★ **TOP 10 PROBLEM** in Bit Manipulation: master this one first

PROBLEM

Given two integers `a` and `b`, return *the sum of the two integers without using the operators* `+` *and* `-`.

Example 1:

```
Input: a = 1, b = 2
Output: 3
```

Example 2:

```
Input: a = 2, b = 3
Output: 5
```

Constraints:

- `-1000 <= a, b <= 1000`

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Add without +/−. Bitwise: the sum without carry is XOR, the carry is AND shifted left. Repeat until the carry vanishes. Python ints are unbounded, so mask with 0xFFFFFFFF to 32 bits. If the sign bit is set, convert two's complement back to a negative.

Python 3

```python
class Solution:
    def getSum(self, a: int, b: int) -> int:
        a, b = a & 0xFFFFFFFF, b & 0xFFFFFFFF
        while b:
            carry = ((a & b) << 1) & 0xFFFFFFFF
            a, b = a ^ b, carry
        return a if a < 0x80000000 else ~(a ^ 0xFFFFFFFF)
```

Complexity. Time: O(1) (at most 32 rounds). Space: O(1).

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

```

PATTERN 27 · BIT MANIPULATION · PROBLEM 12 OF 20

201. Bitwise AND of Numbers Range

Medium · Bit Manipulation

leetcode.com/problems/bitwise-and-of-numbers-range

★ **TOP 10 PROBLEM** in Bit Manipulation: master this one first

PROBLEM

Given two integers `left` and `right` that represent the range `[left, right]`, return *the bitwise AND of all numbers in this range, inclusive*.

Example 1:

```
Input: left = 5, right = 7
Output: 4
```

Example 2:

```
Input: left = 0, right = 0
Output: 0
```

Example 3:

```
Input: left = 1, right = 2147483647
Output: 0
```

Constraints:

- `0 <= left <= right <= 2^31 - 1`

SOLUTION (PYTHON 3)

Solution 1

How to think about it

AND-ing every integer in [left,right] is impossible when the span approaches 2^{31}. The bitwise AND of a contiguous range is their common binary prefix: lower bits are cleared by some number in the range. While left < right, clear the lowest set bit of right (right &= right-1) until right ≤ left. The remaining right is that common prefix.

Python 3

```python
class Solution:
    def rangeBitwiseAnd(self, left: int, right: int) -> int:
        while left < right:
            right &= right - 1
        return right
```

Complexity. Time: O(log right). Space: O(1).

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

421. Maximum XOR of Two Numbers in an Array

Medium · Bit Manipulation, Trie, Array, Hash Table

leetcode.com/problems/maximum-xor-of-two-numbers-in-an-array

★ **TOP 10 PROBLEM** in Bit Manipulation, Trie (Prefix Tree): master this one first

Also appears in pattern 32 Trie (Prefix Tree)

PROBLEM

Given an integer array `nums`, return *the maximum result of* `nums[i] XOR nums[j]`, where `0 <= i <= j < n`.

Example 1:

```
Input: nums = [3,10,5,25,2,8]
Output: 28
Explanation: The maximum result is 5 XOR 25 = 28.
```

Example 2:

```
Input: nums = [14,70,53,83,49,91,36,80,92,51,66,70]
Output: 127
```

Constraints:

- `1 <= nums.length <= 2 * 10^5`
- `0 <= nums[i] <= 2^31 - 1`

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Trying every pair is $O(n^2)$ and n can be 2×10^5. A large XOR wants the opposite bit as early as possible. Insert each number into a binary trie from the high bit. When querying x, prefer the child with the flipped bit so that bit of the answer becomes 1. Thirty-one bits cover the value range. Each query walks the trie once and is equivalent to choosing the best partner among the inserted numbers.

Python 3

```python
class Trie:
    __slots__ = ("children",)

    def __init__(self):
        self.children: List[Trie | None] = [None, None]

    def insert(self, x: int):
        node = self
        for i in range(30, -1, -1):
            v = x >> i & 1
            if node.children[v] is None:
                node.children[v] = Trie()
            node = node.children[v]

    def search(self, x: int) -> int:
        node = self
        ans = 0
        for i in range(30, -1, -1):
            v = x >> i & 1
            if node.children[v ^ 1]:
                ans |= 1 << i
                node = node.children[v ^ 1]
            else:
                node = node.children[v]
        return ans

class Solution:
    def findMaximumXOR(self, nums: List[int]) -> int:
        trie = Trie()
        for x in nums:
            trie.insert(x)
        return max(trie.search(x) for x in nums)
```

PATTERN 27 · BIT MANIPULATION · PROBLEM 14 OF 20

477. Total Hamming Distance

Medium · Bit Manipulation, Array, Math

leetcode.com/problems/total-hamming-distance

PROBLEM

The Hamming distance between two integers is the number of positions at which the corresponding bits are different.

Given an integer array `nums`, return *the sum of **Hamming distances** between all the pairs of the integers in* `nums`.

Example 1:

```
Input: nums = [4,14,2]
Output: 6
Explanation: In binary representation, the 4 is 0100, 14 is 1110, and 2 is 0010 (just
showing the four bits relevant in this case).
The answer will be:
HammingDistance(4, 14) + HammingDistance(4, 2) + HammingDistance(14, 2) = 2 + 2 + 2 = 6.
```

Example 2:

```
Input: nums = [4,14,4]
Output: 4
```

Constraints:

- `1 <= nums.length <= 10^4`
- `0 <= nums[i] <= 10^9`
- The answer for the given input will fit in a **32-bit** integer.

SOLUTION (PYTHON 3)

Solution 1: Bit Manipulation

How to think about it

Sum Hamming distances over every pair. XORing all pairs is O(n^2). Bits contribute independently. On bit i, if a numbers have a 1, then n-a have a 0, and the bit adds a(n-a). Sum over 32 bits. After splitting by bit, each pair that differs on that bit is counted once; pairs are never enumerated.

We enumerate each bit in the range [0, 31]. For the current enumerated bit i, we count the number of numbers where the i-th bit is 1, denoted as a. Therefore, the number of numbers where the i-th bit is 0 is b = n - a, where n is the length of the array. In this way, the sum of the Hamming distance on the i-th bit is a × b. We add the Hamming distances of all bits to get the answer.

The time complexity is O(n × log M), where n and M are the length of the array and the maximum value in the array, respectively. The space complexity is O(1).

Python 3

```python
class Solution:
    def totalHammingDistance(self, nums: List[int]) -> int:
        ans, n = 0, len(nums)
        for i in range(32):
            a = sum(x >> i & 1 for x in nums)
            b = n - a
            ans += a * b
        return ans
```

    return total
```

PATTERN 27 · BIT MANIPULATION · PROBLEM 15 OF 20

393. UTF-8 Validation

Medium · Bit Manipulation, Array

leetcode.com/problems/utf-8-validation

PROBLEM

Given an integer array `data` representing the data, return whether it is a valid **UTF-8** encoding (i.e. it translates to a sequence of valid UTF-8 encoded characters).

A character in **UTF8** can be from **1 to 4 bytes** long, subjected to the following rules:

1. For a **1-byte** character, the first bit is a `0`, followed by its Unicode code.
2. For an **n-bytes** character, the first `n` bits are all one's, the `n + 1` bit is `0`, followed by `n - 1` bytes with the most significant `2` bits being `10`.

This is how the UTF-8 encoding would work:

```
   Number of Bytes   | UTF-8 Octet Sequence
                     | (binary)
   --------------------+-----------------------------------------
            1 | 0xxxxxxx
            2 | 110xxxxx 10xxxxxx
            3 | 1110xxxx 10xxxxxx 10xxxxxx
            4 | 11110xxx 10xxxxxx 10xxxxxx 10xxxxxx
```

`x` denotes a bit in the binary form of a byte that may be either `0` or `1`.

Note: The input is an array of integers. Only the **least significant 8 bits** of each integer is used to store the data. This means each integer represents only 1 byte of data.

Example 1:

```
Input: data = [197,130,1]
Output: true
Explanation: data represents the octet sequence: 11000101 10000010 00000001.
It is a valid utf-8 encoding for a 2-bytes character followed by a 1-byte character.
```

Example 2:

```
Input: data = [235,140,4]
Output: false
Explanation: data represented the octet sequence: 11101011 10001100 00000100.
The first 3 bits are all one's and the 4th bit is 0 means it is a 3-bytes character.
The next byte is a continuation byte which starts with 10 and that's correct.
But the second continuation byte does not start with 10, so it is invalid.
```

Constraints:

- `1 <= data.length <= 2 * 10^4`
- `0 <= data[i] <= 255`

SOLUTION (PYTHON 3)

Solution 1: Single Pass

How to think about it

Validate a UTF-8 byte stream given as integers. The leading prefix dictates how many `10xxxxxx` bytes follow. One pass is enough. `cnt` is remaining continuation bytes, which must be `10xxxxxx`. Otherwise decode a 1–4-byte header and set `cnt`. Fail on a bad prefix; success requires `cnt=0` at the end.

We use a variable cnt to record the current number of bytes that need to be filled starting with 10, initially cnt = 0.

For each integer v in the array:

- If cnt > 0, then check if v starts with 10. If not, return `false`, otherwise decrement cnt.
- If the highest bit of v is 0, then cnt = 0.
- If the highest two bits of v are 110, then cnt = 1.
- If the highest three bits of v are 1110, then cnt = 2.
- If the highest four bits of v are 11110, then cnt = 3.
- Otherwise, return `false`.

Finally, if cnt = 0, return `true`, otherwise return `false`.

The time complexity is O(n), where n is the length of the array `data`. The space complexity is O(1).

Python 3

```
class Solution:
    def validUtf8(self, data: List[int]) -> bool:
        cnt = 0
        for v in data:
            if cnt > 0:
                if v >> 6 != 0b10:
                    return False
                cnt -= 1
            elif v >> 7 == 0:
                cnt = 0
            elif v >> 5 == 0b110:
                cnt = 1
            elif v >> 4 == 0b1110:
                cnt = 2
            elif v >> 3 == 0b11110:
                cnt = 3
            else:
                return False
        return cnt == 0
```

```

29. Divide Two Integers

Medium · Bit Manipulation, Math

leetcode.com/problems/divide-two-integers

★ **TOP 10 PROBLEM** in Bit Manipulation: master this one first

PROBLEM

Given two integers `dividend` and `divisor`, divide two integers **without** using multiplication, division, and mod operator.

The integer division should truncate toward zero, which means losing its fractional part. For example, `8.345` would be truncated to `8`, and `-2.7335` would be truncated to `-2`.

Return *the **quotient** after dividing* `dividend` *by* `divisor`.

Note: Assume we are dealing with an environment that could only store integers within the **32-bit** signed integer range: $[-2^{31}, 2^{31} - 1]$. For this problem, if the quotient is **strictly greater than** $2^{31} - 1$, then return $2^{31} - 1$, and if the quotient is **strictly less than** -2^{31}, then return -2^{31}.

Example 1:

```
Input: dividend = 10, divisor = 3
Output: 3
Explanation: 10/3 = 3.33333.. which is truncated to 3.
```

Example 2:

```
Input: dividend = 7, divisor = -3
Output: -2
Explanation: 7/-3 = -2.33333.. which is truncated to -2.
```

Constraints:

- $-2^{31} <= dividend, divisor <= 2^{31} - 1$
- `divisor != 0`

SOLUTION (PYTHON 3)

Solution 1: Simulation + Fast Power

How to think about it

The first idea is repeated subtraction: each time the dividend still covers the divisor, add 1 to the quotient. |a| can be about 2^{31}, so this times out, and we cannot use multiply, divide, or mod. The bottleneck is removing only 1× b per step. If we can remove 2^k × b at once, the quotient jumps in binary. That is the same idea as fast exponentiation: while the remainder still fits, left-shift b to double it, subtract the largest such chunk, and repeat on what is left. Record the sign separately and compute on negatives so negating a= -2^{31} cannot overflow. Special-case b=1 and a= -2^{31}, b=-1, clamping to $2^{31}-1$.

Division is essentially subtraction. The problem requires us to calculate the integer result after dividing two numbers, which is actually calculating how many divisors and a number less than the divisor constitute the dividend. However, only one subtraction can be done in one loop, which is too inefficient and will lead to timeout. This can be optimized by using the idea of fast power.

It should be noted that since the problem explicitly requires that only 32-bit signed integers can be used at most, the divisor and dividend need to be converted to negative numbers for calculation. Because converting to positive numbers may cause overflow, such as when the dividend is `INT32_MIN`, it will be greater than `INT32_MAX` when converted to a positive number.

Assuming the dividend is a and the divisor is b, the time complexity is O(log a × log b), and the space complexity is O(1).

Python 3

```python
class Solution:
    def divide(self, a: int, b: int) -> int:
        if b == 1:
            return a
        if a == -(2**31) and b == -1:
            return 2**31 - 1
        sign = (a > 0 and b > 0) or (a < 0 and b < 0)
        a = -a if a > 0 else a
        b = -b if b > 0 else b
        ans = 0
        while a <= b:
            x = b
            cnt = 1
            while x >= (-(2**30)) and a <= (x << 1):
                x <<= 1
                cnt <<= 1
            a -= x
            ans += cnt
        return ans if sign else -ans
```

        while multiple << 1 <= a:
            multiple <<= 1
            power <<= 1
        a -= multiple
        quotient += power
    if negative:
        return -quotient
    if a > 0:
        quotient += 1
    return quotient
```

318. Maximum Product of Word Lengths

Medium · Bit Manipulation, Array, String

leetcode.com/problems/maximum-product-of-word-lengths

PROBLEM

Given a string array `words`, return *the maximum value of* `length(word[i]) * length(word[j])` *where the two words do not share common letters*. If no such two words exist, return `0`.

Example 1:

```
Input: words = ["abcw","baz","foo","bar","xtfn","abcdef"]
Output: 16
Explanation: The two words can be "abcw", "xtfn".
```

Example 2:

```
Input: words = ["a","ab","abc","d","cd","bcd","abcd"]
Output: 4
Explanation: The two words can be "ab", "cd".
```

Example 3:

```
Input: words = ["a","aa","aaa","aaaa"]
Output: 0
Explanation: No such pair of words.
```

Constraints:

- `2 <= words.length <= 1000`
- `1 <= words[i].length <= 1000`
- `words[i]` consists only of lowercase English letters.

SOLUTIONS (PYTHON 3)

Solution 1: Bit Manipulation

How to think about it

A product counts only when two words share no letter. Set intersection is O(σ) per pair; we need a cheaper disjointness test. Pack each word into a 26-bit mask; bitwise AND zero means disjoint. Check every pair i>j and keep the max product. n≤ 1000 allows $O(n^2)$.

The problem requires us to find two strings without common letters, so that their length product is maximized. We can represent each string with a binary number mask[i], where each bit of this binary number indicates whether the string contains a certain letter. If two strings do not have common letters, then the bitwise AND result of the two binary numbers corresponding to these strings is 0, that is, mask[i] & mask[j] = 0.

We traverse each string. For the current string words[i] we are traversing, we first calculate the corresponding binary number mask[i], and then traverse all strings words[j] where $j \in [0, i)$. We check whether mask[i] & mask[j] = 0 holds. If it holds, we update the answer to max(ans, |words[i]| × |words[j]|).

After the traversal, we return the answer.

The time complexity is $O(n^2 + L)$, and the space complexity is $O(n)$. Here, n is the length of the string array words, and L is the sum of the lengths of all strings in the string array.

Python 3

```python
class Solution:
    def maxProduct(self, words: List[str]) -> int:
        mask = [0] * len(words)
        ans = 0
        for i, s in enumerate(words):
            for c in s:
                mask[i] |= 1 << (ord(c) - ord("a"))
            for j, t in enumerate(words[:i]):
                if (mask[i] & mask[j]) == 0:
                    ans = max(ans, len(s) * len(t))
        return ans
```

Solution 2

> **How to think about it**
>
> Method 1 compares words that share a mask many times. Store the longest word per mask and compare only against seen masks. Duplicate alphabets collapse to one length.

Python 3

```python
class Solution:
    def maxProduct(self, words: List[str]) -> int:
        mask = defaultdict(int)
        ans = 0
        for s in words:
            a = len(s)
            x = 0
            for c in s:
                x |= 1 << (ord(c) - ord("a"))
            for y, b in mask.items():
                if (x & y) == 0:
                    ans = max(ans, a * b)
            mask[x] = max(mask[x], a)
        return ans
```

Complexity. Time: O(n^2 + L), L = total number of letters. Space: O(n).

    return best
```

1318. Minimum Flips to Make a OR b Equal to c

Medium · Bit Manipulation

leetcode.com/problems/minimum-flips-to-make-a-or-b-equal-to-c

PROBLEM

Given 3 positives numbers `a`, `b` and `c`. Return the minimum flips required in some bits of `a` and `b` to make (`a` OR `b` == `c`). (bitwise OR operation).
Flip operation consists of change **any** single bit 1 to 0 or change the bit 0 to 1 in their binary representation.

Example 1:

```
Input: a = 2, b = 6, c = 5
Output: 3
Explanation: After flips a = 1 , b = 4 , c = 5 such that (a OR b == c)
```

Example 2:

```
Input: a = 4, b = 2, c = 7
Output: 1
```

Example 3:

```
Input: a = 1, b = 2, c = 3
Output: 0
```

Constraints:

- `1 <= a <= 10^9`
- `1 <= b <= 10^9`
- `1 <= c <= 10^9`

SOLUTION (PYTHON 3)

Solution 1: Bit Manipulation

> **How to think about it**
> We want the fewest bit flips so that av b=c. Bits are independent, so we never search over integers. If c's bit is 0, every 1 in a or b must flip; if it is 1, we flip once only when both bits are 0. Summing over 32 bits is enough.

We can enumerate each bit of the binary representation of a, b, and c, denoted as x, y, and z respectively. If the bitwise OR operation result of x and y is different from z, we then check if both x and y are 1. If so, we need to flip twice, otherwise, we only need to flip once. We accumulate all the required flip times.

The time complexity is O(log M), where M is the maximum value of the numbers in the problem. The space complexity is O(1).

Python 3

```python
class Solution:
    def minFlips(self, a: int, b: int, c: int) -> int:
        ans = 0
        for i in range(32):
            x, y, z = a >> i & 1, b >> i & 1, c >> i & 1
            ans += x + y if z == 0 else int(x == 0 and y == 0)
        return ans
```

PATTERN 28 OF 41

Dynamic Programming - Knapsack Style

20 problems · 0 Easy · 14 Medium · 6 Hard

THE IDEA

Pick items to reach a capacity or target. 0/1 knapsack loops the capacity downwards (each item once); unbounded loops it upwards (items reusable).

Signals: subset sum, partition equal subset, coin change, combination sum IV, target sum, last stone weight II, ones and zeroes.

A TEMPLATE TO KEEP IN YOUR HANDS (PYTHON)

```
dp = [False] * (target + 1)
dp[0] = True
for x in nums:                          # each item once
    for t in range(target, x - 1, -1):  # downwards so x is not reused
        dp[t] = dp[t] or dp[t - x]
```

494. Target Sum

Medium · Array, Dynamic Programming, Backtracking, Knapsack, 0-1 Knapsack

leetcode.com/problems/target-sum

★ **TOP 10 PROBLEM** in Dynamic Programming - Knapsack Style: master this one first

PROBLEM

You are given an integer array `nums` and an integer `target`.

You want to build an **expression** out of nums by adding one of the symbols `'+'` and `'-'` before each integer in nums and then concatenate all the integers.

- For example, if `nums = [2, 1]`, you can add a `'+'` before `2` and a `'-'` before `1` and concatenate them to build the expression `"+2-1"`.

Return the number of different **expressions** that you can build, which evaluates to `target`.

Example 1:

```
Input: nums = [1,1,1,1,1], target = 3
Output: 5
Explanation: There are 5 ways to assign symbols to make the sum of nums be target 3.
-1 + 1 + 1 + 1 + 1 = 3
+1 - 1 + 1 + 1 + 1 = 3
+1 + 1 - 1 + 1 + 1 = 3
+1 + 1 + 1 - 1 + 1 = 3
+1 + 1 + 1 + 1 - 1 = 3
```

Example 2:

```
Input: nums = [1], target = 1
Output: 1
```

Constraints:

- `1 <= nums.length <= 20`
- `0 <= nums[i] <= 1000`
- `0 <= sum(nums[i]) <= 1000`
- `-1000 <= target <= 1000`

SOLUTIONS (PYTHON 3)

Solution 1: Dynamic Programming

How to think about it

Assign + or - so the expression equals target. 2^n is tight for n≤ 20; the problem is a subset sum. If the negative part sums to x, then (s-x)-x=target, so x=(s-target)/2. Impossible when s<target or the difference is odd. f[i][j] is the number of ways for the first i numbers to sum to j. The empty subset gives f[0][0]=1. Take-or-skip is the usual 0-1 knapsack count.

Let's denote the sum of all elements in the array nums as s, and the sum of elements to which we assign a negative sign as x. Therefore, the sum of elements with a positive sign is s - x. We have:

$$(s - x) - x = \text{target} \Rightarrow x = (s - \text{target})/2$$

Since x ≥ 0 and x must be an integer, it follows that s ≥ target and s - target must be even. If these two conditions are not met, we directly return 0.

Next, we can transform the problem into: selecting several elements from the array nums such that the sum of these elements equals (s - target)/2. We are asked how many ways there are to make such a selection.

We can use dynamic programming to solve this problem. Define f[i][j] as the number of ways to select several elements from the first i elements of the array nums such that the sum of these elements equals j.

For nums[i - 1], we have two choices: to select or not to select. If we do not select nums[i - 1], then f[i][j] = f[i - 1][j]; if we do select nums[i - 1], then f[i][j] = f[i - 1][j - nums[i - 1]]. Therefore, the state transition equation is:

$$f[i][j] = f[i - 1][j] + f[i - 1][j - nums[i - 1]]$$

This selection is based on the premise that j ≥ nums[i - 1].

The final answer is f[m][n], where m is the length of the array nums, and n = (s - target)/2.

The time complexity is O(m × n), and the space complexity is O(m × n).

Python 3

```python
class Solution:
    def findTargetSumWays(self, nums: List[int], target: int) -> int:
        s = sum(nums)
        if s < target or (s - target) % 2:
            return 0
        m, n = len(nums), (s - target) // 2
        f = [[0] * (n + 1) for _ in range(m + 1)]
        f[0][0] = 1
        for i, x in enumerate(nums, 1):
            for j in range(n + 1):
                f[i][j] = f[i - 1][j]
                if j >= x:
                    f[i][j] += f[i - 1][j - x]
        return f[m][n]
```

Solution 2: Dynamic Programming (Space Optimization)

> **How to think about it**
>
> Row i depends only on row i-1. Update j downward in one array so an item is not reused; space follows the capacity.

We can observe that in the state transition equation of Solution 1, the value of f[i][j] is only related to f[i - 1][j] and f[i - 1][j - nums[i - 1]]. Therefore, we can eliminate the first dimension of the space and use only a one-dimensional array.

The time complexity is O(m × n), and the space complexity is O(n).

Python 3

```python
class Solution:
    def findTargetSumWays(self, nums: List[int], target: int) -> int:
        s = sum(nums)
        if s < target or (s - target) % 2:
            return 0
        n = (s - target) // 2
        f = [0] * (n + 1)
        f[0] = 1
        for x in nums:
            for j in range(n, x - 1, -1):
                f[j] += f[j - x]
        return f[n]
```

1049. Last Stone Weight II

Medium · Array, Dynamic Programming, Knapsack, 0-1 Knapsack

leetcode.com/problems/last-stone-weight-ii

★ **TOP 10 PROBLEM** in Dynamic Programming - Knapsack Style: master this one first

PROBLEM

You are given an array of integers `stones` where `stones[i]` is the weight of the i^{th} stone.

We are playing a game with the stones. On each turn, we choose any two stones and smash them together. Suppose the stones have weights `x` and `y` with `x <= y`. The result of this smash is:

- If `x == y`, both stones are destroyed, and
- If `x != y`, the stone of weight `x` is destroyed, and the stone of weight `y` has new weight `y - x`.

At the end of the game, there is **at most one** stone left.

Return *the smallest possible weight of the left stone*. If there are no stones left, return `0`.

Example 1:

```
Input: stones = [2,7,4,1,8,1]
Output: 1
Explanation:
We can combine 2 and 4 to get 2, so the array converts to [2,7,1,8,1] then,
we can combine 7 and 8 to get 1, so the array converts to [2,1,1,1] then,
we can combine 2 and 1 to get 1, so the array converts to [1,1,1] then,
we can combine 1 and 1 to get 0, so the array converts to [1], then that's the optimal value.
```

Example 2:

```
Input: stones = [31,26,33,21,40]
Output: 5
```

Constraints:

- `1 <= stones.length <= 30`
- `1 <= stones[i] <= 100`

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

Each smash assigns opposite signs to two stones, so the remainder is the absolute difference of two subset sums. n≤ 30 but the total is only a few thousand, which is a 0-1 knapsack of capacity floor(s/2): pack as close to half as possible. dp[i][j] is the best weight of the first i stones that does not exceed j, taking or skipping stone i. The answer is s-2·dp[n][floor(s/2)].

Python 3

```python
class Solution:
    def lastStoneWeightII(self, stones: List[int]) -> int:
        s = sum(stones)
        m, n = len(stones), s >> 1
        dp = [[0] * (n + 1) for _ in range(m + 1)]
        for i in range(1, m + 1):
            for j in range(n + 1):
                dp[i][j] = dp[i - 1][j]
                if stones[i - 1] <= j:
                    dp[i][j] = max(
                        dp[i][j], dp[i - 1][j - stones[i - 1]] + stones[i - 1]
                    )
        return s - 2 * dp[-1][-1]
```

Complexity. Time: O(m * S), S = sum of the stones. Space: O(m * S).

Solution 2: Optimized Dynamic Programming

> **How to think about it**
>
> Row i depends only on row i-1. A one-dimensional array updated from high capacity to low reuses the same transition without packing a stone twice, and the space becomes O(s).

dp[i][j] only depends on the previous row dp[i - 1][·], so we can drop the first dimension and enumerate the capacity from large to small, reducing the space complexity to O(sum).

Python 3

```python
class Solution:
    def lastStoneWeightII(self, stones: List[int]) -> int:
        s = sum(stones)
        m, n = len(stones), s >> 1
        dp = [0] * (n + 1)
        for v in stones:
            for j in range(n, v - 1, -1):
                dp[j] = max(dp[j], dp[j - v] + v)
        return s - dp[-1] * 2
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

474. Ones and Zeroes

Medium · Array, String, Dynamic Programming, Knapsack, 0-1 Knapsack

leetcode.com/problems/ones-and-zeroes

★ **TOP 10 PROBLEM** in Dynamic Programming - Knapsack Style: master this one first

PROBLEM

You are given an array of binary strings `strs` and two integers `m` and `n`.

Return *the size of the largest subset of* `strs` *such that there are* ***at most*** `m` `0`*'s and* `n` `1`*'s in the subset*.

A set `x` is a **subset** of a set `y` if all elements of `x` are also elements of `y`.

Example 1:

```
Input: strs = ["10","0001","111001","1","0"], m = 5, n = 3
Output: 4
Explanation: The largest subset with at most 5 0's and 3 1's is {"10", "0001", "1", "0"}, so the answer is 4.
Other valid but smaller subsets include {"0001", "1"} and {"10", "1", "0"}.
{"111001"} is an invalid subset because it contains 4 1's, greater than the maximum of 3.
```

Example 2:

```
Input: strs = ["10","0","1"], m = 1, n = 1
Output: 2
Explanation: The largest subset is {"0", "1"}, so the answer is 2.
```

Constraints:

- `1 <= strs.length <= 600`
- `1 <= strs[i].length <= 100`
- `strs[i]` consists only of digits `'0'` and `'1'`.
- `1 <= m, n <= 100`

SOLUTIONS (PYTHON 3)

Solution 1: Dynamic Programming

How to think about it

Selecting the most strings under budgets of zeros and ones is 0-1 knapsack with two weights. Subset search is too large. f[i][j][k] is the best count using the first i strings, at most j zeros and k ones. Skip copies the previous row; take adds 1 when the budgets allow. Count 0/1 in the current string before filling the row so the transition uses that item's cost.

We define f[i][j][k] as the maximum number of strings that can be obtained from the first i strings using j zeros and k ones. Initially, f[i][j][k]=0, and the answer is f[sz][m][n], where sz is the length of the array strs.

For f[i][j][k], we have two choices:

- Do not select the i-th string, in which case f[i][j][k]=f[i-1][j][k];
- Select the i-th string, in which case f[i][j][k]=f[i-1][j-a][k-b]+1, where a and b are the number of zeros and ones in the i-th string, respectively.

We take the maximum of these two choices to obtain the value of f[i][j][k].

The final answer is f[sz][m][n].

The time complexity is O(sz × m × n), and the space complexity is O(sz × m × n), where sz is the length of the array strs, and m and n are the upper limits on the number of zeros and ones, respectively.

Python 3

```python
class Solution:
    def findMaxForm(self, strs: List[str], m: int, n: int) -> int:
        sz = len(strs)
        f = [[[0] * (n + 1) for _ in range(m + 1)] for _ in range(sz + 1)]
        for i, s in enumerate(strs, 1):
            a, b = s.count("0"), s.count("1")
            for j in range(m + 1):
                for k in range(n + 1):
                    f[i][j][k] = f[i - 1][j][k]
                    if j >= a and k >= b:
                        f[i][j][k] = max(f[i][j][k], f[i - 1][j - a][k - b] + 1)
        return f[sz][m][n]
```

Solution 2: Dynamic Programming (Space Optimization)

> **How to think about it**
>
> Row i depends only on row i-1. Update j and k downward and drop the first dimension. Space becomes O(mn), and a string cannot be taken twice.

We notice that the calculation of f[i][j][k] only depends on f[i-1][j][k] and f[i-1][j-a][k-b]. Therefore, we can eliminate the first dimension and optimize the space complexity to O(m × n).

Python 3

```python
class Solution:
    def findMaxForm(self, strs: List[str], m: int, n: int) -> int:
        f = [[0] * (n + 1) for _ in range(m + 1)]
        for s in strs:
            a, b = s.count("0"), s.count("1")
            for i in range(m, a - 1, -1):
                for j in range(n, b - 1, -1):
                    f[i][j] = max(f[i][j], f[i - a][j - b] + 1)
        return f[m][n]
```

```

1155. Number of Dice Rolls With Target Sum

Medium · Dynamic Programming

leetcode.com/problems/number-of-dice-rolls-with-target-sum

PROBLEM

You have `n` dice, and each dice has `k` faces numbered from `1` to `k`.

Given three integers `n`, `k`, and `target`, return *the number of possible ways (out of the* k^n *total ways) to roll the dice, so the sum of the face-up numbers equals* `target`. Since the answer may be too large, return it **modulo** $10^9 + 7$.

Example 1:

```
Input: n = 1, k = 6, target = 3
Output: 1
Explanation: You throw one die with 6 faces.
There is only one way to get a sum of 3.
```

Example 2:

```
Input: n = 2, k = 6, target = 7
Output: 6
Explanation: You throw two dice, each with 6 faces.
There are 6 ways to get a sum of 7: 1+6, 2+5, 3+4, 4+3, 5+2, 6+1.
```

Example 3:

```
Input: n = 30, k = 30, target = 500
Output: 222616187
Explanation: The answer must be returned modulo 109 + 7.
```

Constraints:

- `1 <= n, k <= 30`
- `1 <= target <= 1000`

SOLUTIONS (PYTHON 3)

Solution 1: Dynamic Programming

How to think about it

Naively assigning n k-faced dice to sum to target is k^n. Let f[i][j] be the ways for i dice to sum to j; face h on the last die comes from f[i-1][j-h]. One way uses zero dice to make 0. Reduce modulo 10^9+7.

We define f[i][j] as the number of ways to get a sum of j using i dice. Then, we can obtain the following state transition equation:

$$f[i][j] = \sum_{h=1}^{\min(j,\ k)} f[i-1][j-h]$$

where h represents the number of points on the i-th die.

Initially, we have f[0][0] = 1, and the final answer is f[n][target].

The time complexity is O(n × k × target), and the space complexity is O(n × target).

Python 3

```
class Solution:
    def numRollsToTarget(self, n: int, k: int, target: int) -> int:
        f = [[0] * (target + 1) for _ in range(n + 1)]
        f[0][0] = 1
        mod = 10**9 + 7
        for i in range(1, n + 1):
            for j in range(1, min(i * k, target) + 1):
                for h in range(1, min(j, k) + 1):
                    f[i][j] = (f[i][j] + f[i - 1][j - h]) % mod
        return f[n][target]
```

Solution 2: Dynamic Programming (Rolling Array)

> **How to think about it**
>
> Row i of method 1 depends only on row i-1. Two rolling arrays cut space from O(n× target) to O(target) with the same transition.

f[i][j] depends only on the previous row, so two arrays f and g of length target+1 are enough. The space complexity becomes O(target).

Python 3

```
class Solution:
    def numRollsToTarget(self, n: int, k: int, target: int) -> int:
        f = [1] + [0] * target
        mod = 10**9 + 7
        for i in range(1, n + 1):
            g = [0] * (target + 1)
            for j in range(1, min(i * k, target) + 1):
                for h in range(1, min(j, k) + 1):
                    g[j] = (g[j] + f[j - h]) % mod
            f = g
        return f[target]
```

```

1105. Filling Bookcase Shelves

Medium · Array, Dynamic Programming

leetcode.com/problems/filling-bookcase-shelves

PROBLEM

You are given an array `books` where `books[i] = [thickness_i, height_i]` indicates the thickness and height of the i^{th} book. You are also given an integer `shelfWidth`.

We want to place these books in order onto bookcase shelves that have a total width `shelfWidth`.

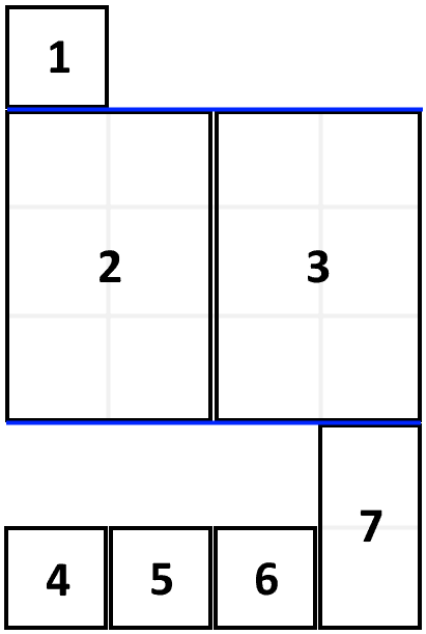
We choose some of the books to place on this shelf such that the sum of their thickness is less than or equal to `shelfWidth`, then build another level of the shelf of the bookcase so that the total height of the bookcase has increased by the maximum height of the books we just put down. We repeat this process until there are no more books to place.

Note that at each step of the above process, the order of the books we place is the same order as the given sequence of books.

- For example, if we have an ordered list of `5` books, we might place the first and second book onto the first shelf, the third book on the second shelf, and the fourth and fifth book on the last shelf.

Return *the minimum possible height that the total bookshelf can be after placing shelves in this manner*.

Example 1:



```
Input: books = [[1,1],[2,3],[2,3],[1,1],[1,1],[1,1],[1,2]], shelfWidth = 4
Output: 6
Explanation:
The sum of the heights of the 3 shelves is 1 + 3 + 2 = 6.
Notice that book number 2 does not have to be on the first shelf.
```

Example 2:

```
Input: books = [[1,3],[2,4],[3,2]], shelfWidth = 6
Output: 4
```

Constraints:

- `1 <= books.length <= 1000`
- `1 <= thickness_i <= shelfWidth <= 1000`

- $1 <= height_i <= 1000$

SOLUTION (PYTHON 3)

Solution 1: Dynamic Programming

> **How to think about it**
>
> Each book may start a new shelf or share one with a prefix of earlier books; the partition count grows exponentially. With n≤ 1000, an $O(n^2)$ DP fits. Let f[i] be the minimum height for the first i books. The last shelf ends at books[i-1]; extend it backward, accumulating width, and stop once it exceeds shelfWidth. The shelf height is the max book height on that shelf, added to f[j-1]. Scanning backward keeps width monotonic.

We define f[i] as the minimum height for placing the first i books, initially f[0] = 0, and the answer is f[n].

Consider f[i], the last book is books[i - 1], its thickness is w, and its height is h.

- If this book is placed on a new layer alone, then f[i] = f[i - 1] + h;
- If this book can be placed on the same layer with the last few books in front, we enumerate the first book books[j-1] on the same layer from back to front, where j ∈ [1, i - 1], accumulate the thickness of the book to w, if w > shelfWidth, it means that books[j-1] can no longer be placed on the same layer with books[i-1], stop enumeration; otherwise, we update the maximum height h = max(h, books[j-1][1]) of the current layer, then f[i] = min(f[i], f[j - 1] + h).

The final answer is f[n].

The time complexity is $O(n^2)$, and the space complexity is O(n). Here, n is the length of the array books.

Python 3

```python
class Solution:
    def minHeightShelves(self, books: List[List[int]], shelfWidth: int) -> int:
        n = len(books)
        f = [0] * (n + 1)
        for i, (w, h) in enumerate(books, 1):
            f[i] = f[i - 1] + h
            for j in range(i - 1, 0, -1):
                w += books[j - 1][0]
                if w > shelfWidth:
                    break
                h = max(h, books[j - 1][1])
                f[i] = min(f[i], f[j - 1] + h)
        return f[n]
```

        i = j
    shelves.reverse()
    return best[n], shelves
```

638. Shopping Offers

Medium · Bit Manipulation, Memoization, Array, Dynamic Programming, Backtracking, Bitmask, Knapsack, Unbounded Knapsack

leetcode.com/problems/shopping-offers

PROBLEM

In LeetCode Store, there are `n` items to sell. Each item has a price. However, there are some special offers, and a special offer consists of one or more different kinds of items with a sale price.

You are given an integer array `price` where `price[i]` is the price of the i^{th} item, and an integer array `needs` where `needs[i]` is the number of pieces of the i^{th} item you want to buy.

You are also given an array `special` where `special[i]` is of size `n + 1` where `special[i][j]` is the number of pieces of the j^{th} item in the i^{th} offer and `special[i][n]` (i.e., the last integer in the array) is the price of the i^{th} offer.

Return *the lowest price you have to pay for exactly certain items as given, where you could make optimal use of the special offers*. You are not allowed to buy more items than you want, even if that would lower the overall price. You could use any of the special offers as many times as you want.

Example 1:

```
Input: price = [2,5], special = [[3,0,5],[1,2,10]], needs = [3,2]
Output: 14
Explanation: There are two kinds of items, A and B. Their prices are $2 and $5 respectively.
In special offer 1, you can pay $5 for 3A and 0B
In special offer 2, you can pay $10 for 1A and 2B.
You need to buy 3A and 2B, so you may pay $10 for 1A and 2B (special offer #2), and $4 for 2A.
```

Example 2:

```
Input: price = [2,3,4], special = [[1,1,0,4],[2,2,1,9]], needs = [1,2,1]
Output: 11
Explanation: The price of A is $2, and $3 for B, $4 for C.
You may pay $4 for 1A and 1B, and $9 for 2A ,2B and 1C.
You need to buy 1A ,2B and 1C, so you may pay $4 for 1A and 1B (special offer #1), and $3 for 1B, $4
for 1C.
You cannot add more items, though only $9 for 2A ,2B and 1C.
```

Constraints:

- `n == price.length == needs.length`
- `1 <= n <= 6`
- `0 <= price[i], needs[i] <= 10`
- `1 <= special.length <= 100`
- `special[i].length == n + 1`
- `0 <= special[i][j] <= 50`
- The input is generated that at least one of `special[i][j]` is non-zero for `0 <= j <= n - 1`.

SOLUTION (PYTHON 3)

Solution 1: State Compression + Memoization Search

> **How to think about it**
>
> At most 6 item types and 10 of each, enumerating offer multiplicities revisits the same leftover list. Pack each need into 4 bits. Memoize on the leftover mask: pay retail, or apply any offer that still fits and recurse.

We notice that the number of types of items $n \le 6$ in the problem, and the quantity of each item needed does not exceed 10. We can use 4 binary bits to represent the quantity of each item needed. Thus, we only need at most $6 \times 4 = 24$ binary bits

to represent the entire shopping list.

First, we convert the shopping list needs into an integer mask, where the quantity of the i-th item needed is stored in the i × 4 to (i + 1) × 4 - 1 bits of mask. For example, when needs = [1, 2, 1], we have mask = 0b0001 0010 0001.

Then, we design a function dfs(cur), representing the minimum amount of money we need to spend when the current state of the shopping list is cur. Therefore, the answer is dfs(mask).

The calculation method of the function dfs(cur) is as follows:

- First, we calculate the cost of the current shopping list cur without using any bundles, denoted as ans.
- Then, we iterate through each bundle offer. If the current shopping list cur can use the bundle offer, i.e., the quantity of each item in cur is not less than that in the bundle offer, then we can try to use this bundle. We subtract the quantity of each item in the bundle offer from cur, obtaining a new shopping list nxt, then recursively calculate the minimum cost of nxt and add the price of the bundle offer[n], updating ans, i.e., ans = min(ans, offer[n] + dfs(nxt)).
- Finally, return ans.

To avoid repeated calculations, we use a hash table f to record the minimum cost corresponding to each state cur.

The time complexity is $O(n \times k \times m^n)$, where n represents the types of items, and k and m respectively represent the number of bundles and the maximum demand for each type of item. The space complexity is $O(n \times m^n)$.

Python 3

```
class Solution:
    def shoppingOffers(
        self, price: List[int], special: List[List[int]], needs: List[int]
    ) -> int:
        @cache
        def dfs(cur: int) -> int:
            ans = sum(p * (cur >> (i * bits) & 0xF) for i, p in enumerate(price))
            for offer in special:
                nxt = cur
                for j in range(len(needs)):
                    if (cur >> (j * bits) & 0xF) < offer[j]:
                        break
                    nxt -= offer[j] << (j * bits)
                else:
                    ans = min(ans, offer[-1] + dfs(nxt))
            return ans

        bits, mask = 4, 0
        for i, need in enumerate(needs):
            mask |= need << i * bits
        return dfs(mask)
```

1449. Form Largest Integer With Digits That Add up to Target

Hard · Array, Dynamic Programming, Knapsack, Unbounded Knapsack

leetcode.com/problems/form-largest-integer-with-digits-that-add-up-to-target

PROBLEM

Given an array of integers `cost` and an integer `target`, return *the **maximum** integer you can paint under the following rules*:

- The cost of painting a digit `(i + 1)` is given by `cost[i]` (**0-indexed**).
- The total cost used must be equal to `target`.
- The integer does not have `0` digits.

Since the answer may be very large, return it as a string. If there is no way to paint any integer given the condition, return `"0"`.

Example 1:

```
Input: cost = [4,3,2,5,6,7,2,5,5], target = 9
Output: "7772"
Explanation: The cost to paint the digit '7' is 2, and the digit '2' is 3. Then cost("7772") = 2*3+ 3*1
= 9. You could also paint "977", but "7772" is the largest number.
Digit cost
  1 -> 4
  2 -> 3
  3 -> 2
  4 -> 5
  5 -> 6
  6 -> 7
  7 -> 2
  8 -> 5
  9 -> 5
```

Example 2:

```
Input: cost = [7,6,5,5,5,6,8,7,8], target = 12
Output: "85"
Explanation: The cost to paint the digit '8' is 7, and the digit '5' is 5. Then cost("85") = 7 + 5 =
12.
```

Example 3:

```
Input: cost = [2,4,6,2,4,6,4,4,4], target = 5
Output: "0"
Explanation: It is impossible to paint any integer with total cost equal to target.
```

Constraints:

- `cost.length == 9`
- `1 <= cost[i], target <= 5000`

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Digits 1– 9 have costs and may be reused to reach `target`. The lexicographically largest integer first maximizes length, then prefers larger digits. f[i][j] is the maximum length using the first i digits and exact cost j (unbounded knapsack). g[i][j] records whether digit i was taken so we can reconstruct from 9 downward. Impossible yields `0`.

Python 3

```
class Solution:
    def largestNumber(self, cost: List[int], target: int) -> str:
        f = [[-inf] * (target + 1) for _ in range(10)]
        f[0][0] = 0
        g = [[0] * (target + 1) for _ in range(10)]
        for i, c in enumerate(cost, 1):
            for j in range(target + 1):
                if j < c or f[i][j - c] + 1 < f[i - 1][j]:
                    f[i][j] = f[i - 1][j]
                    g[i][j] = j
                else:
                    f[i][j] = f[i][j - c] + 1
                    g[i][j] = j - c
        if f[9][target] < 0:
            return "0"
        ans = []
        i, j = 9, target
        while i:
            if j == g[i][j]:

956. Tallest Billboard

Hard · Array, Dynamic Programming, Knapsack, 0-1 Knapsack, Meet in the Middle

leetcode.com/problems/tallest-billboard

★ **TOP 10 PROBLEM** in Dynamic Programming - Knapsack Style: master this one first

PROBLEM

You are installing a billboard and want it to have the largest height. The billboard will have two steel supports, one on each side. Each steel support must be an equal height.

You are given a collection of `rods` that can be welded together. For example, if you have rods of lengths `1`, `2`, and `3`, you can weld them together to make a support of length `6`.

Return *the largest possible height of your billboard installation*. If you cannot support the billboard, return `0`.

Example 1:

```
Input: rods = [1,2,3,6]
Output: 6
Explanation: We have two disjoint subsets {1,2,3} and {6}, which have the same sum = 6.
```

Example 2:

```
Input: rods = [1,2,3,4,5,6]
Output: 10
Explanation: We have two disjoint subsets {2,3,5} and {4,6}, which have the same sum = 10.
```

Example 3:

```
Input: rods = [1,2]
Output: 0
Explanation: The billboard cannot be supported, so we return 0.
```

Constraints:

- `1 <= rods.length <= 20`
- `1 <= rods[i] <= 1000`
- `sum(rods[i]) <= 5000`

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

Each rod goes left, right, or is discarded; the two sides should match and be as tall as possible. 3^n assignments are too many. The useful state is the largest common height after considering rod i with current difference j. Three transitions cover the choices; a difference of 0 is a feasible height. Memoization cuts repeats.

Python 3

```
class Solution:
    def tallestBillboard(self, rods: List[int]) -> int:
        @cache
        def dfs(i: int, j: int) -> int:
            if i >= len(rods):
                return 0 if j == 0 else -inf
            ans = max(dfs(i + 1, j), dfs(i + 1, j + rods[i]))
            ans = max(ans, dfs(i + 1, abs(rods[i] - j)) + min(j, rods[i]))
            return ans

        return dfs(0, 0)
```

Complexity. Time: O(n * S), S = sum of the rods. Space: O(n * S).

Solution 2

> **How to think about it**
>
> The search becomes bottom-up: f[i][j] is the best common height using the first i rods with difference j. The transitions match the recursion, without call overhead. The answer is f[n][0].

Python 3

```
class Solution:
    def tallestBillboard(self, rods: List[int]) -> int:
        n = len(rods)
        s = sum(rods)
        f = [[-inf] * (s + 1) for _ in range(n + 1)]
        f[0][0] = 0
        t = 0
        for i, x in enumerate(rods, 1):
            t += x
            for j in range(t + 1):
                f[i][j] = f[i - 1][j]
                if j >= x:
                    f[i][j] = max(f[i][j], f[i - 1][j - x])
                if j + x <= t:
                    f[i][j] = max(f[i][j], f[i - 1][j + x] + x)
                if j < x:
                    f[i][j] = max(f[i][j], f[i - 1][x - j] + x - j)
        return f[n][0]
```

Complexity. Time: O(n * S), S = sum of the rods. Space: O(n * S).

879. Profitable Schemes

Hard · Array, Dynamic Programming, Knapsack, 0-1 Knapsack

leetcode.com/problems/profitable-schemes

PROBLEM

There is a group of `n` members, and a list of various crimes they could commit. The i^{th} crime generates a `profit[i]` and requires `group[i]` members to participate in it. If a member participates in one crime, that member can't participate in another crime.

Let's call a **profitable scheme** any subset of these crimes that generates at least `minProfit` profit, and the total number of members participating in that subset of crimes is at most `n`.

Return the number of schemes that can be chosen. Since the answer may be very large, **return it modulo** $10^9 + 7$.

Example 1:

```
Input: n = 5, minProfit = 3, group = [2,2], profit = [2,3]
Output: 2
Explanation: To make a profit of at least 3, the group could either commit crimes 0 and 1, or just
crime 1.
In total, there are 2 schemes.
```

Example 2:

```
Input: n = 10, minProfit = 5, group = [2,3,5], profit = [6,7,8]
Output: 7
Explanation: To make a profit of at least 5, the group could commit any crimes, as long as they commit
one.
There are 7 possible schemes: (0), (1), (2), (0,1), (0,2), (1,2), and (0,1,2).
```

Constraints:

- `1 <= n <= 100`
- `0 <= minProfit <= 100`
- `1 <= group.length <= 100`
- `1 <= group[i] <= 100`
- `profit.length == group.length`
- `0 <= profit[i] <= 100`

SOLUTIONS (PYTHON 3)

Solution 1: recursion with memoization

How to think about it

Each crime may be taken or skipped under a people cap and a profit floor. The state is “item i, j people used, profit capped at minProfit”. dfs(i,j,k) skips the crime or takes it when people remain. Capping profit merges all states that already meet the threshold. At the end, k must equal minProfit.

We design a function dfs(i, j, k), which means that we start from the i-th job, and have chosen j employees, and the current profit is k, then the number of schemes in this case is dfs(0, 0, 0).

The execution process of function dfs(i, j, k) is as follows:

- If i = n, it means that all the jobs have been considered. If k ≥ minProfit, the number of schemes is 1, otherwise the number of schemes is 0;
- If i < n, we can choose not to choose the i-th job, then the number of schemes is dfs(i + 1, j, k); if j + group[i] ≤ n, we can also choose the i-th job, then the number of schemes is dfs(i + 1, j + group[i], min(k + profit[i], minProfit)). Here we limit

the profit upper limit to minProfit, because the profit exceeding minProfit has no effect on our answer.

Finally, return dfs(0, 0, 0).

In order to avoid repeated calculation, we can use the method of memoization. We use a three-dimensional array f to record all the results of dfs(i, j, k). When we calculate the value of dfs(i, j, k), we store it in f[i][j][k]. When we call dfs(i, j, k), if f[i][j][k] has been calculated, we return f[i][j][k] directly.

The time complexity is O(m × n × minProfit), and th e space complexity is O(m × n × minProfit). Here m and n are the number of jobs and employees, and minProfit is the minimum profit.

Python 3

```
class Solution:
    def profitableSchemes(
        self, n: int, minProfit: int, group: List[int], profit: List[int]
    ) -> int:
        @cache
        def dfs(i: int, j: int, k: int) -> int:
            if i >= len(group):
                return 1 if k == minProfit else 0
            ans = dfs(i + 1, j, k)
            if j + group[i] <= n:
                ans += dfs(i + 1, j + group[i], min(k + profit[i], minProfit))
            return ans % (10**9 + 7)

        return dfs(0, 0, 0)
```

Solution 2: Dynamic Programming

> **How to think about it**
>
> The same three-dimensional state fills by item index. f[i][j][k] is the number of ways using the first i crimes, j people, and profit at least k. Skipping copies the previous item; taking adds f[i-1][j-x][max(0,k-p)]. The empty plan contributes 1 at profit 0. The answer is f[m][n][minProfit].

We define f[i][j][k] to be the number of schemes to make a profit of at least k with i jobs and j workers. Initially, we have f[0][j][0] = 1, which means that there is only one scheme to make a profit of 0 without any jobs.

For the i-th job, we can choose to work or not to work. If we do not work, then f[i][j][k] = f[i - 1][j][k]; if we work, then f[i][j][k] = f[i - 1][j - group[i - 1]][max(0, k - profit[i - 1])]. We need to enumerate j and k, and add up all the schemes.

The final answer is f[m][n][minProfit].

The time complexity is O(m × n × minProfit), and the space complexity is O(m × n × minProfit). Here m and n are the numbers of jobs and workers, and minProfit is the minimum profit to make.

Python 3

```
class Solution:
    def profitableSchemes(
        self, n: int, minProfit: int, group: List[int], profit: List[int]
    ) -> int:
        mod = 10**9 + 7
        m = len(group)
        f = [[[0] * (minProfit + 1) for _ in range(n + 1)] for _ in range(m + 1)]
        for j in range(n + 1):
            f[0][j][0] = 1
        for i, (x, p) in enumerate(zip(group, profit), 1):
            for j in range(n + 1):
                for k in range(minProfit + 1):
                    f[i][j][k] = f[i - 1][j][k]
                    if j >= x:
                        f[i][j][k] = (f[i][j][k] + f[i - 1][j - x][max(0, k - p)]) % mod
        return f[m][n][minProfit]
```

871. Minimum Number of Refueling Stops

Hard · Greedy, Array, Dynamic Programming, Heap (Priority Queue)

leetcode.com/problems/minimum-number-of-refueling-stops

PROBLEM

A car travels from a starting position to a destination which is `target` miles east of the starting position.

There are gas stations along the way. The gas stations are represented as an array `stations` where `stations[i] = [position`$_i$`, fuel`$_i$`]` indicates that the `i`th gas station is `position`$_i$ miles east of the starting position and has `fuel`$_i$ liters of gas.

The car starts with an infinite tank of gas, which initially has `startFuel` liters of fuel in it. It uses one liter of gas per one mile that it drives. When the car reaches a gas station, it may stop and refuel, transferring all the gas from the station into the car.

Return *the minimum number of refueling stops the car must make in order to reach its destination*. If it cannot reach the destination, return `-1`.

Note that if the car reaches a gas station with `0` fuel left, the car can still refuel there. If the car reaches the destination with `0` fuel left, it is still considered to have arrived.

Example 1:

```
Input: target = 1, startFuel = 1, stations = []
Output: 0
Explanation: We can reach the target without refueling.
```

Example 2:

```
Input: target = 100, startFuel = 1, stations = [[10,100]]
Output: -1
Explanation: We can not reach the target (or even the first gas station).
```

Example 3:

```
Input: target = 100, startFuel = 10, stations = [[10,60],[20,30],[30,30],[60,40]]
Output: 2
Explanation: We start with 10 liters of fuel.
We drive to position 10, expending 10 liters of fuel. We refuel from 0 liters to 60 liters of gas.
Then, we drive from position 10 to position 60 (expending 50 liters of fuel),
and refuel from 10 liters to 50 liters of gas. We then drive to and reach the target.
We made 2 refueling stops along the way, so we return 2.
```

Constraints:

- `1 <= target, startFuel <= 10`^{9}
- `0 <= stations.length <= 500`
- `1 <= position`$_i$ `< position`$_{i+1}$ `< target`
- `1 <= fuel`$_i$ `< 10`^{9}

SOLUTION (PYTHON 3)

Solution 1: Greedy + Priority Queue (Max-Heap)

How to think about it

Choose refuels to reach the target with as few stops as possible. The target is huge and there are ≤ 500 stations. When the tank cannot reach the next station, we should have refueled at the richest station already passed. Scan by position, pushing passed fuel into a max-heap; while the tank is negative, pop the largest fuel. An empty heap means unreachable. The target is treated as a final station.

We can use a priority queue (max-heap) pq to record the fuel amounts of all the gas stations we have passed. Each time the fuel is insufficient, we greedily take out the maximum fuel amount, which is the top element of pq, and accumulate the number of refuels ans. If pq is empty and the current fuel is still insufficient, it means we cannot reach the destination, and we return -1.

The time complexity is O(n × log n), and the space complexity is O(n). Here, n represents the number of gas stations.

Python 3

```python
class Solution:
    def minRefuelStops(
        self, target: int, startFuel: int, stations: List[List[int]]
    ) -> int:
        pq = []
        ans = pre = 0
        stations.append([target, 0])
        for pos, fuel in stations:
            dist = pos - pre
            startFuel -= dist
            while startFuel < 0 and pq:
                startFuel -= heappop(pq)
                ans += 1
            if startFuel < 0:
                return -1
            heappush(pq, -fuel)
            pre = pos
        return ans
```

```

2218. Maximum Value of K Coins From Piles

Hard · Array, Dynamic Programming, Prefix Sum

leetcode.com/problems/maximum-value-of-k-coins-from-piles

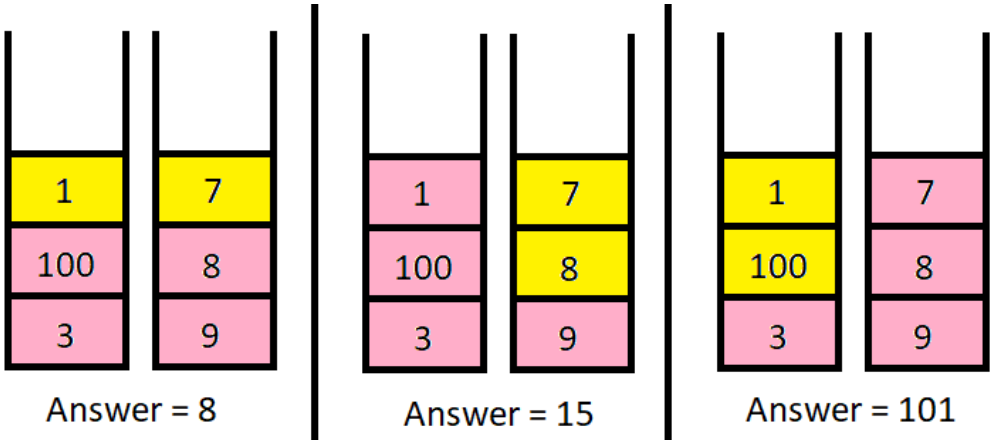
PROBLEM

There are `n` **piles** of coins on a table. Each pile consists of a **positive number** of coins of assorted denominations.

In one move, you can choose any coin on **top** of any pile, remove it, and add it to your wallet.

Given a list `piles`, where `piles[i]` is a list of integers denoting the composition of the i^{th} pile from **top to bottom**, and a positive integer `k`, return *the **maximum total value** of coins you can have in your wallet if you choose **exactly** `k` coins optimally*.

Example 1:



```
Input: piles = [[1,100,3],[7,8,9]], k = 2
Output: 101
Explanation:
The above diagram shows the different ways we can choose k coins.
The maximum total we can obtain is 101.
```

Example 2:

```
Input: piles = [[100],[100],[100],[100],[100],[100],[1,1,1,1,1,1,700]], k = 7
Output: 706
Explanation:
The maximum total can be obtained if we choose all coins from the last pile.
```

Constraints:

- `n == piles.length`
- `1 <= n <= 1000`
- `1 <= piles[i][j] <=` 10^5
- `1 <= k <= sum(piles[i].length) <= 2000`

SOLUTIONS (PYTHON 3)

Solution 1: Dynamic Programming (Grouped Knapsack)

How to think about it

Coins must be taken as a prefix of each pile, at most k in total. Searching allocations would recompute the same prefixes; n and k are up to a thousand and there are 2000 coins. Piles are independent groups: taking the first h coins of a pile is one item of size h. Let f[i][j] be the best value from the first i piles using j coins. Prefix-sum pile i into s[h] and relax f[i][j] by f[i-1][j-h]+s[h]. The work is proportional to k times the total number of coins.

We define f[i][j] as the maximum value sum of taking j coins from the first i piles. The answer is f[n][k], where n is the number of piles.

For the i-th pile, we can choose to take the first 0, 1, 2, …, k coins. We can use a prefix sum array s to quickly calculate the value sum of taking the first h coins.

The state transition equation is:

$$f[i][j] = \max(f[i][j], f[i - 1][j - h] + s[h])$$

where $0 \le h \le j$, and s[h] represents the value sum of taking the first h coins from the i-th pile.

The time complexity is $O(k \times L)$, and the space complexity is $O(n \times k)$. Here, L is the total number of coins, and n is the number of piles.

Python 3

```python
class Solution:
    def maxValueOfCoins(self, piles: List[List[int]], k: int) -> int:
        n = len(piles)
        f = [[0] * (k + 1) for _ in range(n + 1)]
        for i, nums in enumerate(piles, 1):
            s = list(accumulate(nums, initial=0))
            for j in range(k + 1):
                for h, w in enumerate(s):
                    if j < h:
                        break
                    f[i][j] = max(f[i][j], f[i - 1][j - h] + w)
        return f[n][k]
```

Solution 2: Dynamic Programming (Space Optimization)

How to think about it

Solution 1 only reads the previous row f[i-1][·], so the full table is unnecessary. After flattening f, capacity j must be enumerated downwards so the same pile is not used twice. Each pile is still prefix-summed, then j and h update f[j] in place. Time is unchanged; extra space drops to O(k).

We can observe that for the i-th pile, we only need to use f[i - 1][j] and f[i][j - h], so we can optimize the two-dimensional array to a one-dimensional array.

The time complexity is $O(k \times L)$, and the space complexity is $O(k)$.

Python 3

```python
class Solution:
    def maxValueOfCoins(self, piles: List[List[int]], k: int) -> int:
        f = [0] * (k + 1)
        for nums in piles:
            s = list(accumulate(nums, initial=0))
            for j in range(k, -1, -1):
                for h, w in enumerate(s):
                    if j < h:
                        break
                    f[j] = max(f[j], f[j - h] + w)
        return f[k]
```

PATTERN 28 · DYNAMIC PROGRAMMING - KNAPSACK STYLE · PROBLEM 19 OF 20

1755. Closest Subsequence Sum

Hard · Bit Manipulation, Array, Two Pointers, Dynamic Programming, Bitmask, Sorting, Meet in the Middle

leetcode.com/problems/closest-subsequence-sum

PROBLEM

You are given an integer array `nums` and an integer `goal`.

You want to choose a subsequence of `nums` such that the sum of its elements is the closest possible to `goal`. That is, if the sum of the subsequence's elements is `sum`, then you want to **minimize the absolute difference** `abs(sum - goal)`.

Return *the **minimum** possible value of* `abs(sum - goal)`.

Note that a subsequence of an array is an array formed by removing some elements **(possibly all or none)** of the original array.

Example 1:

```
Input: nums = [5,-7,3,5], goal = 6
Output: 0
Explanation: Choose the whole array as a subsequence, with a sum of 6.
This is equal to the goal, so the absolute difference is 0.
```

Example 2:

```
Input: nums = [7,-9,15,-2], goal = -5
Output: 1
Explanation: Choose the subsequence [7,-9,-2], with a sum of -4.
The absolute difference is abs(-4 - (-5)) = abs(1) = 1, which is the minimum.
```

Example 3:

```
Input: nums = [1,2,3], goal = -7
Output: 7
```

Constraints:

- `1 <= nums.length <= 40`
- -10^7 `<= nums[i] <=` 10^7
- -10^9 `<= goal <=` 10^9

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

Find a subsequence sum closest to goal. n≤ 40 makes 2^n too large, but $2^{n/2}$ is acceptable. Split the array, DFS all subset sums on each half, and for every left sum binary-search goal-l in the sorted right sums, keeping the two nearest candidates.

Python 3

```
class Solution:
    def minAbsDifference(self, nums: List[int], goal: int) -> int:
        n = len(nums)
        left = set()
        right = set()

        self.getSubSeqSum(0, 0, nums[: n // 2], left)
        self.getSubSeqSum(0, 0, nums[n // 2 :], right)

        result = inf
        right = sorted(right)
        rl = len(right)

        for l in left:
            remaining = goal - l
            idx = bisect_left(right, remaining)

            if idx < rl:
                result = min(result, abs(remaining - right[idx]))

            if idx > 0:
                result = min(result, abs(remaining - right[idx - 1]))

        return result

    def getSubSeqSum(self, i: int, curr: int, arr: List[int], result: Set[int]):
        if i == len(arr):
            result.add(curr)
            return

        self.getSubSeqSum(i + 1, curr, arr, result)
        self.getSubSeqSum(i + 1, curr + arr[i], arr, result)
```

Complexity. Time: O(2^(n/2) * n). Space: O(2^(n/2)).

Solution 2

> **How to think about it**
>
> Solution 2 is the same meet-in-the-middle search; the DFS simply tries skip-then-take. The algorithm is unchanged, the code is tighter.

Python 3

```
class Solution:
    def minAbsDifference(self, nums: List[int], goal: int) -> int:
        def dfs(arr, res, i, s):
            if i == len(arr):
                res.add(s)
                return
            dfs(arr, res, i + 1, s)
            dfs(arr, res, i + 1, s + arr[i])

        n = len(nums)
        left, right = set(), set()
        dfs(nums[: n >> 1], left, 0, 0)
        dfs(nums[n >> 1 :], right, 0, 0)
        right = sorted(right)
        ans = inf
        for l in left:
            x = goal - l
            i = bisect_left(right, x)
            if i < len(right):
                ans = min(ans, abs(x - right[i]))
            if i:
                ans = min(ans, abs(x - right[i - 1]))
        return ans
```

Complexity. Time: O(2^(n/2) * n). Space: O(2^(n/2)).

```

1269. Number of Ways to Stay in the Same Place After Some Steps

Hard · Dynamic Programming

leetcode.com/problems/number-of-ways-to-stay-in-the-same-place-after-some-steps

PROBLEM

You have a pointer at index `0` in an array of size `arrLen`. At each step, you can move 1 position to the left, 1 position to the right in the array, or stay in the same place (The pointer should not be placed outside the array at any time).

Given two integers `steps` and `arrLen`, return the number of ways such that your pointer is still at index `0` after **exactly** `steps` steps. Since the answer may be too large, return it **modulo** $10^9 + 7$.

Example 1:

```
Input: steps = 3, arrLen = 2
Output: 4
Explanation: There are 4 differents ways to stay at index 0 after 3 steps.
Right, Left, Stay
Stay, Right, Left
Right, Stay, Left
Stay, Stay, Stay
```

Example 2:

```
Input: steps = 2, arrLen = 4
Output: 2
Explanation: There are 2 differents ways to stay at index 0 after 2 steps
Right, Left
Stay, Stay
```

Example 3:

```
Input: steps = 4, arrLen = 2
Output: 8
```

Constraints:

- `1 <= steps <= 500`
- `1 <= arrLen <= 10^6`

SOLUTION (PYTHON 3)

Solution 1: Memoization Search

How to think about it

We walk steps steps on an array of length arrLen and return to the origin. arrLen may be 10^6, but steps ≤ 500, so reachable cells are at most steps. The count depends on position and remaining steps. dfs(i,j) is the number of ways from index i with j steps left to finish at 0; we may go left, right, or stay. If i>j we cannot return. Memoized states are O(steps^2).

We observe the data range of the problem and find that steps does not exceed 500, which means that we can only go to the right for up to 500 steps.

We can design a function dfs(i, j), which represents the number of schemes when we are currently at position i and the remaining steps are j. So the answer is dfs(0, steps).

The execution process of the function dfs(i, j) is as follows:

1. If i > j or i ≥ arrLen or i < 0 or j < 0, then return 0.
1. If i = 0 and j = 0, then the pointer has stopped in place and there are no remaining steps, so return 1.
1. Otherwise, we can choose to move one step to the left, one step to the right, or stay still, so return dfs(i - 1, j - 1) + dfs(i + 1, j - 1) + dfs(i, j - 1). Note the modulo operation of the answer.

During the process, we can use memoization search to avoid repeated calculations.

The time complexity is O(steps × steps), and the space complexity is O(steps × steps). Where steps is the number of steps given in the problem.

Python 3

```
class Solution:
    def numWays(self, steps: int, arrLen: int) -> int:
        @cache
        def dfs(i, j):
            if i > j or i >= arrLen or i < 0 or j < 0:
                return 0
            if i == 0 and j == 0:
                return 1
            ans = 0
            for k in range(-1, 2):
                ans += dfs(i + k, j - 1)
                ans %= mod
            return ans

        mod = 10**9 + 7
        return dfs(0, steps)
```

PATTERN 29 · DESIGN PROBLEMS · PROBLEM 1 OF 20

706. Design HashMap

Easy · Design, Array, Hash Table, Linked List, Hash Function

leetcode.com/problems/design-hashmap

★ **TOP 10 PROBLEM** in Design Problems: master this one first

PROBLEM

Design a HashMap without using any built-in hash table libraries.

Implement the `MyHashMap` class:

- `MyHashMap()` initializes the object with an empty map.
- `void put(int key, int value)` inserts a `(key, value)` pair into the HashMap. If the `key` already exists in the map, update the corresponding `value`.
- `int get(int key)` returns the `value` to which the specified `key` is mapped, or `-1` if this map contains no mapping for the `key`.
- `void remove(key)` removes the `key` and its corresponding `value` if the map contains the mapping for the `key`.

Example 1:

```
Input
["MyHashMap", "put", "put", "get", "get", "put", "get", "remove", "get"]
[[], [1, 1], [2, 2], [1], [3], [2, 1], [2], [2], [2]]
Output
[null, null, null, 1, -1, null, 1, null, -1]

Explanation
MyHashMap myHashMap = new MyHashMap();
myHashMap.put(1, 1); // The map is now [[1,1]]
myHashMap.put(2, 2); // The map is now [[1,1], [2,2]]
myHashMap.get(1); // return 1, The map is now [[1,1], [2,2]]
myHashMap.get(3); // return -1 (i.e., not found), The map is now [[1,1], [2,2]]
myHashMap.put(2, 1); // The map is now [[1,1], [2,1]] (i.e., update the existing value)
myHashMap.get(2); // return 1, The map is now [[1,1], [2,1]]
myHashMap.remove(2); // remove the mapping for 2, The map is now [[1,1]]
myHashMap.get(2); // return -1 (i.e., not found), The map is now [[1,1]]
```

Constraints:

- `0 <= key, value <= 10^6`
- At most `10^4` calls will be made to `put`, `get`, and `remove`.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

We need a map whose keys and values lie in [0, 10^6], with at most 10^4 operations. As with the hash set, the key itself is a valid index. Allocate an array of length 10^6+1 filled with -1. put, get, and remove become an assignment, a read, and a write of -1. The sentinel -1 is outside the value range, so it cannot collide with a stored value. Space follows the universe, which is acceptable here.

Python 3

```
class MyHashMap:
    def __init__(self):
        self.data = [-1] * 1000001

    def put(self, key: int, value: int) -> None:
        self.data[key] = value

    def get(self, key: int) -> int:
        return self.data[key]

    def remove(self, key: int) -> None:
        self.data[key] = -1

# Your MyHashMap object will be instantiated and called as such:
# obj = MyHashMap()
# obj.put(key,value)
# param_2 = obj.get(key)
# obj.remove(key)
```

Complexity. Time: O(1) per operation. Space: O(M), M = 10^6 slots.

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

Built on the solutions above: helper functions, then the function for each follow-up. No tests and no restating of the question.

```
# FOLLOW-UPS (answered below, in this order):
# 1. Grow the table when it gets too full (keep chains
# short)
# 2. List all keys, in the order they were first inserted

# ============================================================
# FOLLOW-UP 1: Grow the table when it gets too full (keep
# chains short)
# ============================================================

# ---- follow-up 1: function ----
# Answer: Count the entries; when entries / buckets passes
# 0.75, double the number of buckets and move every pair
# into its new bucket.
# Time: put, get and remove are O(1) amortised; growing
# costs O(n) occasionally.  Space: O(n).
class ResizingHashMap:
    def __init__(self):
        self.buckets = [[] for _ in range(8)]
        self.size = 0

    def put(self, key, value):
        bucket = self.buckets[key % len(self.buckets)]
        for pair in bucket:
            if pair[0] == key:
                pair[1] = value
                return
        bucket.append([key, value])
        self.size += 1
        if self.size > 0.75 * len(self.buckets):
            self.grow()

    def get(self, key):
        for pair in self.buckets[key % len(self.buckets)]:
            if pair[0] == key:
                return pair[1]

        self.data = {}

    def put(self, key, value):
        self.data[key] = value

    def get(self, key):
        return self.data.get(key, -1)

    def remove(self, key):
        if key in self.data:
            del self.data[key]

    def keys(self):
        return list(self.data.keys())
```

PATTERN 29 · DESIGN PROBLEMS · PROBLEM 4 OF 20

208. Implement Trie (Prefix Tree)

Medium · Design, Trie, Hash Table, String

leetcode.com/problems/implement-trie-prefix-tree

★ **TOP 10 PROBLEM** in Design Problems, Trie (Prefix Tree): master this one first

Also appears in pattern 32 Trie (Prefix Tree)

PROBLEM

A **trie** (pronounced as "try") or **prefix tree** is a tree data structure used to efficiently store and retrieve keys in a dataset of strings. There are various applications of this data structure, such as autocomplete and spellchecker.

Implement the Trie class:

- `Trie()` Initializes the trie object.
- `void insert(String word)` Inserts the string `word` into the trie.
- `boolean search(String word)` Returns `true` if the string `word` is in the trie (i.e., was inserted before), and `false` otherwise.
- `boolean startsWith(String prefix)` Returns `true` if there is a previously inserted string `word` that has the prefix `prefix`, and `false` otherwise.

Example 1:

```
Input
["Trie", "insert", "search", "search", "startsWith", "insert", "search"]
[[], ["apple"], ["apple"], ["app"], ["app"], ["app"], ["app"]]
Output
[null, null, true, false, true, null, true]

Explanation
Trie trie = new Trie();
trie.insert("apple");
trie.search("apple"); // return True
trie.search("app"); // return False
trie.startsWith("app"); // return True
trie.insert("app");
trie.search("app"); // return True
```

Constraints:

- `1 <= word.length, prefix.length <= 2000`
- `word` and `prefix` consist only of lowercase English letters.
- At most `3 * 10^4` calls **in total** will be made to `insert`, `search`, and `startsWith`.

SOLUTION (PYTHON 3)

Solution 1: Trie (Prefix Tree)

How to think about it

Scanning every inserted word for each prefix query repeats work on shared prefixes. Letters are lowercase, so a 26-way tree can layer characters. Insertion walks (and creates) nodes and marks isEnd at the last one. Prefix search follows the same path; full-word search also checks the end flag.

Each node in the trie contains two parts:

1. An array of pointers to child nodes `children`. For this problem, the array length is 26, representing the number of lowercase English letters. `children[0]` corresponds to lowercase letter 'a', ..., and `children[25]` corresponds to

lowercase letter 'z'.

2. A boolean field `isEnd` indicating whether the node is the end of a string.

1. Insert a String

We start from the root of the trie and insert the string. For the child node corresponding to the current character, there are two cases:

- The child node exists. Move along the pointer to the child node and continue processing the next character.
- The child node does not exist. Create a new child node, record it in the corresponding position of the `children` array, then move along the pointer to the child node and continue searching for the next character.

Repeat the above steps until the last character of the string is processed, then mark the current node as the end of the string.

2. Search for a Prefix

We start from the root of the trie and search for the prefix. For the child node corresponding to the current character, there are two cases:

- The child node exists. Move along the pointer to the child node and continue searching for the next character.
- The child node does not exist. This means the trie does not contain the prefix, so return a null pointer.

Repeat the above steps until a null pointer is returned or the last character of the prefix is searched.

If we search to the end of the prefix, it means the trie contains the prefix. Additionally, if the `isEnd` of the node corresponding to the end of the prefix is true, it means the trie contains the string.

The time complexity for inserting a string is $O(m \times |\Sigma|)$, and the time complexity for searching a prefix is $O(m)$, where m is the length of the string and $|\Sigma|$ is the size of the character set (26 in this problem). The space complexity is $O(q \times m \times |\Sigma|)$, where q is the number of inserted strings.

Python 3

```python
class Trie:
    def __init__(self):
        self.children = [None] * 26
        self.is_end = False

    def insert(self, word: str) -> None:
        node = self
        for c in word:
            idx = ord(c) - ord('a')
            if node.children[idx] is None:
                node.children[idx] = Trie()
            node = node.children[idx]
        node.is_end = True

    def search(self, word: str) -> bool:
        node = self._search_prefix(word)
        return node is not None and node.is_end

    def startsWith(self, prefix: str) -> bool:
        node = self._search_prefix(prefix)
        return node is not None

    def _search_prefix(self, prefix: str):
        node = self
        for c in prefix:
            idx = ord(c) - ord('a')
            if node.children[idx] is None:
                return None
            node = node.children[idx]
        return node

# Your Trie object will be instantiated and called as such:
# obj = Trie()
# obj.insert(word)
# param_2 = obj.search(word)
# param_3 = obj.startsWith(prefix)
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

Built on the solutions above: helper functions, then the function for each follow-up. No tests and no restating of the question.

```python
# FOLLOW-UPS (answered below, in this order):
# 1. Delete a word
# 2. Count how many inserted words start with a prefix

# ============================================================
# FOLLOW-UP 1: Delete a word
# ============================================================

# ---- follow-up 1: function ----
# Answer: Walk down the word, then walk back up removing

```

355. Design Twitter

Medium · Design, Hash Table, Linked List, Heap (Priority Queue)

leetcode.com/problems/design-twitter

★ **TOP 10 PROBLEM** in Design Problems: master this one first

PROBLEM

Design a simplified version of Twitter where users can post tweets, follow/unfollow another user, and is able to see the `10` most recent tweets in the user's news feed.

Implement the `Twitter` class:

- `Twitter()` Initializes your twitter object.
- `void postTweet(int userId, int tweetId)` Composes a new tweet with ID `tweetId` by the user `userId`. Each call to this function will be made with a unique `tweetId`.
- `List<Integer> getNewsFeed(int userId)` Retrieves the `10` most recent tweet IDs in the user's news feed. Each item in the news feed must be posted by users who the user followed or by the user themself. Tweets must be **ordered from most recent to least recent**.
- `void follow(int followerId, int followeeId)` The user with ID `followerId` started following the user with ID `followeeId`.
- `void unfollow(int followerId, int followeeId)` The user with ID `followerId` started unfollowing the user with ID `followeeId`.

Example 1:

```
Input
["Twitter", "postTweet", "getNewsFeed", "follow", "postTweet", "getNewsFeed", "unfollow",
"getNewsFeed"]
[[], [1, 5], [1], [1, 2], [2, 6], [1], [1, 2], [1]]
Output
[null, null, [5], null, null, [6, 5], null, [5]]

Explanation
Twitter twitter = new Twitter();
twitter.postTweet(1, 5); // User 1 posts a new tweet (id = 5).
twitter.getNewsFeed(1); // User 1's news feed should return a list with 1 tweet id -> [5]. return [5]
twitter.follow(1, 2); // User 1 follows user 2.
twitter.postTweet(2, 6); // User 2 posts a new tweet (id = 6).
twitter.getNewsFeed(1); // User 1's news feed should return a list with 2 tweet ids -> [6, 5]. Tweet id
6 should precede tweet id 5 because it is posted after tweet id 5.
twitter.unfollow(1, 2); // User 1 unfollows user 2.
twitter.getNewsFeed(1); // User 1's news feed should return a list with 1 tweet id -> [5], since user 1
is no longer following user 2.
```

Constraints:

- `1 <= userId, followerId, followeeId <= 500`
- `0 <= tweetId <= 10^4`
- All the tweets have **unique** IDs.
- At most `3 * 10^4` calls will be made to `postTweet`, `getNewsFeed`, `follow`, and `unfollow`.
- A user cannot follow himself.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Post, follow, and fetch the ten most recent tweets from a user and followees. A full scan of all tweets is wasteful. Store each user's tweets and follow set, and stamp tweets with a global clock. A feed gathers the latest ten from each relevant user and keeps the ten newest. Follow/unfollow only edit the set.

Python 3

```
class Twitter:
    def __init__(self):
        """
        Initialize your data structure here.
        """
        self.user_tweets = defaultdict(list)
        self.user_following = defaultdict(set)
        self.tweets = defaultdict()
        self.time = 0

    def postTweet(self, userId: int, tweetId: int) -> None:
        """
        Compose a new tweet.
        """
        self.time += 1
        self.user_tweets[userId].append(tweetId)
        self.tweets[tweetId] = self.time

    def getNewsFeed(self, userId: int) -> List[int]:
        """
        Retrieve the 10 most recent tweet ids in the user's news feed. Each item in the news feed must be
posted by users who the user followed or by the user herself. Tweets must be ordered from most recent to
least recent.
        """
        following = self.user_following[userId]
        users = set(following)
        users.add(userId)
        tweets = [self.user_tweets[u][::-1][:10] for u in users]
        tweets = sum(tweets, [])
        return nlargest(10, tweets, key=lambda tweet: self.tweets[tweet])

    def follow(self, followerId: int, followeeId: int) -> None:
        """
        Follower follows a followee. If the operation is invalid, it should be a no-op.
        """
        self.user_following[followerId].add(followeeId)

    def unfollow(self, followerId: int, followeeId: int) -> None:
        """
        Follower unfollows a followee. If the operation is invalid, it should be a no-op.
        """
        following = self.user_following[followerId]
        if followeeId in following:
            following.remove(followeeId)

# Your Twitter object will be instantiated and called as such:
# obj = Twitter()
# obj.postTweet(userId,tweetId)
# param_2 = obj.getNewsFeed(userId)
# obj.follow(followerId,followeeId)
# obj.unfollow(followerId,followeeId)
```

Complexity. Time: postTweet, follow, unfollow O(1); getNewsFeed O(F), F = people followed (it looks at 10 tweets of each). Space: O(T + U), T = tweets, U = follow pairs.

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

Built on the solutions above: helper functions, then the function for each follow-up. No tests and no restating of the question.

```

    start = page * page_size
    return [tweet_id for stamp, tweet_id in feed[start:start + page_size]]
```

1396. Design Underground System

Medium · Design, Hash Table, String

leetcode.com/problems/design-underground-system

PROBLEM

An underground railway system is keeping track of customer travel times between different stations. They are using this data to calculate the average time it takes to travel from one station to another.

Implement the `UndergroundSystem` class:

- `void checkIn(int id, string stationName, int t)`
  - A customer with a card ID equal to `id`, checks in at the station `stationName` at time `t`.
  - A customer can only be checked into one place at a time.
- `void checkOut(int id, string stationName, int t)`
  - A customer with a card ID equal to `id`, checks out from the station `stationName` at time `t`.
- `double getAverageTime(string startStation, string endStation)`
  - Returns the average time it takes to travel from `startStation` to `endStation`.
  - The average time is computed from all the previous traveling times from `startStation` to `endStation` that happened **directly**, meaning a check in at `startStation` followed by a check out from `endStation`.
  - The time it takes to travel from `startStation` to `endStation` **may be different** from the time it takes to travel from `endStation` to `startStation`.
  - There will be at least one customer that has traveled from `startStation` to `endStation` before `getAverageTime` is called.

You may assume all calls to the `checkIn` and `checkOut` methods are consistent. If a customer checks in at time t_1 then checks out at time t_2, then $t_1 < t_2$. All events happen in chronological order.

Example 1:

Input
```
["UndergroundSystem","checkIn","checkIn","checkIn","checkOut","checkOut","checkOut","getAverageTime","
getAverageTime","checkIn","getAverageTime","checkOut","getAverageTime"]
[[],[45,"Leyton",3],[32,"Paradise",8],[27,"Leyton",10],[45,"Waterloo",15],[27,"Waterloo",20],[32,"Camb
ridge",22],["Paradise","Cambridge"],["Leyton","Waterloo"],[10,"Leyton",24],["Leyton","Waterloo"],[10,"
Waterloo",38],["Leyton","Waterloo"]]
```

Output
```
[null,null,null,null,null,null,null,14.00000,11.00000,null,11.00000,null,12.00000]
```

Explanation
```
UndergroundSystem undergroundSystem = new UndergroundSystem();
undergroundSystem.checkIn(45, "Leyton", 3);
undergroundSystem.checkIn(32, "Paradise", 8);
undergroundSystem.checkIn(27, "Leyton", 10);
undergroundSystem.checkOut(45, "Waterloo", 15); // Customer 45 "Leyton" -> "Waterloo" in 15-3 = 12
undergroundSystem.checkOut(27, "Waterloo", 20); // Customer 27 "Leyton" -> "Waterloo" in 20-10 = 10
undergroundSystem.checkOut(32, "Cambridge", 22); // Customer 32 "Paradise" -> "Cambridge" in 22-8 = 14
undergroundSystem.getAverageTime("Paradise", "Cambridge"); // return 14.00000. One trip "Paradise" ->
"Cambridge", (14) / 1 = 14
undergroundSystem.getAverageTime("Leyton", "Waterloo"); // return 11.00000. Two trips "Leyton" ->
"Waterloo", (10 + 12) / 2 = 11
undergroundSystem.checkIn(10, "Leyton", 24);
undergroundSystem.getAverageTime("Leyton", "Waterloo"); // return 11.00000
undergroundSystem.checkOut(10, "Waterloo", 38); // Customer 10 "Leyton" -> "Waterloo" in 38-24 = 14
undergroundSystem.getAverageTime("Leyton", "Waterloo"); // return 12.00000. Three trips "Leyton" ->
"Waterloo", (10 + 12 + 14) / 3 = 12
```

Example 2:

Input
```
["UndergroundSystem","checkIn","checkOut","getAverageTime","checkIn","checkOut","getAverageTime","chec
kIn","checkOut","getAverageTime"]
[[],[10,"Leyton",3],[10,"Paradise",8],["Leyton","Paradise"],[5,"Leyton",10],[5,"Paradise",16],["Leyton
","Paradise"],[2,"Leyton",21],[2,"Paradise",30],["Leyton","Paradise"]]
```

Output
```
[null,null,null,5.00000,null,null,5.50000,null,null,6.66667]
```

Explanation
```
UndergroundSystem undergroundSystem = new UndergroundSystem();
undergroundSystem.checkIn(10, "Leyton", 3);
undergroundSystem.checkOut(10, "Paradise", 8); // Customer 10 "Leyton" -> "Paradise" in 8-3 = 5
undergroundSystem.getAverageTime("Leyton", "Paradise"); // return 5.00000, (5) / 1 = 5
undergroundSystem.checkIn(5, "Leyton", 10);
undergroundSystem.checkOut(5, "Paradise", 16); // Customer 5 "Leyton" -> "Paradise" in 16-10 = 6
undergroundSystem.getAverageTime("Leyton", "Paradise"); // return 5.50000, (5 + 6) / 2 = 5.5
undergroundSystem.checkIn(2, "Leyton", 21);
undergroundSystem.checkOut(2, "Paradise", 30); // Customer 2 "Leyton" -> "Paradise" in 30-21 = 9
undergroundSystem.getAverageTime("Leyton", "Paradise"); // return 6.66667, (5 + 6 + 9) / 3 = 6.66667
```

Constraints:

- `1 <= id, t <= 10^6`
- `1 <= stationName.length, startStation.length, endStation.length <= 10`
- All strings consist of uppercase and lowercase English letters and digits.
- There will be at most `2 * 10^4` calls **in total** to `checkIn`, `checkOut`, and `getAverageTime`.
- Answers within `10^-5` of the actual value will be accepted.

SOLUTION (PYTHON 3)

Solution 1: Hash Table

> **How to think about it**
>
> Check-in, check-out, and the average time between two stations must be O(1). Map each id to its check-in time and station; on check-out, add the duration into a (start,end)↦(total,count) table. The average is that ratio.

We use two hash tables to store data:

- `ts`: Stores the passenger's id, check-in time, and check-in station. The key is the passenger's id, and the value is a tuple `(t, stationName)`.
- `d`: Stores the passenger's check-in station, check-out station, travel time, and number of trips. The key is a tuple `(startStation, endStation)`, and the value is a tuple `(totalTime, count)`.

When a passenger checks in, we store the passenger's id, check-in time, and check-in station in `ts`, i.e., `ts[id] = (t, stationName)`.

When a passenger checks out, we retrieve the passenger's check-in time and station `(t0, station)` from `ts`, then calculate the passenger's travel time t - t_0, and store the passenger's travel time and number of trips in `d`.

When we want to calculate a passenger's average travel time, we retrieve the passenger's total travel time and number of trips `(totalTime, count)` from `d`, then calculate the average travel time as totalTime / count.

The time complexity is O(1), and the space complexity is O(n). Where n is the number of passengers.

Python 3

```python
class UndergroundSystem:
    def __init__(self):
        self.ts = {}
        self.d = {}

    def checkIn(self, id: int, stationName: str, t: int) -> None:
        self.ts[id] = (t, stationName)

    def checkOut(self, id: int, stationName: str, t: int) -> None:
        t0, station = self.ts[id]
        x = self.d.get((station, stationName), (0, 0))
        self.d[(station, stationName)] = (x[0] + t - t0, x[1] + 1)

    def getAverageTime(self, startStation: str, endStation: str) -> float:
        x = self.d[(startStation, endStation)]
        return x[0] / x[1]

# Your UndergroundSystem object will be instantiated and called as such:
# obj = UndergroundSystem()
# obj.checkIn(id,stationName,t)
# obj.checkOut(id,stationName,t)
# param_3 = obj.getAverageTime(startStation,endStation)
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

Built on the solutions above: helper functions, then the function for each follow-up. No tests and no restating of the question.

```python
# FOLLOW-UPS (answered below, in this order):
# 1. Average time from ANY station to a given station
# 2. The pair of stations with the longest average trip

# ============================================================
# FOLLOW-UP 1: Average time from ANY station to a given
# station
# ============================================================

# ---- follow-up 1: function ----
```

```
# Answer: Keep one total and one count per end station as
# well.
# Time: check_in, check_out and average_to are each O(1).
# Space: O(riders + pairs).
class UndergroundByEnd:
    def __init__(self):
        self.riding = {}
        self.pair_totals = {}

        if average > best_average:
            best_average = average
            best_pair = pair
    return best_pair, best_average
```

1472. Design Browser History

Medium · Stack, Design, Array, Linked List, Data Stream, Doubly-Linked List

leetcode.com/problems/design-browser-history

PROBLEM

You have a **browser** of one tab where you start on the `homepage` and you can visit another `url`, get back in the history number of `steps` or move forward in the history number of `steps`.

Implement the `BrowserHistory` class:

- `BrowserHistory(string homepage)` Initializes the object with the `homepage` of the browser.
- `void visit(string url)` Visits `url` from the current page. It clears up all the forward history.
- `string back(int steps)` Move `steps` back in history. If you can only return `x` steps in the history and `steps > x`, you will return only `x` steps. Return the current `url` after moving back in history **at most** `steps`.
- `string forward(int steps)` Move `steps` forward in history. If you can only forward `x` steps in the history and `steps > x`, you will forward only `x` steps. Return the current `url` after forwarding in history **at most** `steps`.

Example:

```
Input:
["BrowserHistory","visit","visit","visit","back","back","forward","visit","forward","back","back"]
[["leetcode.com"],["google.com"],["facebook.com"],["youtube.com"],[1],[1],[1],["linkedin.com"],[2],[2]
,[7]]
Output:
[null,null,null,null,"facebook.com","google.com","facebook.com",null,"linkedin.com","google.com","leet
code.com"]

Explanation:
BrowserHistory browserHistory = new BrowserHistory("leetcode.com");
browserHistory.visit("google.com"); // You are in "leetcode.com". Visit "google.com"
browserHistory.visit("facebook.com"); // You are in "google.com". Visit "facebook.com"
browserHistory.visit("youtube.com"); // You are in "facebook.com". Visit "youtube.com"
browserHistory.back(1); // You are in "youtube.com", move back to "facebook.com" return "facebook.com"
browserHistory.back(1); // You are in "facebook.com", move back to "google.com" return "google.com"
browserHistory.forward(1); // You are in "google.com", move forward to "facebook.com" return
"facebook.com"
browserHistory.visit("linkedin.com"); // You are in "facebook.com". Visit "linkedin.com"
browserHistory.forward(2); // You are in "linkedin.com", you cannot move forward any steps.
browserHistory.back(2); // You are in "linkedin.com", move back two steps to "facebook.com" then to
"google.com". return "google.com"
browserHistory.back(7); // You are in "google.com", you can move back only one step to "leetcode.com".
return "leetcode.com"
```

Constraints:

- `1 <= homepage.length <= 20`
- `1 <= url.length <= 20`
- `1 <= steps <= 100`
- `homepage` and `url` consist of '.' or lower case English letters.
- At most `5000` calls will be made to `visit`, `back`, and `forward`.

SOLUTION (PYTHON 3)

Solution 1: Two Stacks

> **How to think about it**
>
> `visit` drops forward history; `back`/`forward` walk a timeline. stk1 holds the path to the current page, stk2 the forward pages. A visit pushes onto stk1 and clears stk2; back pops onto stk2, forward pops back.

We can use two stacks, stk1 and stk2, to store the back and forward pages, respectively. Initially, stk1 contains the homepage, and stk2 is empty.

When calling visit(url), we add url to stk1 and clear stk2. The time complexity is O(1).

When calling back(steps), we pop the top element from stk1 and push it to stk2. We repeat this operation steps times until the length of stk1 is 1 or steps is 0. Finally, we return the top element of stk1. The time complexity is O(steps).

When calling forward(steps), we pop the top element from stk2 and push it to stk1. We repeat this operation steps times until stk2 is empty or steps is 0. Finally, we return the top element of stk1. The time complexity is O(steps).

The space complexity is O(n), where n is the length of the browsing history.

Python 3

```python
class BrowserHistory:
    def __init__(self, homepage: str):
        self.stk1 = []
        self.stk2 = []
        self.visit(homepage)

    def visit(self, url: str) -> None:
        self.stk1.append(url)
        self.stk2.clear()

    def back(self, steps: int) -> str:
        while steps and len(self.stk1) > 1:
            self.stk2.append(self.stk1.pop())
            steps -= 1
        return self.stk1[-1]

    def forward(self, steps: int) -> str:
        while steps and self.stk2:
            self.stk1.append(self.stk2.pop())
            steps -= 1
        return self.stk1[-1]

# Your BrowserHistory object will be instantiated and called as such:
# obj = BrowserHistory(homepage)
# obj.visit(url)
# param_2 = obj.back(steps)
# param_3 = obj.forward(steps)
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

Built on the solutions above: helper functions, then the function for each follow-up. No tests and no restating of the question.

            steps -= 1
        return self.current.url
```

PATTERN 29 · DESIGN PROBLEMS · PROBLEM 11 OF 20

1146. Snapshot Array

Medium · Design, Array, Hash Table, Binary Search, Persistent Data Structure

leetcode.com/problems/snapshot-array

★ **TOP 10 PROBLEM** in Design Problems: master this one first

PROBLEM

Implement a SnapshotArray that supports the following interface:

- `SnapshotArray(int length)` initializes an array-like data structure with the given length. **Initially, each element equals 0**.
- `void set(index, val)` sets the element at the given `index` to be equal to `val`.
- `int snap()` takes a snapshot of the array and returns the `snap_id`: the total number of times we called `snap()` minus `1`.
- `int get(index, snap_id)` returns the value at the given `index`, at the time we took the snapshot with the given `snap_id`

Example 1:

```
Input: ["SnapshotArray","set","snap","set","get"]
[[3],[0,5],[],[0,6],[0,0]]
Output: [null,null,0,null,5]
Explanation:
SnapshotArray snapshotArr = new SnapshotArray(3); // set the length to be 3
snapshotArr.set(0,5); // Set array[0] = 5
snapshotArr.snap(); // Take a snapshot, return snap_id = 0
snapshotArr.set(0,6);
snapshotArr.get(0,0); // Get the value of array[0] with snap_id = 0, return 5
```

Constraints:

- `1 <= length <= 5 * 10^4`
- `0 <= index < length`
- `0 <= val <= 10^9`
- `0 <= snap_id <` (the total number of times we call `snap()`)
- At most `5 * 10^4` calls will be made to `set`, `snap`, and `get`.

SOLUTION (PYTHON 3)

Solution 1: Array + Binary Search

How to think about it

Copying the whole array on every `snap` costs space proportional to length times snapshot count. Each index stores a history of (snap id,value); `set` appends the current id. `get` binary-searches the last change with id ≤ snap_id, or 0 if none.

We maintain an array of length `length`. Each element in the array is a list, which is used to store the value set each time and the corresponding snapshot ID.

When the `set` method is called, we add the value and snapshot ID to the list at the corresponding index. The time complexity is O(1).

When the `snap` method is called, we first increment the snapshot ID, then return the snapshot ID minus one. The time complexity is O(1).

When the `get` method is called, we use binary search to find the first snapshot ID greater than `snap_id` at the corresponding position, and then return the previous value. If it cannot be found, return 0. The time complexity is O(log n).

The space complexity is O(n).

Python 3

```
class SnapshotArray:

    def __init__(self, length: int):
        self.arr = [[] for _ in range(length)]
        self.i = 0

    def set(self, index: int, val: int) -> None:
        self.arr[index].append((self.i, val))

    def snap(self) -> int:
        self.i += 1
        return self.i - 1

    def get(self, index: int, snap_id: int) -> int:
        i = bisect_left(self.arr[index], (snap_id, inf)) - 1
        return 0 if i < 0 else self.arr[index][i][1]

# Your SnapshotArray object will be instantiated and called as such:
# obj = SnapshotArray(length)
# obj.set(index,val)
# param_2 = obj.snap()
# param_3 = obj.get(index,snap_id)
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

    # history[i] is the sorted list of (snap_id, value) for index i
    def value_at(changes, snap_id):
        position = bisect.bisect_right(changes, (snap_id, float("inf"))) - 1
        return changes[position][1]

    result = []
```

```
    for index in range(len(history)):
        if value_at(history[index], first_snap) != value_at(history[index], second_snap):
            result.append(index)
    return result
```

211. Design Add and Search Words Data Structure

Medium · Depth-First Search, Design, Trie, String

leetcode.com/problems/design-add-and-search-words-data-structure

★ **TOP 10 PROBLEM** in Trie (Prefix Tree): master this one first

Also appears in pattern 32 Trie (Prefix Tree)

PROBLEM

Design a data structure that supports adding new words and finding if a string matches any previously added string.

Implement the `WordDictionary` class:

- `WordDictionary()` Initializes the object.
- `void addWord(word)` Adds `word` to the data structure, it can be matched later.
- `bool search(word)` Returns `true` if there is any string in the data structure that matches `word` or `false` otherwise. `word` may contain dots `'.'` where dots can be matched with any letter.

Example:

```
Input
["WordDictionary","addWord","addWord","addWord","search","search","search","search"]
[[],["bad"],["dad"],["mad"],["pad"],["bad"],[".ad"],["b.."]]
Output
[null,null,null,null,false,true,true,true]

Explanation
WordDictionary wordDictionary = new WordDictionary();
wordDictionary.addWord("bad");
wordDictionary.addWord("dad");
wordDictionary.addWord("mad");
wordDictionary.search("pad"); // return False
wordDictionary.search("bad"); // return True
wordDictionary.search(".ad"); // return True
wordDictionary.search("b.."); // return True
```

Constraints:

- `1 <= word.length <= 25`
- `word` in `addWord` consists of lowercase English letters.
- `word` in `search` consist of `'.'` or lowercase English letters.
- There will be at most `2` dots in `word` for `search` queries.
- At most 10^4 calls will be made to `addWord` and `search`.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Exact lookup could use a hash set, but . matches any letter, so scanning every word is awkward. Words use lowercase letters, which fit a trie. Add walks a 26-way path. Search follows a fixed edge on a letter and branches over every non-empty child on .; a match must end on a word node.

Python 3

```python
class Trie:
    def __init__(self):
        self.children = [None] * 26
        self.is_end = False

class WordDictionary:
    def __init__(self):
        self.trie = Trie()

    def addWord(self, word: str) -> None:
        node = self.trie
        for c in word:
            idx = ord(c) - ord('a')
            if node.children[idx] is None:
                node.children[idx] = Trie()
            node = node.children[idx]
        node.is_end = True

    def search(self, word: str) -> bool:
        def search(word, node):
            for i in range(len(word)):
                c = word[i]
                idx = ord(c) - ord('a')
                if c != '.' and node.children[idx] is None:
                    return False
                if c == '.':
                    for child in node.children:
                        if child is not None and search(word[i + 1 :], child):
                            return True
                    return False

2034. Stock Price Fluctuation

Medium · Design, Hash Table, Data Stream, Ordered Set, Heap (Priority Queue)

leetcode.com/problems/stock-price-fluctuation

PROBLEM

You are given a stream of **records** about a particular stock. Each record contains a **timestamp** and the corresponding **price** of the stock at that timestamp.

Unfortunately due to the volatile nature of the stock market, the records do not come in order. Even worse, some records may be incorrect. Another record with the same timestamp may appear later in the stream **correcting** the price of the previous wrong record.

Design an algorithm that:

- **Updates** the price of the stock at a particular timestamp, **correcting** the price from any previous records at the timestamp.
- Finds the **latest price** of the stock based on the current records. The **latest price** is the price at the latest timestamp recorded.
- Finds the **maximum price** the stock has been based on the current records.
- Finds the **minimum price** the stock has been based on the current records.

Implement the `StockPrice` class:

- `StockPrice()` Initializes the object with no price records.
- `void update(int timestamp, int price)` Updates the `price` of the stock at the given `timestamp`.
- `int current()` Returns the **latest price** of the stock.
- `int maximum()` Returns the **maximum price** of the stock.
- `int minimum()` Returns the **minimum price** of the stock.

Example 1:

```
Input
["StockPrice", "update", "update", "current", "maximum", "update", "maximum", "update", "minimum"]
[[], [1, 10], [2, 5], [], [], [1, 3], [], [4, 2], []]
Output
[null, null, null, 5, 10, null, 5, null, 2]

Explanation
StockPrice stockPrice = new StockPrice();
stockPrice.update(1, 10); // Timestamps are [1] with corresponding prices [10].
stockPrice.update(2, 5); // Timestamps are [1,2] with corresponding prices [10,5].
stockPrice.current(); // return 5, the latest timestamp is 2 with the price being 5.
stockPrice.maximum(); // return 10, the maximum price is 10 at timestamp 1.
stockPrice.update(1, 3); // The previous timestamp 1 had the wrong price, so it is updated to 3.
                         // Timestamps are [1,2] with corresponding prices [3,5].
stockPrice.maximum(); // return 5, the maximum price is 5 after the correction.
stockPrice.update(4, 2); // Timestamps are [1,2,4] with corresponding prices [3,5,2].
stockPrice.minimum(); // return 2, the minimum price is 2 at timestamp 4.
```

Constraints:

- $1 <= timestamp, price <= 10^9$
- At most 10^5 calls will be made **in total** to `update`, `current`, `maximum`, and `minimum`.
- `current`, `maximum`, and `minimum` will be called **only after** `update` has been called **at least once**.

SOLUTION (PYTHON 3)

Solution 1: Hash Table + Ordered Set

How to think about it

We must correct past timestamps and query current, max, and min prices in 10^5 operations. A hash map alone cannot get extrema; a sorted set alone cannot overwrite by time. Map d stores time→price; ordered multiset ls stores live prices. On update, remove the old price if the time exists, insert the new one, and track the latest time last. Current is d[last]; extrema are the ends of ls.

We define the following data structures or variables:

- `d`: a hash table that stores the timestamp and the corresponding price;
- `ls`: an ordered set that stores all prices;
- `last`: the timestamp of the last update.

Then, we can perform the following operations:

- `update(timestamp, price)`: update the price corresponding to the timestamp `timestamp` to `price`. If `timestamp` already exists, we need to first remove its corresponding price from the ordered set, and then update it to `price`. Otherwise, we directly update it to `price`. Then, we need to update `last` to `max(last, timestamp)`. The time complexity is O(log n).
- `current()`: return the price corresponding to `last`. The time complexity is O(1).
- `maximum()`: return the maximum value in the ordered set. The time complexity is O(log n).
- `minimum()`: return the minimum value in the ordered set. The time complexity is O(log n).

The space complexity is O(n), where n is the number of `update` operations.

Python 3

```
class StockPrice:
    def __init__(self):
        self.d = {}
        self.ls = SortedList()
        self.last = 0

    def update(self, timestamp: int, price: int) -> None:
        if timestamp in self.d:
            self.ls.remove(self.d[timestamp])
        self.d[timestamp] = price
        self.ls.add(price)
        self.last = max(self.last, timestamp)

    def current(self) -> int:
        return self.d[self.last]

    def maximum(self) -> int:
        return self.ls[-1]

    def minimum(self) -> int:
        return self.ls[0]

# Your StockPrice object will be instantiated and called as such:
# obj = StockPrice()
# obj.update(timestamp,price)
# param_2 = obj.current()
# param_3 = obj.maximum()
# param_4 = obj.minimum()
```

```

2353. Design a Food Rating System

Medium · Design, Array, Hash Table, String, Ordered Set, Heap (Priority Queue)

leetcode.com/problems/design-a-food-rating-system

PROBLEM

Design a food rating system that can do the following:

- **Modify** the rating of a food item listed in the system.
- Return the highest-rated food item for a type of cuisine in the system.

Implement the `FoodRatings` class:

- `FoodRatings(String[] foods, String[] cuisines, int[] ratings)` Initializes the system. The food items are described by `foods`, `cuisines` and `ratings`, all of which have a length of `n`.
  - `foods[i]` is the name of the i^{th} food,
  - `cuisines[i]` is the type of cuisine of the i^{th} food, and
  - `ratings[i]` is the initial rating of the i^{th} food.
- `void changeRating(String food, int newRating)` Changes the rating of the food item with the name `food`.
- `String highestRated(String cuisine)` Returns the name of the food item that has the highest rating for the given type of `cuisine`. If there is a tie, return the item with the **lexicographically smaller** name.

Note that a string `x` is lexicographically smaller than string `y` if `x` comes before `y` in dictionary order, that is, either `x` is a prefix of `y`, or if `i` is the first position such that `x[i] != y[i]`, then `x[i]` comes before `y[i]` in alphabetic order.

Example 1:

```
Input
["FoodRatings", "highestRated", "highestRated", "changeRating", "highestRated", "changeRating",
"highestRated"]
[[["kimchi", "miso", "sushi", "moussaka", "ramen", "bulgogi"], ["korean", "japanese", "japanese",
"greek", "japanese", "korean"], [9, 12, 8, 15, 14, 7]], ["korean"], ["japanese"], ["sushi", 16],
["japanese"], ["ramen", 16], ["japanese"]]
Output
[null, "kimchi", "ramen", null, "sushi", null, "ramen"]

Explanation
FoodRatings foodRatings = new FoodRatings(["kimchi", "miso", "sushi", "moussaka", "ramen", "bulgogi"],
["korean", "japanese", "japanese", "greek", "japanese", "korean"], [9, 12, 8, 15, 14, 7]);
foodRatings.highestRated("korean"); // return "kimchi"
                                    // "kimchi" is the highest rated korean food with a rating of 9.
foodRatings.highestRated("japanese"); // return "ramen"
                                      // "ramen" is the highest rated japanese food with a rating of
14.
foodRatings.changeRating("sushi", 16); // "sushi" now has a rating of 16.
foodRatings.highestRated("japanese"); // return "sushi"
                                      // "sushi" is the highest rated japanese food with a rating of
16.
foodRatings.changeRating("ramen", 16); // "ramen" now has a rating of 16.
foodRatings.highestRated("japanese"); // return "ramen"
                                      // Both "sushi" and "ramen" have a rating of 16.
                                      // However, "ramen" is lexicographically smaller than "sushi".
```

Constraints:

- $1 <= n <= 2 * 10^4$
- `n == foods.length == cuisines.length == ratings.length`
- `1 <= foods[i].length, cuisines[i].length <= 10`

- `foods[i]`, `cuisines[i]` consist of lowercase English letters.
- `1 <= ratings[i] <= 10^8`
- All the strings in `foods` are **distinct**.
- `food` will be the name of a food item in the system across all calls to `changeRating`.
- `cuisine` will be a type of cuisine of **at least one** food item in the system across all calls to `highestRated`.
- At most `2 * 10^4` calls **in total** will be made to `changeRating` and `highestRated`.

SOLUTION (PYTHON 3)

Solution 1: Hash Table + Ordered Set

> **How to think about it**
>
> We query the highest-rated food of a cuisine (breaking ties lexicographically) and update ratings. Up to 2×10^4 calls make a linear scan too slow. Each cuisine keeps a sorted set of (-rating, food); a map stores each food's rating and cuisine. An update removes the old pair and inserts the new one; a query reads the first food name.

We can use a hash table d to store the foods for each cuisine, where the key is the cuisine and the value is an ordered set. Each element in the ordered set is a tuple (rating, food), sorted by rating in descending order, and if the ratings are the same, sorted by food name in lexicographical order.

We can also use a hash table g to store the rating and cuisine for each food. That is, g[food] = (rating, cuisine).

In the constructor, we iterate through foods, cuisines, and ratings, storing the rating and cuisine for each food in d and g.

In the changeRating function, we first get the original rating oldRating and cuisine cuisine of the food food, then update the rating of g[food] to newRating, remove (oldRating, food) from d[cuisine], and add (newRating, food) to d[cuisine].

In the highestRated function, we directly return the food name of the first element in d[cuisine].

In terms of time complexity, the constructor has a time complexity of O(n log n), where n is the number of foods. The other operations have a time complexity of O(log n). The space complexity is O(n).

Python 3

```python
class FoodRatings:

    def __init__(self, foods: List[str], cuisines: List[str], ratings: List[int]):
        self.d = defaultdict(SortedList)
        self.g = {}
        for food, cuisine, rating in zip(foods, cuisines, ratings):
            self.d[cuisine].add((-rating, food))
            self.g[food] = (rating, cuisine)

    def changeRating(self, food: str, newRating: int) -> None:
        oldRating, cuisine = self.g[food]
        self.g[food] = (newRating, cuisine)
        self.d[cuisine].remove((-oldRating, food))
        self.d[cuisine].add((-newRating, food))

    def highestRated(self, cuisine: str) -> str:
        return self.d[cuisine][0][1]

# Your FoodRatings object will be instantiated and called as such:
# obj = FoodRatings(foods, cuisines, ratings)
# obj.changeRating(food,newRating)
# param_2 = obj.highestRated(cuisine)
```

    if not entries:
        del by_cuisine[cuisine]
```

1797. Design Authentication Manager

Medium · Design, Hash Table, Linked List, Doubly-Linked List

leetcode.com/problems/design-authentication-manager

PROBLEM

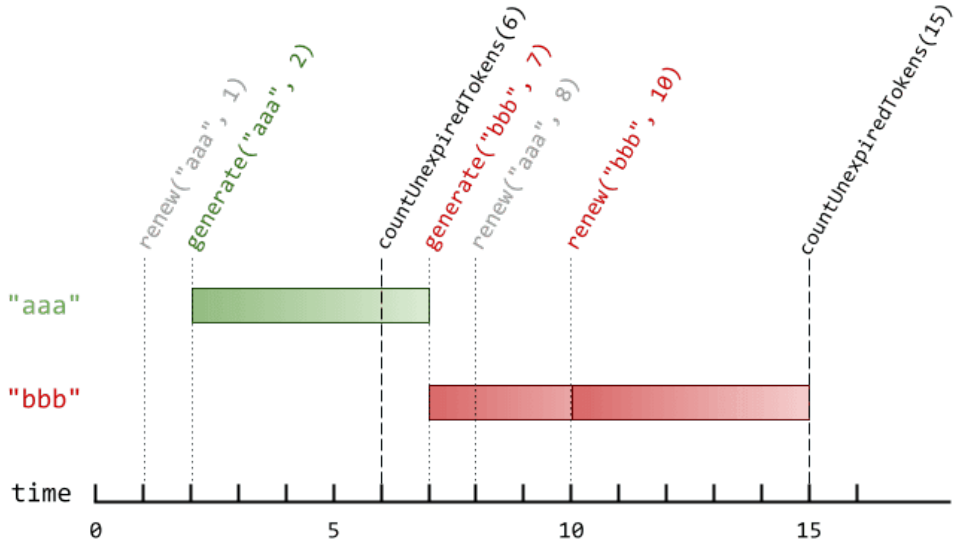
There is an authentication system that works with authentication tokens. For each session, the user will receive a new authentication token that will expire `timeToLive` seconds after the `currentTime`. If the token is renewed, the expiry time will be **extended** to expire `timeToLive` seconds after the (potentially different) `currentTime`.

Implement the `AuthenticationManager` class:

- `AuthenticationManager(int timeToLive)` constructs the `AuthenticationManager` and sets the `timeToLive`.
- `generate(string tokenId, int currentTime)` generates a new token with the given `tokenId` at the given `currentTime` in seconds.
- `renew(string tokenId, int currentTime)` renews the **unexpired** token with the given `tokenId` at the given `currentTime` in seconds. If there are no unexpired tokens with the given `tokenId`, the request is ignored, and nothing happens.
- `countUnexpiredTokens(int currentTime)` returns the number of **unexpired** tokens at the given currentTime.

Note that if a token expires at time `t`, and another action happens on time `t` (`renew` or `countUnexpiredTokens`), the expiration takes place **before** the other actions.

Example 1:



```
Input
["AuthenticationManager", "renew", "generate", "countUnexpiredTokens", "generate", "renew", "renew",
"countUnexpiredTokens"]
[[5], ["aaa", 1], ["aaa", 2], [6], ["bbb", 7], ["aaa", 8], ["bbb", 10], [15]]
Output
[null, null, null, 1, null, null, null, 0]

Explanation
AuthenticationManager authenticationManager = new AuthenticationManager(5); // Constructs the
AuthenticationManager with timeToLive = 5 seconds.
authenticationManager.renew("aaa", 1); // No token exists with tokenId "aaa" at time 1, so nothing
happens.
authenticationManager.generate("aaa", 2); // Generates a new token with tokenId "aaa" at time 2.
authenticationManager.countUnexpiredTokens(6); // The token with tokenId "aaa" is the only unexpired
one at time 6, so return 1.
authenticationManager.generate("bbb", 7); // Generates a new token with tokenId "bbb" at time 7.
authenticationManager.renew("aaa", 8); // The token with tokenId "aaa" expired at time 7, and 8 >= 7,
so at time 8 the renew request is ignored, and nothing happens.
authenticationManager.renew("bbb", 10); // The token with tokenId "bbb" is unexpired at time 10, so
the renew request is fulfilled and now the token will expire at time 15.
authenticationManager.countUnexpiredTokens(15); // The token with tokenId "bbb" expires at time 15,
and the token with tokenId "aaa" expired at time 7, so currently no token is unexpired, so return 0.
```

Constraints:

- `1 <= timeToLive <= 10^8`
- `1 <= currentTime <= 10^8`
- `1 <= tokenId.length <= 5`
- `tokenId` consists only of lowercase letters.
- All calls to `generate` will contain unique values of `tokenId`.
- The values of `currentTime` across all the function calls will be **strictly increasing**.
- At most `2000` calls will be made to all functions combined.

SOLUTION (PYTHON 3)

Solution 1: Hash Table

> **How to think about it**
>
> A token expires at currentTime+timeToLive after generate or renew. The operation count is modest, so a hash map of expiry times suffices. Generate writes an expiry; renew updates only if still valid; count scans how many expiries are still in the future.

We can simply maintain a hash table d, where the key is `tokenId` and the value is the expiration time.

- During the `generate` operation, we store `tokenId` as the key and `currentTime + timeToLive` as the value in the hash table d.
- During the `renew` operation, if `tokenId` is not in the hash table d, or `currentTime >= d[tokenId]`, we ignore this operation; otherwise, we update `d[tokenId]` to `currentTime + timeToLive`.
- During the `countUnexpiredTokens` operation, we traverse the hash table d and count the number of unexpired `tokenId`.

In terms of time complexity, both `generate` and `renew` operations have a time complexity of O(1), and the `countUnexpiredTokens` operation has a time complexity of O(n), where n is the number of key-value pairs in the hash table d.

The space complexity is O(n), where n is the number of key-value pairs in the hash table d.

Python 3

```python
class AuthenticationManager:
    def __init__(self, timeToLive: int):
        self.t = timeToLive
        self.d = defaultdict(int)

    def generate(self, tokenId: str, currentTime: int) -> None:
        self.d[tokenId] = currentTime + self.t

    def renew(self, tokenId: str, currentTime: int) -> None:
        if self.d[tokenId] <= currentTime:
            return
        self.d[tokenId] = currentTime + self.t

    def countUnexpiredTokens(self, currentTime: int) -> int:
        return sum(exp > currentTime for exp in self.d.values())

# Your AuthenticationManager object will be instantiated and called as such:
# obj = AuthenticationManager(timeToLive)
# obj.generate(tokenId,currentTime)
# obj.renew(tokenId,currentTime)
# param_3 = obj.countUnexpiredTokens(currentTime)
```

460. LFU Cache

Hard · Design, Hash Table, Linked List, Doubly-Linked List

leetcode.com/problems/lfu-cache

★ **TOP 10 PROBLEM** in Design Problems: master this one first

PROBLEM

Design and implement a data structure for a Least Frequently Used (LFU) cache.

Implement the `LFUCache` class:

- `LFUCache(int capacity)` Initializes the object with the `capacity` of the data structure.
- `int get(int key)` Gets the value of the `key` if the `key` exists in the cache. Otherwise, returns `-1`.
- `void put(int key, int value)` Update the value of the `key` if present, or inserts the `key` if not already present. When the cache reaches its `capacity`, it should invalidate and remove the **least frequently used** key before inserting a new item. For this problem, when there is a **tie** (i.e., two or more keys with the same frequency), the **least recently used** `key` would be invalidated.

To determine the least frequently used key, a **use counter** is maintained for each key in the cache. The key with the smallest **use counter** is the least frequently used key.

When a key is first inserted into the cache, its **use counter** is set to `1` (due to the `put` operation). The **use counter** for a key in the cache is incremented either a `get` or `put` operation is called on it.

The functions `get` and `put` must each run in `O(1)` average time complexity.

Example 1:

```
Input
["LFUCache", "put", "put", "get", "put", "get", "get", "put", "get", "get", "get"]
[[2], [1, 1], [2, 2], [1], [3, 3], [2], [3], [4, 4], [1], [3], [4]]
Output
[null, null, null, 1, null, -1, 3, null, -1, 3, 4]

Explanation
// cnt(x) = the use counter for key x
// cache=[] will show the last used order for tiebreakers (leftmost element is most recent)
LFUCache lfu = new LFUCache(2);
lfu.put(1, 1); // cache=[1,_], cnt(1)=1
lfu.put(2, 2); // cache=[2,1], cnt(2)=1, cnt(1)=1
lfu.get(1); // return 1
                // cache=[1,2], cnt(2)=1, cnt(1)=2
lfu.put(3, 3); // 2 is the LFU key because cnt(2)=1 is the smallest, invalidate 2.
                // cache=[3,1], cnt(3)=1, cnt(1)=2
lfu.get(2); // return -1 (not found)
lfu.get(3); // return 3
                // cache=[3,1], cnt(3)=2, cnt(1)=2
lfu.put(4, 4); // Both 1 and 3 have the same cnt, but 1 is LRU, invalidate 1.
                // cache=[4,3], cnt(4)=1, cnt(3)=2
lfu.get(1); // return -1 (not found)
lfu.get(3); // return 3
                // cache=[3,4], cnt(4)=1, cnt(3)=3
lfu.get(4); // return 4
                // cache=[4,3], cnt(4)=2, cnt(3)=3
```

Constraints:

- $1 <= capacity <= 10^4$
- $0 <= key <= 10^5$
- $0 <= value <= 10^9$

- At most `2 * 10^5` calls will be made to `get` and `put`.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

LFU must get and put in O(1) and, when full, evict the least frequent key, breaking ties by LRU. One hash map finds a value but cannot track frequency and recency together. A key-to-node map gives lookup. A frequency-to-list map stores nodes of equal frequency, newest at the head. minFreq points at the victim list's tail. A hit moves the node onto the freq+1 list; if the old list is empty and was the minimum, bump minFreq. A brand-new key has frequency 1 and resets the minimum to 1.

Python 3

```
class Node:
    def __init__(self, key: int, value: int) -> None:
        self.key = key
        self.value = value
        self.freq = 1
        self.prev = None
        self.next = None

class DoublyLinkedList:
    def __init__(self) -> None:
        self.head = Node(-1, -1)
        self.tail = Node(-1, -1)
        self.head.next = self.tail
        self.tail.prev = self.head

    def add_first(self, node: Node) -> None:
        node.prev = self.head
        node.next = self.head.next
        self.head.next.prev = node
        self.head.next = node

    def remove(self, node: Node) -> Node:
        node.next.prev = node.prev
        node.prev.next = node.next
        node.next, node.prev = None, None
        return node

    def remove_last(self) -> Node:
        return self.remove(self.tail.prev)

    def is_empty(self) -> bool:
        return self.head.next == self.tail

class LFUCache:
    def __init__(self, capacity: int):
        self.capacity = capacity

PATTERN 29 · DESIGN PROBLEMS · PROBLEM 19 OF 20

295. Find Median from Data Stream

Hard · Design, Two Pointers, Data Stream, Sorting, Heap (Priority Queue)

leetcode.com/problems/find-median-from-data-stream

★ **TOP 10 PROBLEM** in Design Problems, Two Heaps: master this one first

Also appears in pattern 37 Two Heaps

PROBLEM

The **median** is the middle value in an ordered integer list. If the size of the list is even, there is no middle value, and the median is the mean of the two middle values.

- For example, for `arr = [2,3,4]`, the median is `3`.
- For example, for `arr = [2,3]`, the median is `(2 + 3) / 2 = 2.5`.

Implement the MedianFinder class:

- `MedianFinder()` initializes the `MedianFinder` object.
- `void addNum(int num)` adds the integer `num` from the data stream to the data structure.
- `double findMedian()` returns the median of all elements so far. Answers within 10^{-5} of the actual answer will be accepted.

Example 1:

```
Input
["MedianFinder", "addNum", "addNum", "findMedian", "addNum", "findMedian"]
[[], [1], [2], [], [3], []]
Output
[null, null, null, 1.5, null, 2.0]

Explanation
MedianFinder medianFinder = new MedianFinder();
medianFinder.addNum(1); // arr = [1]
medianFinder.addNum(2); // arr = [1, 2]
medianFinder.findMedian(); // return 1.5 (i.e., (1 + 2) / 2)
medianFinder.addNum(3); // arr[1, 2, 3]
medianFinder.findMedian(); // return 2.0
```

Constraints:

- -10^5 `<= num <=` 10^5
- There will be at least one element in the data structure before calling `findMedian`.
- At most `5 *` 10^4 calls will be made to `addNum` and `findMedian`.

Follow up:

- If all integer numbers from the stream are in the range `[0, 100]`, how would you optimize your solution?
- If `99%` of all integer numbers from the stream are in the range `[0, 100]`, how would you optimize your solution?

SOLUTION (PYTHON 3)

Solution 1: Min Heap and Max Heap (Priority Queue)

How to think about it

Sorting after every insertion is too slow for a running median. A max-heap holds the lower half and a min-heap the upper half; the tops form the median. A new value goes into the max-heap then is moved to the min-heap, keeping the min-heap at most one larger. Even counts average the two tops; odd counts take the min-heap top.

We can use two heaps to maintain all the elements, a min heap minQ and a max heap maxQ, where the min heap minQ stores the larger half, and the max heap maxQ stores the smaller half.

When calling the `addNum` method, we first add the element to the max heap maxQ, then pop the top element of maxQ and add it to the min heap minQ. If at this time the size difference between minQ and maxQ is greater than 1, we pop the top element of minQ and add it to maxQ. The time complexity is O(log n).

When calling the `findMedian` method, if the size of minQ is equal to the size of maxQ, it means the total number of elements is even, and we can return the average value of the top elements of minQ and maxQ; otherwise, we return the top element of minQ. The time complexity is O(1).

The space complexity is O(n), where n is the number of elements.

Python 3

```
class MedianFinder:

    def __init__(self):
        self.minq = []
        self.maxq = []

    def addNum(self, num: int) -> None:
        heappush(self.minq, -heappushpop(self.maxq, -num))
        if len(self.minq) - len(self.maxq) > 1:
            heappush(self.maxq, -heappop(self.minq))

    def findMedian(self) -> float:
        if len(self.minq) == len(self.maxq):
            return (self.minq[0] - self.maxq[0]) / 2
        return self.minq[0]

# Your MedianFinder object will be instantiated and called as such:
# obj = MedianFinder()
# obj.addNum(num)
# param_2 = obj.findMedian()
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

        position = bisect.bisect_left(self.items, num)
        if position < len(self.items) and self.items[position] == num:
            self.items.pop(position)
            return True
```

```
        return False

    def find_median(self):
        n = len(self.items)
        if n % 2 == 1:
            return float(self.items[n // 2])
        return (self.items[n // 2 - 1] + self.items[n // 2]) / 2
```

297. Serialize and Deserialize Binary Tree

Hard · Tree, Depth-First Search, Breadth-First Search, Design, String, Binary Tree

leetcode.com/problems/serialize-and-deserialize-binary-tree

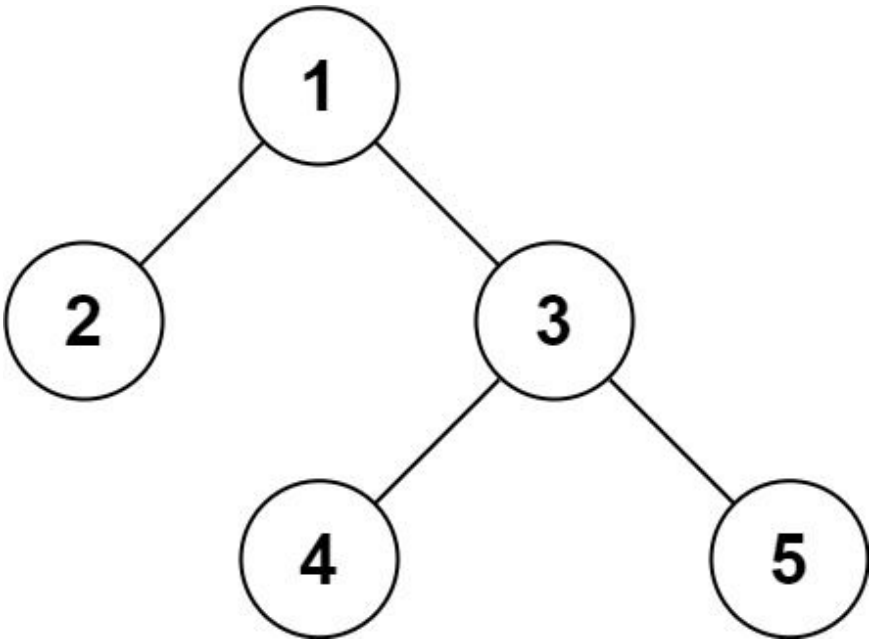
PROBLEM

Serialization is the process of converting a data structure or object into a sequence of bits so that it can be stored in a file or memory buffer, or transmitted across a network connection link to be reconstructed later in the same or another computer environment.

Design an algorithm to serialize and deserialize a binary tree. There is no restriction on how your serialization/deserialization algorithm should work. You just need to ensure that a binary tree can be serialized to a string and this string can be deserialized to the original tree structure.

Clarification: The input/output format is the same as how LeetCode serializes a binary tree. You do not necessarily need to follow this format, so please be creative and come up with different approaches yourself.

Example 1:



```
Input: root = [1,2,3,null,null,4,5]
Output: [1,2,3,null,null,4,5]
```

Example 2:

```
Input: root = []
Output: []
```

Constraints:

- The number of nodes in the tree is in the range `[0, 10^4]`.
- `-1000 <= Node.val <= 1000`

SOLUTION (PYTHON 3)

Solution 1: Level Order Traversal

> **How to think about it**
>
> A general binary tree must record missing children; storing only present values loses shape. Level order writes # for nulls so parent–child slots can be rebuilt. Serialize by enqueueing both children; deserialize assigns the next two tokens as the front node's left and right.

We can use level order traversal to serialize the binary tree. Starting from the root node, we add the nodes of the binary tree to the queue in the order from top to bottom, from left to right. Then we dequeue the nodes in the queue one by one. If the node is not null, we add its value to the serialized string; otherwise, we add a special character `#`. Finally, we return the serialized string.

During deserialization, we split the serialized string by the delimiter to get a string array, and then add the elements in the string array to the queue in order. The elements in the queue are the nodes of the binary tree. We dequeue the elements from the queue one by one. If the element is not `#`, we convert it to an integer and use it as the value of the node, and then add the node to the queue; otherwise, we set it to `null`. Finally, we return the root node.

The time complexity is O(n), and the space complexity is O(n). Where n is the number of nodes in the binary tree.

Python 3

```
# Definition for a binary tree node.
# class TreeNode(object):
#     def __init__(self, x):
#         self.val = x
#         self.left = None
#         self.right = None

class Codec:
    def serialize(self, root):
        """Encodes a tree to a single string.

        :type root: TreeNode
        :rtype: str
        """
        if root is None:
            return ""
        q = deque([root])
        ans = []
        while q:
            node = q.popleft()
            if node:
                ans.append(str(node.val))
                q.append(node.left)
                q.append(node.right)
            else:
                ans.append("#")
        return ",".join(ans)

    def deserialize(self, data):
        """Decodes your encoded data to tree.

        :type data: str
        :rtype: TreeNode
        """
        if not data:
            return None
        vals = data.split(",")
        root = TreeNode(int(vals[0]))
        q = deque([root])
        i = 1
        while q:
            node = q.popleft()

PATTERN 30 OF 41

Topological Sort

20 problems · 0 Easy · 13 Medium · 7 Hard

THE IDEA

Order tasks so every prerequisite comes first. Kahn's algorithm repeatedly takes nodes with no remaining prerequisites; if some are never taken there is a cycle.

Signals: course schedule, alien dictionary, build order, parallel courses, sequence reconstruction, minimum height trees.

A TEMPLATE TO KEEP IN YOUR HANDS (PYTHON)

```
from collections import deque
indeg = [0] * n
for a, b in edges:                    # b before a
    graph[b].append(a)
    indeg[a] += 1
q = deque(i for i in range(n) if indeg[i] == 0)
order = []
while q:
    u = q.popleft()
    order.append(u)
    for v in graph[u]:
        indeg[v] -= 1
        if indeg[v] == 0:
            q.append(v)
return len(order) == n
```

210. Course Schedule II

Medium · Depth-First Search, Breadth-First Search, Graph, Topological Sort

leetcode.com/problems/course-schedule-ii

★ **TOP 10 PROBLEM** in Topological Sort: master this one first

PROBLEM

There are a total of `numCourses` courses you have to take, labeled from `0` to `numCourses - 1`. You are given an array `prerequisites` where `prerequisites[i] = [a_i, b_i]` indicates that you **must** take course `b_i` first if you want to take course `a_i`.

- For example, the pair `[0, 1]`, indicates that to take course `0` you have to first take course `1`.

Return *the ordering of courses you should take to finish all courses*. If there are many valid answers, return **any** of them. If it is impossible to finish all courses, return **an empty array**.

Example 1:

```
Input: numCourses = 2, prerequisites = [[1,0]]
Output: [0,1]
Explanation: There are a total of 2 courses to take. To take course 1 you should have finished course
0. So the correct course order is [0,1].
```

Example 2:

```
Input: numCourses = 4, prerequisites = [[1,0],[2,0],[3,1],[3,2]]
Output: [0,2,1,3]
Explanation: There are a total of 4 courses to take. To take course 3 you should have finished both
courses 1 and 2. Both courses 1 and 2 should be taken after you finished course 0.
So one correct course order is [0,1,2,3]. Another correct ordering is [0,2,1,3].
```

Example 3:

```
Input: numCourses = 1, prerequisites = []
Output: [0]
```

Constraints:

- `1 <= numCourses <= 2000`
- `0 <= prerequisites.length <= numCourses * (numCourses - 1)`
- `prerequisites[i].length == 2`
- `0 <= a_i, b_i < numCourses`
- `a_i != b_i`
- All the pairs `[a_i, b_i]` are **distinct**.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

As in the decision version, prerequisites form a directed graph; here we also need one valid order. The dequeue order of a topological sort is such a sequence. If fewer than numCourses vertices enter the queue, a cycle exists and we return an empty array.

Python 3

```
class Solution:
    def findOrder(self, numCourses: int, prerequisites: List[List[int]]) -> List[int]:
        g = defaultdict(list)
        indeg = [0] * numCourses
        for a, b in prerequisites:
            g[b].append(a)
            indeg[a] += 1
        ans = []
        q = deque(i for i, x in enumerate(indeg) if x == 0)
        while q:
            i = q.popleft()
            ans.append(i)
            for j in g[i]:
                indeg[j] -= 1
                if indeg[j] == 0:
                    q.append(j)
        return ans if len(ans) == numCourses else []
```

Complexity. Time: O(V + E). Space: O(V + E).

1462. Course Schedule IV

Medium · Depth-First Search, Breadth-First Search, Graph, Topological Sort

leetcode.com/problems/course-schedule-iv

PROBLEM

There are a total of `numCourses` courses you have to take, labeled from `0` to `numCourses - 1`. You are given an array `prerequisites` where `prerequisites[i] = [a_i, b_i]` indicates that you **must** take course `a_i` first if you want to take course `b_i`.

- For example, the pair `[0, 1]` indicates that you have to take course `0` before you can take course `1`.

Prerequisites can also be **indirect**. If course `a` is a prerequisite of course `b`, and course `b` is a prerequisite of course `c`, then course `a` is a prerequisite of course `c`.

You are also given an array `queries` where `queries[j] = [u_j, v_j]`. For the `j^th` query, you should answer whether course `u_j` is a prerequisite of course `v_j` or not.

Return *a boolean array* `answer`*, where* `answer[j]` *is the answer to the* `j^th` *query.*

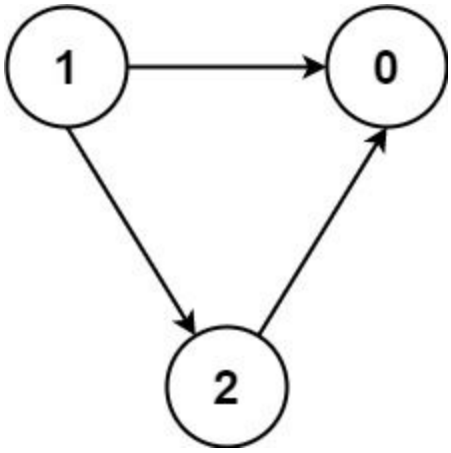
Example 1:

```
Input: numCourses = 2, prerequisites = [[1,0]], queries = [[0,1],[1,0]]
Output: [false,true]
Explanation: The pair [1, 0] indicates that you have to take course 1 before you can take course 0.
Course 0 is not a prerequisite of course 1, but the opposite is true.
```

Example 2:

```
Input: numCourses = 2, prerequisites = [], queries = [[1,0],[0,1]]
Output: [false,false]
Explanation: There are no prerequisites, and each course is independent.
```

Example 3:



```
Input: numCourses = 3, prerequisites = [[1,2],[1,0],[2,0]], queries = [[1,0],[1,2]]
Output: [true,true]
```

Constraints:

- `2 <= numCourses <= 100`

- `0 <= prerequisites.length <= (numCourses * (numCourses - 1) / 2)`
- `prerequisites[i].length == 2`
- `0 <= a_i, b_i <= numCourses - 1`
- `a_i != b_i`
- All the pairs `[a_i, b_i]` are **unique**.
- The prerequisites graph has no cycles.
- `1 <= queries.length <= 10^4`
- `0 <= u_i, v_i <= numCourses - 1`
- `u_i != v_i`

SOLUTIONS (PYTHON 3)

Solution 1: Floyd's Algorithm

> **How to think about it**
>
> Each query asks whether a is a prerequisite of b, i.e. reachability. With a modest number of courses, Floyd on a Boolean matrix closes the graph; each query is then O(1).

We create a 2D array f, where f[i][j] indicates whether node i can reach node j.

Next, we iterate through the prerequisites array prerequisites. For each item [a, b] in it, we set f[a][b] to true.

Then, we use Floyd's algorithm to compute the reachability between all pairs of nodes.

Specifically, we use three nested loops: first enumerating the intermediate node k, then the starting node i, and finally the ending node j. For each iteration, if node i can reach node k and node k can reach node j, then node i can also reach node j, and we set f[i][j] to true.

After computing the reachability between all pairs of nodes, for each query [a, b], we can directly return f[a][b].

The time complexity is $O(n^3)$, and the space complexity is $O(n^2)$, where n is the number of nodes.

Python 3

```python
class Solution:
    def checkIfPrerequisite(
        self, n: int, prerequisites: List[List[int]], queries: List[List[int]]
    ) -> List[bool]:
        f = [[False] * n for _ in range(n)]
        for a, b in prerequisites:
            f[a][b] = True
        for k in range(n):
            for i in range(n):
                for j in range(n):
                    if f[i][k] and f[k][j]:
                        f[i][j] = True
        return [f[a][b] for a, b in queries]
```

Solution 2: Topological Sorting

> **How to think about it**
>
> Method 1 pays $O(n^3)$ for an all-pairs closure. A topological pass unions each node's reachability into its successors, filling the same f[i][j] along the DAG.

Similar to Solution 1, we create a 2D array f, where f[i][j] indicates whether node i can reach node j. Additionally, we create an adjacency list g, where g[i] represents all successor nodes of node i, and an array indeg, where indeg[i] represents the in-degree of node i.

Next, we iterate through the prerequisites array prerequisites. For each item [a, b] in it, we update the adjacency list g and the in-degree array indeg.

Then, we use topological sorting to compute the reachability between all pairs of nodes.

We define a queue q, initially adding all nodes with an in-degree of 0 to the queue. Then, we continuously perform the following operations: remove the front node i from the queue, then iterate through all nodes j in g[i], setting f[i][j] to true. Next, we enumerate node h, and if f[h][i] is true, we also set f[h][j] to true. After this, we decrease the in-degree of j by 1. If the in-degree of j becomes 0, we add j to the queue.

After computing the reachability between all pairs of nodes, for each query [a, b], we can directly return f[a][b].

The time complexity is $O(n^3)$, and the space complexity is $O(n^2)$, where n is the number of nodes.

Python 3

```python
class Solution:
    def checkIfPrerequisite(
        self, n: int, prerequisites: List[List[int]], queries: List[List[int]]
    ) -> List[bool]:
        f = [[False] * n for _ in range(n)]
        g = [[] for _ in range(n)]
        indeg = [0] * n
        for a, b in prerequisites:
            g[a].append(b)
            indeg[b] += 1
        q = deque(i for i, x in enumerate(indeg) if x == 0)
        while q:
            i = q.popleft()
            for j in g[i]:
                f[i][j] = True
                for h in range(n):
                    f[h][j] = f[h][j] or f[h][i]
                indeg[j] -= 1
                if indeg[j] == 0:
                    q.append(j)
        return [f[a][b] for a, b in queries]
```

310. Minimum Height Trees

Medium · Depth-First Search, Breadth-First Search, Graph, Topological Sort

leetcode.com/problems/minimum-height-trees

★ **TOP 10 PROBLEM** in Topological Sort: master this one first

PROBLEM

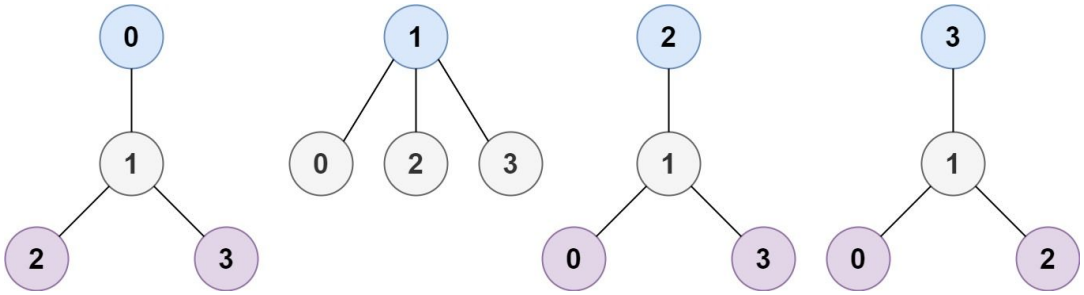
A tree is an undirected graph in which any two vertices are connected by *exactly* one path. In other words, any connected graph without simple cycles is a tree.

Given a tree of `n` nodes labelled from `0` to `n - 1`, and an array of `n - 1` `edges` where `edges[i] = [a_i, b_i]` indicates that there is an undirected edge between the two nodes a_i and b_i in the tree, you can choose any node of the tree as the root. When you select a node `x` as the root, the result tree has height `h`. Among all possible rooted trees, those with minimum height (i.e. `min(h)`) are called **minimum height trees** (MHTs).

Return *a list of all **MHTs'** root labels*. You can return the answer in **any order**.

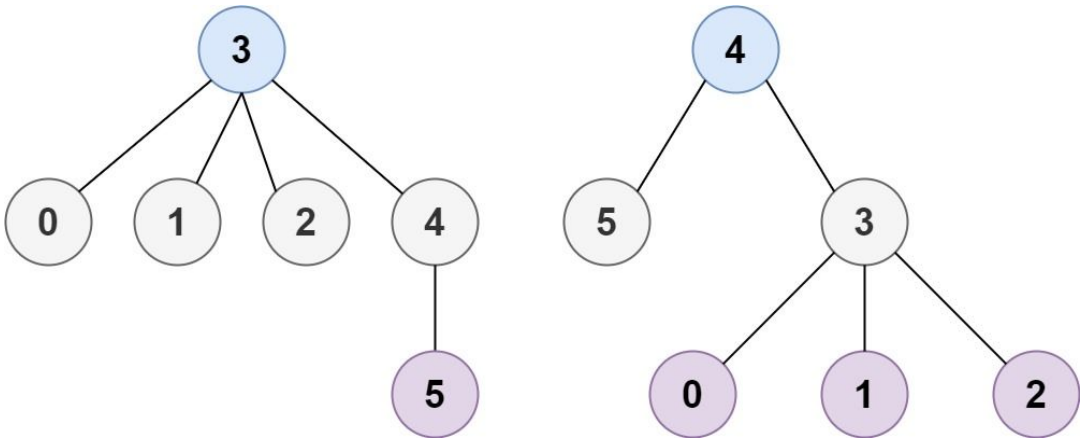
The **height** of a rooted tree is the number of edges on the longest downward path between the root and a leaf.

Example 1:



```
Input: n = 4, edges = [[1,0],[1,2],[1,3]]
Output: [1]
Explanation: As shown, the height of the tree is 1 when the root is the node with label 1 which is the only MHT.
```

Example 2:



```
Input: n = 6, edges = [[3,0],[3,1],[3,2],[3,4],[5,4]]
Output: [3,4]
```

Constraints:

- `1 <= n <= 2 * 10^4`
- `edges.length == n - 1`

- $0 <= a_i, b_i < n$
- $a_i != b_i$
- All the pairs (a_i, b_i) are distinct.
- The given input is **guaranteed** to be a tree and there will be **no repeated** edges.

SOLUTION (PYTHON 3)

Solution 1: Topological Sorting

> **How to think about it**
>
> Height is the distance from the root to the farthest leaf. BFS from every node is $O(n^2)$. The center of the tree diameter — one or two nodes — is exactly the set of minimum-height roots. Leaves have degree 1. Peel them inward together (a topological peel): each layer decrements neighbors, and new degree-1 nodes enqueue. The last remaining layer is the center. A single node is returned as-is.

If the tree only has one node, then this node is the root of the minimum height tree. We can directly return this node.

If the tree has multiple nodes, there must be leaf nodes. A leaf node is a node that only has one adjacent node. We can use topological sorting to peel off the leaf nodes from the outside to the inside. When we reach the last layer, the remaining nodes are the root nodes of the minimum height tree.

The time complexity is O(n) and the space complexity is O(n), where n is the number of nodes.

Python 3

```python
class Solution:
    def findMinHeightTrees(self, n: int, edges: List[List[int]]) -> List[int]:
        if n == 1:
            return [0]
        g = [[] for _ in range(n)]
        degree = [0] * n
        for a, b in edges:
            g[a].append(b)
            g[b].append(a)
            degree[a] += 1

2192. All Ancestors of a Node in a Directed Acyclic Graph

Medium · Depth-First Search, Breadth-First Search, Graph, Topological Sort, Directed Acyclic Graph

leetcode.com/problems/all-ancestors-of-a-node-in-a-directed-acyclic-graph

★ **TOP 10 PROBLEM** in Topological Sort: master this one first

PROBLEM

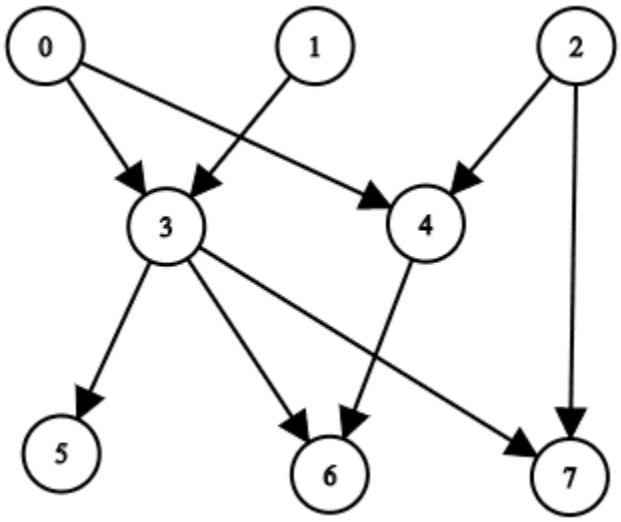
You are given a positive integer `n` representing the number of nodes of a **Directed Acyclic Graph** (DAG). The nodes are numbered from `0` to `n - 1` (**inclusive**).

You are also given a 2D integer array `edges`, where `edges[i] = [from`$_i$`, to`$_i$`]` denotes that there is a **unidirectional** edge from `from`$_i$ to `to`$_i$ in the graph.

Return *a list* `answer`*, where* `answer[i]` *is the* ***list of ancestors*** *of the* `i`th *node, sorted in* ***ascending order***.

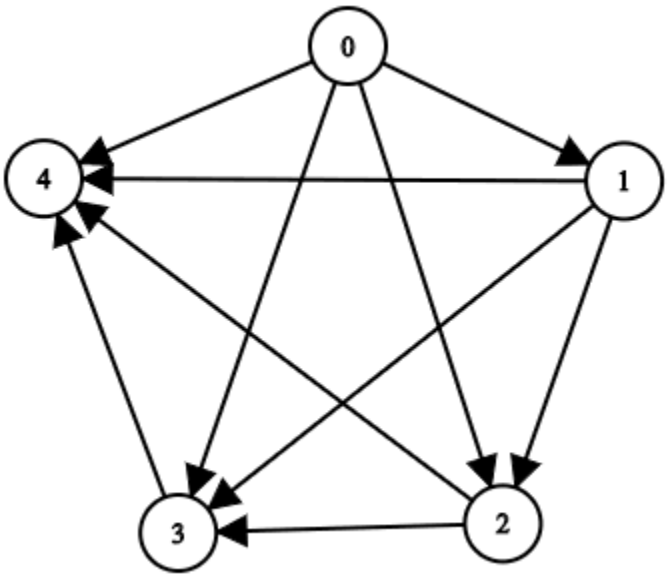
A node `u` is an **ancestor** of another node `v` if `u` can reach `v` via a set of edges.

Example 1:



```
Input: n = 8, edgeList = [[0,3],[0,4],[1,3],[2,4],[2,7],[3,5],[3,6],[3,7],[4,6]]
Output: [[],[],[],[0,1],[0,2],[0,1,3],[0,1,2,3,4],[0,1,2,3]]
Explanation:
The above diagram represents the input graph.
- Nodes 0, 1, and 2 do not have any ancestors.
- Node 3 has two ancestors 0 and 1.
- Node 4 has two ancestors 0 and 2.
- Node 5 has three ancestors 0, 1, and 3.
- Node 6 has five ancestors 0, 1, 2, 3, and 4.
- Node 7 has four ancestors 0, 1, 2, and 3.
```

Example 2:



```
Input: n = 5, edgeList = [[0,1],[0,2],[0,3],[0,4],[1,2],[1,3],[1,4],[2,3],[2,4],[3,4]]
Output: [[],[0],[0,1],[0,1,2],[0,1,2,3]]
Explanation:
The above diagram represents the input graph.
- Node 0 does not have any ancestor.
- Node 1 has one ancestor 0.
- Node 2 has two ancestors 0 and 1.
- Node 3 has three ancestors 0, 1, and 2.
- Node 4 has four ancestors 0, 1, 2, and 3.
```

Constraints:

- `1 <= n <= 1000`
- `0 <= edges.length <= min(2000, n * (n - 1) / 2)`
- `edges[i].length == 2`
- $0 <= from_i, to_i <= n - 1$
- $from_i != to_i$
- There are no duplicate edges.
- The graph is **directed** and **acyclic**.

SOLUTION (PYTHON 3)

Solution 1: BFS

How to think about it

List every ancestor of each node in a DAG, sorted by id. Reverse DFS from every node repeats shared in-edges and still needs sorting. With n≤ 1000 we can walk descendants of each i and append i to those lists, which is already sorted by i. Build the adjacency list, BFS from every i, and record i on every reachable node. A visited set prevents re-enqueue. Each answer row is increasing because sources are enumerated in order.

First, we construct the adjacency list g based on the two-dimensional array edges, where g[i] represents all successor nodes of node i.

Then, we enumerate node i as the ancestor node from small to large, use BFS to search all successor nodes of node i, and add node i to the ancestor list of these successor nodes.

The time complexity is $O(n^2)$, and the space complexity is $O(n^2)$. Where n is the number of nodes.

Python 3

```python
class Solution:
    def getAncestors(self, n: int, edges: List[List[int]]) -> List[List[int]]:
        def bfs(s: int):
            q = deque([s])
            vis = {s}
            while q:
                i = q.popleft()
                for j in g[i]:
                    if j not in vis:
                        vis.add(j)
                        q.append(j)
                        ans[j].append(s)

        g = defaultdict(list)
        for u, v in edges:
            g[u].append(v)
        ans = [[] for _ in range(n)]
        for i in range(n):
            bfs(i)
        return ans
```

            if waiting[nxt] == 0:
                queue.append(nxt)
    return [len(s) for s in above]
```

PATTERN 30 · TOPOLOGICAL SORT · PROBLEM 7 OF 20

1136. Parallel Courses

Medium · Graph, Topological Sort, Directed Acyclic Graph

leetcode.com/problems/parallel-courses

★ **TOP 10 PROBLEM** in Topological Sort: master this one first

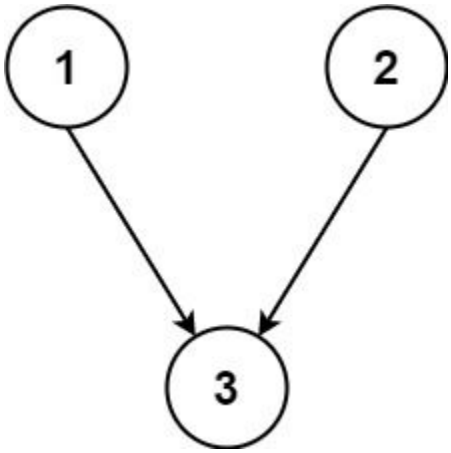
PROBLEM

You are given an integer `n`, which indicates that there are `n` courses labeled from `1` to `n`. You are also given an array `relations` where `relations[i] = [prevCourse`$_i$`, nextCourse`$_i$`]`, representing a prerequisite relationship between course `prevCourse`$_i$ and course `nextCourse`$_i$: course `prevCourse`$_i$ has to be taken before course `nextCourse`$_i$.

In one semester, you can take **any number** of courses as long as you have taken all the prerequisites in the **previous** semester for the courses you are taking.

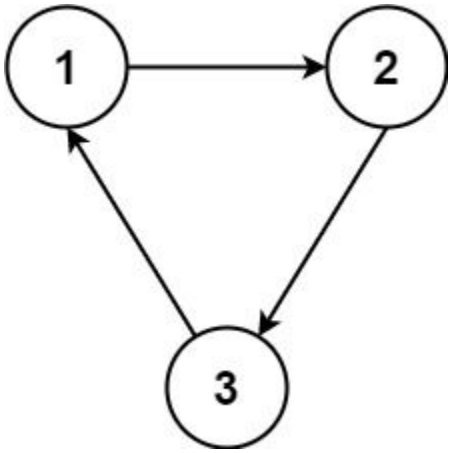
Return *the **minimum** number of semesters needed to take all courses*. If there is no way to take all the courses, return `-1`.

Example 1:



```
Input: n = 3, relations = [[1,3],[2,3]]
Output: 2
Explanation: The figure above represents the given graph.
In the first semester, you can take courses 1 and 2.
In the second semester, you can take course 3.
```

Example 2:



```
Input: n = 3, relations = [[1,2],[2,3],[3,1]]
Output: -1
Explanation: No course can be studied because they are prerequisites of each other.
```

Constraints:

- `1 <= n <= 5000`
- `1 <= relations.length <= 5000`
- `relations[i].length == 2`
- `1 <= prevCourse`$_i$`, nextCourse`$_i$ `<= n`
- `prevCourse`$_i$ `!= nextCourse`$_i$
- All the pairs `[prevCourse`$_i$`, nextCourse`$_i$`]` are **unique**.

SOLUTION (PYTHON 3)

Solution 1: Topological Sorting

> **How to think about it**
>
> The number of semesters is the longest chain of prerequisites; a semester can take every course whose indegree is now 0. Layered Kahn topology: each layer is one semester. Leftover courses mean a cycle, so return -1.

We can first build a graph g to represent the prerequisite relationships between courses, and count the in-degree indeg of each course.

Then we enqueue the courses with an in-degree of 0 and start topological sorting. Each time, we dequeue a course from the queue, reduce the in-degree of the courses that it points to by 1, and if the in-degree becomes 0 after reduction, we enqueue that course. When the queue is empty, if there are still courses that have not been completed, it means that it is impossible to complete all courses, so we return -1. Otherwise, we return the number of semesters required to complete all courses.

The time complexity is O(n + m), and the space complexity is O(n + m). Here, n and m are the number of courses and the number of prerequisite relationships, respectively.

Python 3

```python
class Solution:
    def minimumSemesters(self, n: int, relations: List[List[int]]) -> int:
        g = defaultdict(list)
        indeg = [0] * n
        for prev, nxt in relations:
            prev, nxt = prev - 1, nxt - 1
            g[prev].append(nxt)
            indeg[nxt] += 1
        q = deque(i for i, v in enumerate(indeg) if v == 0)
        ans = 0
        while q:
            ans += 1
            for _ in range(len(q)):
                i = q.popleft()
                n -= 1
                for j in g[i]:
                    indeg[j] -= 1
                    if indeg[j] == 0:
                        q.append(j)
        return -1 if n else ans
```

2115. Find All Possible Recipes from Given Supplies

Medium · Graph, Topological Sort, Array, Hash Table, String, Directed Acyclic Graph

leetcode.com/problems/find-all-possible-recipes-from-given-supplies

★ **TOP 10 PROBLEM** in Topological Sort: master this one first

PROBLEM

You have information about `n` different recipes. You are given a string array `recipes` and a 2D string array `ingredients`. The `i`th recipe has the name `recipes[i]`, and you can **create** it if you have **all** the needed ingredients from `ingredients[i]`. A recipe can also be an ingredient for **other** recipes, i.e., `ingredients[i]` may contain a string that is in `recipes`.

You are also given a string array `supplies` containing all the ingredients that you initially have, and you have an infinite supply of all of them.

Return *a list of all the recipes that you can create.* You may return the answer in **any order**.

Note that two recipes may contain each other in their ingredients.

Example 1:

```
Input: recipes = ["bread"], ingredients = [["yeast","flour"]], supplies = ["yeast","flour","corn"]
Output: ["bread"]
Explanation:
We can create "bread" since we have the ingredients "yeast" and "flour".
```

Example 2:

```
Input: recipes = ["bread","sandwich"], ingredients = [["yeast","flour"],["bread","meat"]], supplies =
["yeast","flour","meat"]
Output: ["bread","sandwich"]
Explanation:
We can create "bread" since we have the ingredients "yeast" and "flour".
We can create "sandwich" since we have the ingredient "meat" and can create the ingredient "bread".
```

Example 3:

```
Input: recipes = ["bread","sandwich","burger"], ingredients =
[["yeast","flour"],["bread","meat"],["sandwich","meat","bread"]], supplies = ["yeast","flour","meat"]
Output: ["bread","sandwich","burger"]
Explanation:
We can create "bread" since we have the ingredients "yeast" and "flour".
We can create "sandwich" since we have the ingredient "meat" and can create the ingredient "bread".
We can create "burger" since we have the ingredient "meat" and can create the ingredients "bread" and
"sandwich".
```

Constraints:

- `n == recipes.length == ingredients.length`
- `1 <= n <= 100`
- `1 <= ingredients[i].length, supplies.length <= 100`
- `1 <= recipes[i].length, ingredients[i][j].length, supplies[k].length <= 10`
- `recipes[i], ingredients[i][j]`, and `supplies[k]` consist only of lowercase English letters.
- All the values of `recipes` and `supplies` combined are unique.
- Each `ingredients[i]` does not contain any duplicate values.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

A recipe is cookable once every ingredient is available from the initial supplies or from already cooked recipes, which is a directed dependency graph. Rechecking ingredients per recipe repeats work and mishandles chains. Point each ingredient to recipes that need it, with in-degree equal to the number of ingredients. Supplies are the sources; a recipe whose in-degree falls to zero can be cooked and used to unlock others. We build that graph and run Kahn's algorithm from supplies, appending a recipe when its in-degree hits zero.

Python 3

```python
class Solution:
    def findAllRecipes(
        self, recipes: List[str], ingredients: List[List[str]], supplies: List[str]
    ) -> List[str]:
        g = defaultdict(list)
        indeg = defaultdict(int)
        for a, b in zip(recipes, ingredients):
            for v in b:
                g[v].append(a)
            indeg[a] += len(b)
        q = supplies
        ans = []
        for i in q:
            for j in g[i]:
                indeg[j] -= 1
                if indeg[j] == 0:
                    ans.append(j)
                    q.append(j)
        return ans
```

Complexity. Time: O(n + m), n = recipes plus supplies, m = total ingredients. Space: O(n + m).

851. Loud and Rich

Medium · Depth-First Search, Graph, Topological Sort, Array, Directed Acyclic Graph

leetcode.com/problems/loud-and-rich

PROBLEM

There is a group of `n` people labeled from `0` to `n - 1` where each person has a different amount of money and a different level of quietness.

You are given an array `richer` where `richer[i] = [a_i, b_i]` indicates that `a_i` has more money than `b_i` and an integer array `quiet` where `quiet[i]` is the quietness of the `i^th` person. All the given data in richer are **logically correct** (i.e., the data will not lead you to a situation where `x` is richer than `y` and `y` is richer than `x` at the same time).

Return *an integer array* `answer` *where* `answer[x] = y` *if* `y` *is the least quiet person (that is, the person* `y` *with the smallest value of* `quiet[y]`*) among all people who definitely have equal to or more money than the person* `x`.

Example 1:

```
Input: richer = [[1,0],[2,1],[3,1],[3,7],[4,3],[5,3],[6,3]], quiet = [3,2,5,4,6,1,7,0]
Output: [5,5,2,5,4,5,6,7]
Explanation:
answer[0] = 5.
Person 5 has more money than 3, which has more money than 1, which has more money than 0.
The only person who is quieter (has lower quiet[x]) is person 7, but it is not clear if they have more money than person 0.
answer[7] = 7.
Among all people that definitely have equal to or more money than person 7 (which could be persons 3, 4, 5, 6, or 7), the person who is the quietest (has lower quiet[x]) is person 7.
The other answers can be filled out with similar reasoning.
```

Example 2:

```
Input: richer = [], quiet = [0]
Output: [0]
```

Constraints:

- `n == quiet.length`
- `1 <= n <= 500`
- `0 <= quiet[i] < n`
- All the values of `quiet` are **unique**.
- `0 <= richer.length <= n * (n - 1) / 2`
- `0 <= a_i, b_i < n`
- `a_i != b_i`
- All the pairs of `richer` are **unique**.
- The observations in `richer` are all logically consistent.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

On the DAG of “richer than”, each person wants the quietest among themselves and all richer people. n≤ 500, so a fresh search per person retraces the same subgraphs. Point edges from poorer to richer and memoize DFS: start with oneself, then take the quieter answer among richer neighbors. Each node is computed once.

Python 3

```
class Solution:
    def loudAndRich(self, richer: List[List[int]], quiet: List[int]) -> List[int]:
        def dfs(i: int):
            if ans[i] != -1:
                return
            ans[i] = i
            for j in g[i]:
                dfs(j)
                if quiet[ans[j]] < quiet[ans[i]]:
                    ans[i] = ans[j]

        g = defaultdict(list)
        for a, b in richer:
            g[b].append(a)
        n = len(quiet)
        ans = [-1] * n
        for i in range(n):
            dfs(i)
        return ans
```

Complexity. Time: O(n + e), e = len(richer). Space: O(n + e).

```
    return sorted(seen, key=lambda p: quiet[p])
```

1557. Minimum Number of Vertices to Reach All Nodes

Medium · Graph, Directed Acyclic Graph

leetcode.com/problems/minimum-number-of-vertices-to-reach-all-nodes

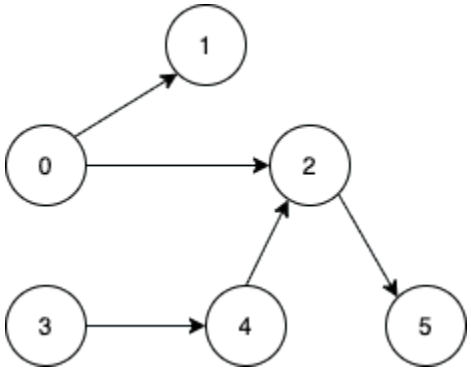
PROBLEM

Given a **directed acyclic graph**, with `n` vertices numbered from `0` to `n-1`, and an array `edges` where `edges[i] = [from_i, to_i]` represents a directed edge from node `from_i` to node `to_i`.

Find *the smallest set of vertices from which all nodes in the graph are reachable*. It's guaranteed that a unique solution exists.

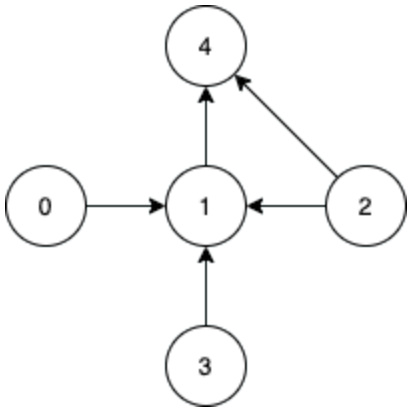
Notice that you can return the vertices in any order.

Example 1:



```
Input: n = 6, edges = [[0,1],[0,2],[2,5],[3,4],[4,2]]
Output: [0,3]
Explanation: It's not possible to reach all the nodes from a single vertex. From 0 we can reach
[0,1,2,5]. From 3 we can reach [3,4,2,5]. So we output [0,3].
```

Example 2:



```
Input: n = 5, edges = [[0,1],[2,1],[3,1],[1,4],[2,4]]
Output: [0,2,3]
Explanation: Notice that vertices 0, 3 and 2 are not reachable from any other node, so we must include
them. Also any of these vertices can reach nodes 1 and 4.
```

Constraints:

- `2 <= n <= 10^5`
- `1 <= edges.length <= min(10^5, n * (n - 1) / 2)`
- `edges[i].length == 2`

- $0 <= from_i, to_i < n$
- All pairs $(from_i, to_i)$ are distinct.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Choose as few vertices as possible so that every node is reachable from the set in a DAG. n and the number of edges reach 10^5, so we cannot enumerate subsets. A vertex of in-degree 0 cannot be reached from anyone else and must be chosen. Every other vertex has an in-edge and is therefore reachable from some source in the DAG. The answer is exactly the set of in-degree-zero vertices.

Python 3

```
class Solution:
    def findSmallestSetOfVertices(self, n: int, edges: List[List[int]]) -> List[int]:
        cnt = Counter(t for _, t in edges)
        return [i for i in range(n) if cnt[i] == 0]
```

Complexity. Time: O(n + e). Space: O(n).

444. Sequence Reconstruction

Medium · Graph, Topological Sort, Array, Directed Acyclic Graph

leetcode.com/problems/sequence-reconstruction

★ **TOP 10 PROBLEM** in Topological Sort: master this one first

PROBLEM

You are given an integer array `nums` of length `n` where `nums` is a permutation of the integers in the range `[1, n]`. You are also given a 2D integer array `sequences` where `sequences[i]` is a subsequence of `nums`.

Check if `nums` is the shortest possible and the only **supersequence**. The shortest **supersequence** is a sequence **with the shortest length** and has all `sequences[i]` as subsequences. There could be multiple valid **supersequences** for the given array `sequences`.

- For example, for `sequences = [[1,2],[1,3]]`, there are two shortest **supersequences**, `[1,2,3]` and `[1,3,2]`.
- While for `sequences = [[1,2],[1,3],[1,2,3]]`, the only shortest **supersequence** possible is `[1,2,3]`. `[1,2,3,4]` is a possible supersequence but not the shortest.

Return `true` *if* `nums` *is the only shortest* ***supersequence*** *for* `sequences`*, or* `false` *otherwise*.

A **subsequence** is a sequence that can be derived from another sequence by deleting some or no elements without changing the order of the remaining elements.

Example 1:

```
Input: nums = [1,2,3], sequences = [[1,2],[1,3]]
Output: false
Explanation: There are two possible supersequences: [1,2,3] and [1,3,2].
The sequence [1,2] is a subsequence of both: [1,2,3] and [1,3,2].
The sequence [1,3] is a subsequence of both: [1,2,3] and [1,3,2].
Since nums is not the only shortest supersequence, we return false.
```

Example 2:

```
Input: nums = [1,2,3], sequences = [[1,2]]
Output: false
Explanation: The shortest possible supersequence is [1,2].
The sequence [1,2] is a subsequence of it: [1,2].
Since nums is not the shortest supersequence, we return false.
```

Example 3:

```
Input: nums = [1,2,3], sequences = [[1,2],[1,3],[2,3]]
Output: true
Explanation: The shortest possible supersequence is [1,2,3].
The sequence [1,2] is a subsequence of it: [1,2,3].
The sequence [1,3] is a subsequence of it: [1,2,3].
The sequence [2,3] is a subsequence of it: [1,2,3].
Since nums is the only shortest supersequence, we return true.
```

Constraints:

- `n == nums.length`
- `1 <= n <= 10^4`
- `nums` is a permutation of all the integers in the range `[1, n]`.
- `1 <= sequences.length <= 10^4`
- `1 <= sequences[i].length <= 10^4`
- `1 <= sum(sequences[i].length) <= 10^5`

- `1 <= sequences[i][j] <= n`
- All the arrays of `sequences` are **unique**.
- `sequences[i]` is a subsequence of `nums`.

SOLUTION (PYTHON 3)

Solution 1: Topological Sorting

> **How to think about it**
>
> We must decide whether nums is the unique shortest supersequence of the given sequences. Several topological orders would mean several supersequences. Turn consecutive pairs in each seq into directed edges and record indegrees. The queue may hold only one zero-indegree node at a time—two candidates mean the order is not unique. An empty queue at the end means every node was forced. We need not compare against nums position-wise: if a unique order exists, it has to be nums.

We can first traverse each subsequence `seq`. For each pair of adjacent elements a and b, we establish a directed edge a → b. At the same time, we count the in-degree of each node, and finally add all nodes with an in-degree of 0 to the queue.

When the number of nodes in the queue is equal to 1, we take out the head node i, remove i from the graph, and decrease the in-degree of all adjacent nodes of i by 1. If the in-degree of the adjacent nodes becomes 0 after decreasing, add these nodes to the queue. Repeat the above operation until the length of the queue is not 1. At this point, check whether the queue is empty. If it is not empty, it means there are multiple shortest supersequences, return `false`; if it is empty, it means there is only one shortest supersequence, return `true`.

The time complexity is O(n + m), and the space complexity is O(n + m). Where n and m are the number of nodes and edges, respectively.

Python 3

```python
class Solution:
    def sequenceReconstruction(
        self, nums: List[int], sequences: List[List[int]]
    ) -> bool:
        n = len(nums)
        g = [[] for _ in range(n)]
        indeg = [0] * n
        for seq in sequences:
            for a, b in pairwise(seq):
                a, b = a - 1, b - 1
                g[a].append(b)
                indeg[b] += 1
        q = deque(i for i, x in enumerate(indeg) if x == 0)
        while len(q) == 1:
            i = q.popleft()
            for j in g[i]:
                indeg[j] -= 1
                if indeg[j] == 0:
                    q.append(j)
        return len(q) == 0
```

1976. Number of Ways to Arrive at Destination

Medium · Graph, Topological Sort, Dynamic Programming, Shortest Path, Dijkstra

leetcode.com/problems/number-of-ways-to-arrive-at-destination

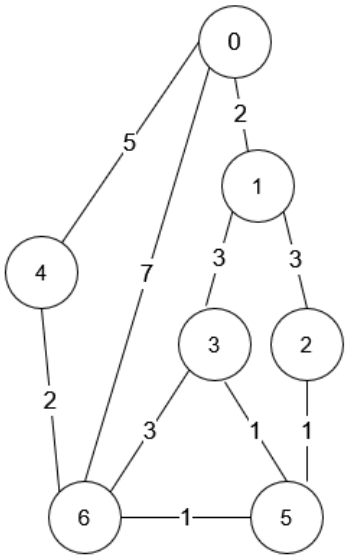
PROBLEM

You are in a city that consists of `n` intersections numbered from `0` to `n - 1` with **bi-directional** roads between some intersections. The inputs are generated such that you can reach any intersection from any other intersection and that there is at most one road between any two intersections.

You are given an integer `n` and a 2D integer array `roads` where `roads[i] = [u_i, v_i, time_i]` means that there is a road between intersections u_i and v_i that takes $time_i$ minutes to travel. You want to know in how many ways you can travel from intersection `0` to intersection `n - 1` in the **shortest amount of time**.

Return *the **number of ways** you can arrive at your destination in the **shortest amount of time***. Since the answer may be large, return it **modulo** $10^9 + 7$.

Example 1:



```
Input: n = 7, roads =
[[0,6,7],[0,1,2],[1,2,3],[1,3,3],[6,3,3],[3,5,1],[6,5,1],[2,5,1],[0,4,5],[4,6,2]]
Output: 4
Explanation: The shortest amount of time it takes to go from intersection 0 to intersection 6 is 7
minutes.
The four ways to get there in 7 minutes are:
- 0 → 6
- 0 → 4 → 6
- 0 → 1 → 2 → 5 → 6
- 0 → 1 → 3 → 5 → 6
```

Example 2:

```
Input: n = 2, roads = [[1,0,10]]
Output: 1
Explanation: There is only one way to go from intersection 0 to intersection 1, and it takes 10
minutes.
```

Constraints:

- `1 <= n <= 200`
- `n - 1 <= roads.length <= n * (n - 1) / 2`
- `roads[i].length == 3`
- $0 \le u_i, v_i \le n - 1$
- $1 \le time_i \le 10^9$
- $u_i \ne v_i$
- There is at most one road connecting any two intersections.
- You can reach any intersection from any other intersection.

SOLUTION (PYTHON 3)

Solution 1: Naive Dijkstra Algorithm

How to think about it

We need both the shortest path and the number of such paths. n≤ 200 makes dense Dijkstra $O(n^2)$ acceptable. When a strictly better distance appears, copy the predecessor's count; when the distance ties, add it. The destination count is taken modulo 10^9+7.

We define the following arrays:

- `g` represents the adjacency matrix of the graph. `g[i][j]` represents the shortest path length from point `i` to point `j`. Initially, all are infinity, while `g[0][0]` is 0. Then we traverse `roads` and update `g[u][v]` and `g[v][u]` to `t`.
- `dist[i]` represents the shortest path length from the starting point to point `i`. Initially, all are infinity, while `dist[0]` is 0.
- `f[i]` represents the number of shortest paths from the starting point to point `i`. Initially, all are 0, while `f[0]` is 1.
- `vis[i]` represents whether point `i` has been visited. Initially, all are `False`.

Then, we use the naive Dijkstra algorithm to find the shortest path length from the starting point to the end point, and record the number of shortest paths for each point during the process.

Finally, we return `f[n - 1]`. Since the answer may be very large, we need to take the modulus of $10^9 + 7$.

The time complexity is $O(n^2)$, and the space complexity is $O(n^2)$, where n is the number of points.

Python 3

```
class Solution:
    def countPaths(self, n: int, roads: List[List[int]]) -> int:
        g = [[inf] * n for _ in range(n)]
        for u, v, t in roads:
            g[u][v] = g[v][u] = t
        g[0][0] = 0
        dist = [inf] * n
        dist[0] = 0
        f = [0] * n
        f[0] = 1
        vis = [False] * n
        for _ in range(n):
            t = -1
            for j in range(n):
                if not vis[j] and (t == -1 or dist[j] < dist[t]):
                    t = j
            vis[t] = True
            for j in range(n):
                if j == t:
                    continue
                ne = dist[t] + g[t][j]

1559. Detect Cycles in 2D Grid

Medium · Depth-First Search, Breadth-First Search, Union Find, Array, Matrix

leetcode.com/problems/detect-cycles-in-2d-grid

PROBLEM

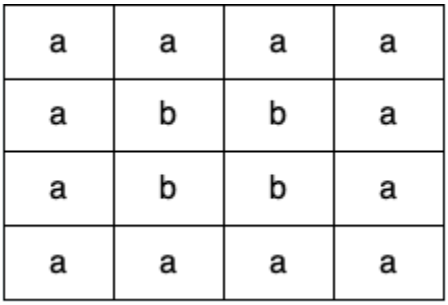
Given a 2D array of characters `grid` of size `m x n`, you need to find if there exists any cycle consisting of the **same value** in `grid`.

A cycle is a path of **length 4 or more** in the grid that starts and ends at the same cell. From a given cell, you can move to one of the cells adjacent to it - in one of the four directions (up, down, left, or right), if it has the **same value** of the current cell.

Also, you cannot move to the cell that you visited in your last move. For example, the cycle `(1, 1) -> (1, 2) -> (1, 1)` is invalid because from `(1, 2)` we visited `(1, 1)` which was the last visited cell.

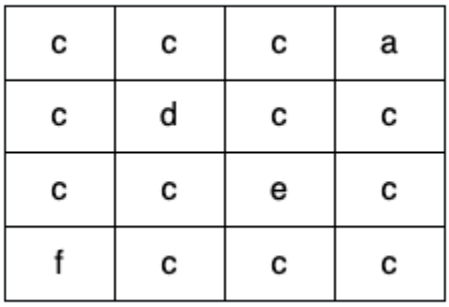
Return `true` if any cycle of the same value exists in `grid`, otherwise, return `false`.

Example 1:



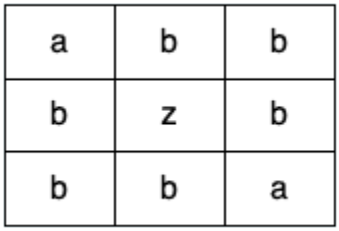
```
Input: grid = [["a","a","a","a"],["a","b","b","a"],["a","b","b","a"],["a","a","a","a"]]
Output: true
Explanation: There are two valid cycles shown in different colors in the image below:
```

Example 2:



```
Input: grid = [["c","c","c","a"],["c","d","c","c"],["c","c","e","c"],["f","c","c","c"]]
Output: true
Explanation: There is only one valid cycle highlighted in the image below:
```

Example 3:



```
Input: grid = [["a","b","b"],["b","z","b"],["b","b","a"]]
Output: false
```

Constraints:

- `m == grid.length`
- `n == grid[i].length`
- `1 <= m, n <= 500`
- `grid` consists only of lowercase English letters.

SOLUTIONS (PYTHON 3)

Solution 1: BFS

How to think about it

Detect a cycle of identical letters with length at least 4. The grid is small enough for one graph search, but stepping straight back to the parent must not count as a cycle. From every unvisited cell run BFS, walking only to same-letter neighbors and remembering the parent. A neighbor that is already visited and is not the parent closes a cycle. Each connected component is searched once.

We can traverse each cell in the 2D grid. For each cell, if the cell grid[i][j] has not been visited, we start a breadth-first search (BFS) from that cell. During the search, we need to record the parent node of each cell and the coordinates of the previous cell. If the value of the next cell is the same as the current cell, and it is not the previous cell, and it has already been visited, then it indicates the presence of a cycle, and we return true. After traversing all cells, if no cycle is found, we return false.

The time complexity is O(m × n), and the space complexity is O(m × n). Here, m and n are the number of rows and columns of the 2D grid, respectively.

Python 3

```python
class Solution:
    def containsCycle(self, grid: List[List[str]]) -> bool:
        m, n = len(grid), len(grid[0])
        vis = [[False] * n for _ in range(m)]
        dirs = (-1, 0, 1, 0, -1)
        for i, row in enumerate(grid):
            for j, x in enumerate(row):
                if vis[i][j]:
                    continue
                vis[i][j] = True
                q = [(i, j, -1, -1)]
                while q:
                    x, y, px, py = q.pop()
                    for dx, dy in pairwise(dirs):
                        nx, ny = x + dx, y + dy
                        if 0 <= nx < m and 0 <= ny < n:
                            if grid[nx][ny] != grid[i][j] or (nx == px and ny == py):
                                continue
                            if vis[nx][ny]:
                                return True
                            vis[nx][ny] = True
                            q.append((nx, ny, x, y))
        return False
```

Solution 2: DFS

> **How to think about it**
>
> BFS needs an explicit queue. DFS uses the call stack for the same parent test and is shorter. The visited mark and the "visited non-parent means a cycle" rule stay unchanged; only the traversal order differs.

We can traverse each cell in the 2D grid. For each cell, if the cell grid[i][j] has not been visited, we start a depth-first search (DFS) from that cell. During the search, we need to record the parent node of each cell and the coordinates of the previous cell. If the value of the next cell is the same as the current cell, and it is not the previous cell, and it has already been visited, then it indicates the presence of a cycle, and we return true. After traversing all cells, if no cycle is found, we return false.

The time complexity is O(m × n), and the space complexity is O(m × n). Here, m and n are the number of rows and columns of the 2D grid, respectively.

Python 3

```python
class Solution:
    def containsCycle(self, grid: List[List[str]]) -> bool:
        def dfs(x: int, y: int, px: int, py: int) -> bool:
            vis[x][y] = True
            for dx, dy in pairwise(dirs):
                nx, ny = x + dx, y + dy
                if 0 <= nx < m and 0 <= ny < n:
                    if grid[nx][ny] != grid[x][y] or (nx == px and ny == py):
                        continue
                    if vis[nx][ny] or dfs(nx, ny, x, y):
                        return True
            return False

        m, n = len(grid), len(grid[0])
        vis = [[False] * n for _ in range(m)]
        dirs = (-1, 0, 1, 0, -1)
        for i in range(m):
            for j in range(n):
                if vis[i][j]:
                    continue
                if dfs(i, j, -1, -1):
                    return True
        return False
```

2050. Parallel Courses III

Hard · Graph, Topological Sort, Array, Dynamic Programming, Directed Acyclic Graph

leetcode.com/problems/parallel-courses-iii

★ **TOP 10 PROBLEM** in Topological Sort: master this one first

PROBLEM

You are given an integer `n`, which indicates that there are `n` courses labeled from `1` to `n`. You are also given a 2D integer array `relations` where `relations[j] = [prevCourse`$_j$`, nextCourse`$_j$`]` denotes that course `prevCourse`$_j$ has to be completed **before** course `nextCourse`$_j$ (prerequisite relationship). Furthermore, you are given a **0-indexed** integer array `time` where `time[i]` denotes how many **months** it takes to complete the `(i+1)`th course.

You must find the **minimum** number of months needed to complete all the courses following these rules:

- You may start taking a course at **any time** if the prerequisites are met.
- **Any number of courses** can be taken at the **same time**.

Return *the **minimum** number of months needed to complete all the courses*.

Note: The test cases are generated such that it is possible to complete every course (i.e., the graph is a directed acyclic graph).

Example 1:

```
Input: n = 3, relations = [[1,3],[2,3]], time = [3,2,5]
Output: 8
Explanation: The figure above represents the given graph and the time required to complete each
course.
We start course 1 and course 2 simultaneously at month 0.
Course 1 takes 3 months and course 2 takes 2 months to complete respectively.
Thus, the earliest time we can start course 3 is at month 3, and the total time required is 3 + 5 = 8
months.
```

Example 2:

```
Input: n = 5, relations = [[1,5],[2,5],[3,5],[3,4],[4,5]], time = [1,2,3,4,5]
Output: 12
Explanation: The figure above represents the given graph and the time required to complete each
course.
You can start courses 1, 2, and 3 at month 0.
You can complete them after 1, 2, and 3 months respectively.
Course 4 can be taken only after course 3 is completed, i.e., after 3 months. It is completed after 3 +
4 = 7 months.
Course 5 can be taken only after courses 1, 2, 3, and 4 have been completed, i.e., after max(1,2,3,7) =
7 months.
Thus, the minimum time needed to complete all the courses is 7 + 5 = 12 months.
```

Constraints:

- `1 <= n <= 5 * 10`^{4}
- `0 <= relations.length <= min(n * (n - 1) / 2, 5 * 10`^{4}`)`
- `relations[j].length == 2`
- `1 <= prevCourse`$_j$`, nextCourse`$_j$` <= n`
- `prevCourse`$_j$` != nextCourse`$_j$
- All the pairs `[prevCourse`$_j$`, nextCourse`$_j$`]` are **unique**.
- `time.length == n`
- `1 <= time[i] <= 10`^{4}

- The given graph is a directed acyclic graph.

SOLUTION (PYTHON 3)

Solution 1: Topological Sorting + Dynamic Programming

> **How to think about it**
>
> Courses have prerequisites and durations; the finish time is the heaviest path in the DAG. With $n \le 5 \times 10^4$ we cannot list paths. Sources start immediately and finish in their own `time`. In topological order, f[j] = max(f[j], f[i]+time[j]) once every predecessor i is done. The answer is the maximum f. A queue of zero in-degree nodes updates each course only after all prerequisites.

First, we construct a directed acyclic graph based on the given prerequisite course relationships, perform topological sorting on this graph, and then use dynamic programming to find the minimum time required to complete all courses according to the results of the topological sorting.

We define the following data structures or variables:

- Adjacency list g stores the directed acyclic graph, and an array indeg stores the in-degree of each node;
- Queue q stores all nodes with an in-degree of 0;
- Array f stores the earliest completion time of each node, initially f[i] = 0;
- Variable ans records the final answer, initially ans = 0;

When q is not empty, take out the head node i in turn, traverse each node j in g[i], update f[j] = max(f[j], f[i] + time[j]), update ans = max(ans, f[j]) at the same time, and reduce the in-degree of j by 1. If the in-degree of j is 0 at this time, add j to the queue q;

Finally, return ans.

The time complexity is O(m + n), and the space complexity is O(m + n). Where m is the length of the array relations.

Python 3

```python
class Solution:
    def minimumTime(self, n: int, relations: List[List[int]], time: List[int]) -> int:
        g = defaultdict(list)
        indeg = [0] * n
        for a, b in relations:
            g[a - 1].append(b - 1)
            indeg[b - 1] += 1
        q = deque()
        f = [0] * n
        ans = 0
        for i, (v, t) in enumerate(zip(indeg, time)):
            if v == 0:
                q.append(i)
                f[i] = t
                ans = max(ans, t)
        while q:
            i = q.popleft()
            for j in g[i]:
                f[j] = max(f[j], f[i] + time[j])
                ans = max(ans, f[j])
                indeg[j] -= 1
                if indeg[j] == 0:
                    q.append(j)
        return ans
```

        latest[c] = total - time[c - 1]
        for nxt in unlocks[c]:
            latest[c] = min(latest[c], latest[nxt] - time[c - 1])
    return [latest[c] - earliest[c] for c in range(1, n + 1)]
```

1203. Sort Items by Groups Respecting Dependencies

Hard · Depth-First Search, Breadth-First Search, Graph, Topological Sort, Directed Acyclic Graph

leetcode.com/problems/sort-items-by-groups-respecting-dependencies

PROBLEM

There are `n` items each belonging to zero or one of `m` groups where `group[i]` is the group that the `i`-th item belongs to and it's equal to `-1` if the `i`-th item belongs to no group. The items and the groups are zero indexed. A group can have no item belonging to it.

Return a sorted list of the items such that:

- The items that belong to the same group are next to each other in the sorted list.
- There are some relations between these items where `beforeItems[i]` is a list containing all the items that should come before the `i`-th item in the sorted array (to the left of the `i`-th item).

Return any solution if there is more than one solution and return an **empty list** if there is no solution.

Example 1:

Item	Group	Before
0	-1	
1	-1	6
2	1	5
3	0	6
4	0	3, 6
5	1	
6	0	
7	-1	

```
Input: n = 8, m = 2, group = [-1,-1,1,0,0,1,0,-1], beforeItems = [[],[6],[5],[6],[3,6],[],[],[]]
Output: [6,3,4,1,5,2,0,7]
```

Example 2:

```
Input: n = 8, m = 2, group = [-1,-1,1,0,0,1,0,-1], beforeItems = [[],[6],[5],[6],[3],[],[4],[]]
Output: []
Explanation: This is the same as example 1 except that 4 needs to be before 6 in the sorted list.
```

Constraints:

- `1 <= m <= n <= 3 * 10^4`
- `group.length == beforeItems.length == n`
- `-1 <= group[i] <= m - 1`
- `0 <= beforeItems[i].length <= n - 1`
- `0 <= beforeItems[i][j] <= n - 1`
- `i != beforeItems[i][j]`
- `beforeItems[i]` does not contain duplicates elements.

SOLUTION (PYTHON 3)

Solution 1: Topological Sorting

How to think about it

A single topological sort on items can split a group, so items from the same group need not stay together. With $n \le 3 \times 10^4$ we need linear-time graph construction. Constraints sit on two layers: groups precede other groups, and items precede other items inside a group. Ungrouped items become singleton groups. Cross-group dependencies become group edges; same-group dependencies become item edges. We topologically sort groups first, then items inside each group in that order. A cycle at either layer means no answer. The two graphs separate “groups stay contiguous” from “item order”, each handled by Kahn's algorithm.

First, we traverse the array group. For each project, if it does not belong to any group, we create a new group for it with the ID m, and increment m. This ensures that all projects belong to some group. Then, we use an array groupItems to record the projects contained in each group. The array index is the group ID, and the array value is the list of projects in the group.

Next, we need to build the graph. For each project, we need to build two types of graphs: one for the projects and one for the groups. We traverse the array group. For the current project i, its group is group[i]. We traverse beforeItems[i], and for each project j in it, if group[i] = group[j], it means that i and j belong to the same group. We add an edge j → i in the project graph. Otherwise, it means that i and j belong to different groups. We add an edge group[j] → group[i] in the group graph, and update the corresponding in-degree array.

Next, we perform topological sorting on the group graph to get the sorted group list groupOrder. If the length of the sorted list is not equal to the total number of groups, it means that the sorting cannot be completed, so we return an empty list. Otherwise, we traverse groupOrder, and for each group gi, we perform topological sorting on the project list groupItems[gi] to get the sorted project list itemOrder. If the length of the sorted list is not equal to the total number of projects in the group, it means that the sorting cannot be completed, so we return an empty list. Otherwise, we add the projects in itemOrder to the answer array, and finally return this answer array.

The time complexity is O(n + m), and the space complexity is O(n + m). Here, n and m are the total number of projects and groups, respectively.

Python 3

```python
class Solution:
    def sortItems(
        self, n: int, m: int, group: List[int], beforeItems: List[List[int]]
    ) -> List[int]:
        def topo_sort(degree, graph, items):
            q = deque(i for _, i in enumerate(items) if degree[i] == 0)
            res = []
            while q:
                i = q.popleft()
                res.append(i)
                for j in graph[i]:
                    degree[j] -= 1
                    if degree[j] == 0:
                        q.append(j)
            return res if len(res) == len(items) else []

        idx = m
        group_items = [[] for _ in range(n + m)]
        for i, g in enumerate(group):
            if g == -1:
                group[i] = idx
                idx += 1
            group_items[group[i]].append(i)

        item_degree = [0] * n
        group_degree = [0] * (n + m)
        item_graph = [[] for _ in range(n)]
        group_graph = [[] for _ in range(n + m)]
        for i, gi in enumerate(group):
            for j in beforeItems[i]:
                gj = group[j]
                if gi == gj:
                    item_degree[i] += 1
                    item_graph[j].append(i)
                else:
                    group_degree[gi] += 1
                    group_graph[gj].append(gi)

        group_order = topo_sort(group_degree, group_graph, range(n + m))
        if not group_order:
            return []
        ans = []
        for gi in group_order:
            items = group_items[gi]
            item_order = topo_sort(item_degree, item_graph, items)
            if len(items) != len(item_order):
                return []
            ans.extend(item_order)
        return ans
```

2392. Build a Matrix With Conditions

Hard · Graph, Topological Sort, Array, Directed Acyclic Graph, Matrix

leetcode.com/problems/build-a-matrix-with-conditions

PROBLEM

You are given a **positive** integer `k`. You are also given:

- a 2D integer array `rowConditions` of size `n` where `rowConditions[i] = [above`$_i$`, below`$_i$`]`, and
- a 2D integer array `colConditions` of size `m` where `colConditions[i] = [left`$_i$`, right`$_i$`]`.

The two arrays contain integers from `1` to `k`.

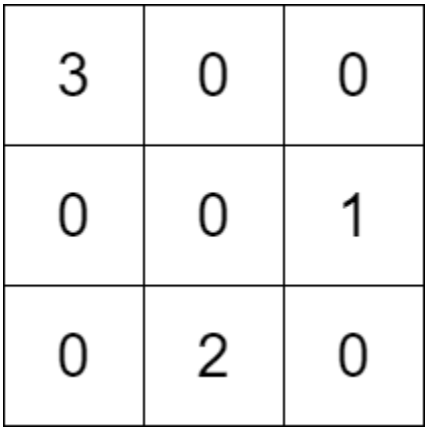
You have to build a `k x k` matrix that contains each of the numbers from `1` to `k` **exactly once**. The remaining cells should have the value `0`.

The matrix should also satisfy the following conditions:

- The number `above`$_i$ should appear in a **row** that is strictly **above** the row at which the number `below`$_i$ appears for all `i` from `0` to `n - 1`.
- The number `left`$_i$ should appear in a **column** that is strictly **left** of the column at which the number `right`$_i$ appears for all `i` from `0` to `m - 1`.

Return ***any** matrix that satisfies the conditions*. If no answer exists, return an empty matrix.

Example 1:



```
Input: k = 3, rowConditions = [[1,2],[3,2]], colConditions = [[2,1],[3,2]]
Output: [[3,0,0],[0,0,1],[0,2,0]]
Explanation: The diagram above shows a valid example of a matrix that satisfies all the conditions.
The row conditions are the following:
- Number 1 is in row 1, and number 2 is in row 2, so 1 is above 2 in the matrix.
- Number 3 is in row 0, and number 2 is in row 2, so 3 is above 2 in the matrix.
The column conditions are the following:
- Number 2 is in column 1, and number 1 is in column 2, so 2 is left of 1 in the matrix.
- Number 3 is in column 0, and number 2 is in column 1, so 3 is left of 2 in the matrix.
Note that there may be multiple correct answers.
```

Example 2:

```
Input: k = 3, rowConditions = [[1,2],[2,3],[3,1],[2,3]], colConditions = [[2,1]]
Output: []
Explanation: From the first two conditions, 3 has to be below 1 but the third conditions needs 3 to be
above 1 to be satisfied.
No matrix can satisfy all the conditions, so we return the empty matrix.
```

Constraints:

- `2 <= k <= 400`
- `1 <= rowConditions.length, colConditions.length <= 10^4`
- `rowConditions[i].length == colConditions[i].length == 2`
- `1 <= above_i, below_i, left_i, right_i <= k`
- `above_i != below_i`
- `left_i != right_i`

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Each of 1..k appears once; row and column conditions are order constraints. k ≤ 400, so treat them as directed edges and topological-sort. A cycle means impossible. Topo-sort rows and columns separately, then write each value at the paired indices. If either order is shorter than k, return an empty matrix.

Python 3

```
class Solution:
    def buildMatrix(
        self, k: int, rowConditions: List[List[int]], colConditions: List[List[int]]
    ) -> List[List[int]]:
        def f(cond):
            g = defaultdict(list)
            indeg = [0] * (k + 1)
            for a, b in cond:
                g[a].append(b)
                indeg[b] += 1
            q = deque([i for i, v in enumerate(indeg[1:], 1) if v == 0])
            res = []
            while q:
                for _ in range(len(q)):
                    i = q.popleft()
                    res.append(i)
                    for j in g[i]:
                        indeg[j] -= 1
                        if indeg[j] == 0:
                            q.append(j)
            return None if len(res) != k else res

        row = f(rowConditions)
        col = f(colConditions)
        if row is None or col is None:
            return []
        ans = [[0] * k for _ in range(k)]
        m = [0] * (k + 1)
        for i, v in enumerate(col):
            m[v] = i
        for i, v in enumerate(row):
            ans[i][m[v]] = v
        return ans
```

Complexity. Time: O(k^2 + r + c), r and c = number of row and column conditions. Space: O(k^2 + r + c).

1857. Largest Color Value in a Directed Graph

Hard · Graph, Topological Sort, Memoization, Hash Table, String, Dynamic Programming, Counting, Directed Acyclic Graph

leetcode.com/problems/largest-color-value-in-a-directed-graph

★ **TOP 10 PROBLEM** in Topological Sort: master this one first

PROBLEM

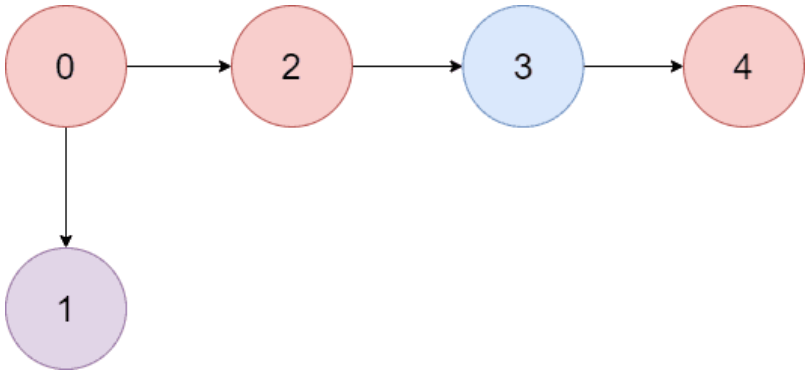
There is a **directed graph** of `n` colored nodes and `m` edges. The nodes are numbered from `0` to `n - 1`.

You are given a string `colors` where `colors[i]` is a lowercase English letter representing the **color** of the i^{th} node in this graph (**0-indexed**). You are also given a 2D array `edges` where `edges[j] = [a_j, b_j]` indicates that there is a **directed edge** from node a_j to node b_j.

A valid **path** in the graph is a sequence of nodes $x_1 \to x_2 \to x_3 \to \ldots \to x_k$ such that there is a directed edge from x_i to x_{i+1} for every $1 \le i < k$. The **color value** of the path is the number of nodes that are colored the **most frequently** occurring color along that path.

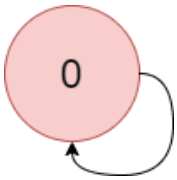
Return *the **largest color value** of any valid path in the given graph, or* `-1` *if the graph contains a cycle*.

Example 1:



```
Input: colors = "abaca", edges = [[0,1],[0,2],[2,3],[3,4]]
Output: 3
Explanation: The path 0 -> 2 -> 3 -> 4 contains 3 nodes that are colored "a" (red in the above image).
```

Example 2:



```
Input: colors = "a", edges = [[0,0]]
Output: -1
Explanation: There is a cycle from 0 to 0.
```

Constraints:

- `n == colors.length`
- `m == edges.length`
- `1 <= n <= 10^5`
- `0 <= m <= 10^5`
- `colors` consists of lowercase English letters.
- `0 <= a_j, b_j < n`

SOLUTION (PYTHON 3)

Solution 1: Topological Sort + Dynamic Programming

How to think about it

We need the maximum count of any single color on a directed path, or -1 if a cycle exists. There are exponentially many paths and $n,m \leq 10^5$. A topological order processes a node after all predecessors. dp[i][c] is the best count of color c on a path ending at i; we take a coordinate-wise maximum over in-edges and add the node's own color. If fewer than n nodes leave the queue, the graph has a cycle.

Calculate the in-degree of each node and perform a topological sort.

Define a 2D array dp, where dp[i][j] represents the number of nodes with color j on the path from the start node to node i.

From node i, traverse all outgoing edges i → j, and update dp[j][k] = max(dp[j][k], dp[i][k] + (c == k)), where c is the color of node j.

The answer is the maximum value in the dp array.

If there is a cycle in the graph, it is impossible to visit all nodes, so return -1.

The time complexity is O((n + m) × |Σ|), and the space complexity is O(m + n × |Σ|). Here, |Σ| is the size of the alphabet (26 in this case), and n and m are the number of nodes and edges, respectively.

Python 3

```python
class Solution:
    def largestPathValue(self, colors: str, edges: List[List[int]]) -> int:
        n = len(colors)
        indeg = [0] * n
        g = defaultdict(list)
        for a, b in edges:
            g[a].append(b)
            indeg[b] += 1
        q = deque()
        dp = [[0] * 26 for _ in range(n)]
        for i, v in enumerate(indeg):
            if v == 0:
                q.append(i)
                c = ord(colors[i]) - ord('a')
                dp[i][c] += 1
        cnt = 0
        ans = 1
        while q:
            i = q.popleft()
            cnt += 1
            for j in g[i]:
                indeg[j] -= 1
                if indeg[j] == 0:
                    q.append(j)
                c = ord(colors[j]) - ord('a')
                for k in range(26):
                    dp[j][k] = max(dp[j][k], dp[i][k] + (c == k))
                    ans = max(ans, dp[j][k])
        return -1 if cnt < n else ans
```

2127. Maximum Employees to Be Invited to a Meeting

Hard · Depth-First Search, Graph, Topological Sort, Array, Dynamic Programming, Kosaraju, Tarjan

leetcode.com/problems/maximum-employees-to-be-invited-to-a-meeting

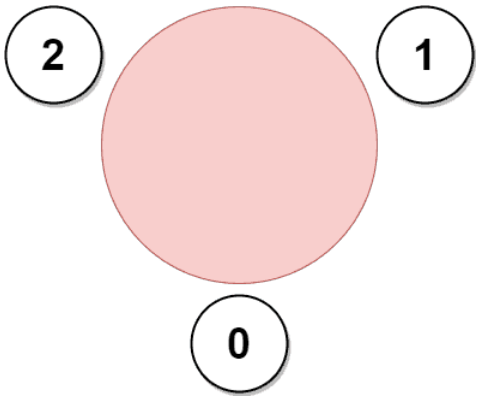
PROBLEM

A company is organizing a meeting and has a list of `n` employees, waiting to be invited. They have arranged for a large **circular** table, capable of seating **any number** of employees.

The employees are numbered from `0` to `n - 1`. Each employee has a **favorite** person and they will attend the meeting **only if** they can sit next to their favorite person at the table. The favorite person of an employee is **not** themself.

Given a **0-indexed** integer array `favorite`, where `favorite[i]` denotes the favorite person of the i^{th} employee, return *the **maximum number of employees** that can be invited to the meeting*.

Example 1:

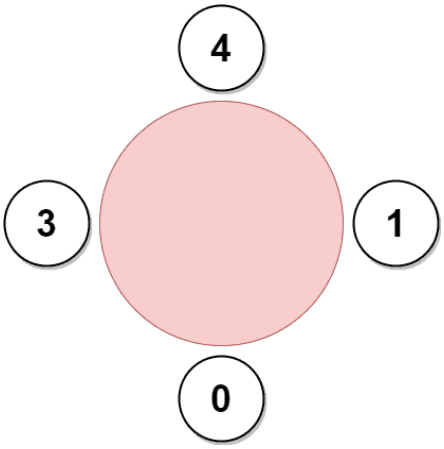


```
Input: favorite = [2,2,1,2]
Output: 3
Explanation:
The above figure shows how the company can invite employees 0, 1, and 2, and seat them at the round
table.
All employees cannot be invited because employee 2 cannot sit beside employees 0, 1, and 3,
simultaneously.
Note that the company can also invite employees 1, 2, and 3, and give them their desired seats.
The maximum number of employees that can be invited to the meeting is 3.
```

Example 2:

```
Input: favorite = [1,2,0]
Output: 3
Explanation:
Each employee is the favorite person of at least one other employee, and the only way the company can
invite them is if they invite every employee.
The seating arrangement will be the same as that in the figure given in example 1:
- Employee 0 will sit between employees 2 and 1.
- Employee 1 will sit between employees 0 and 2.
- Employee 2 will sit between employees 1 and 0.
The maximum number of employees that can be invited to the meeting is 3.
```

Example 3:



```
Input: favorite = [3,0,1,4,1]
Output: 4
Explanation:
The above figure shows how the company will invite employees 0, 1, 3, and 4, and seat them at the round table.
Employee 2 cannot be invited because the two spots next to their favorite employee 1 are taken.
So the company leaves them out of the meeting.
The maximum number of employees that can be invited to the meeting is 4.
```

Constraints:

- `n == favorite.length`
- `2 <= n <= 10^5`
- `0 <= favorite[i] <= n - 1`
- `favorite[i] != i`

SOLUTION (PYTHON 3)

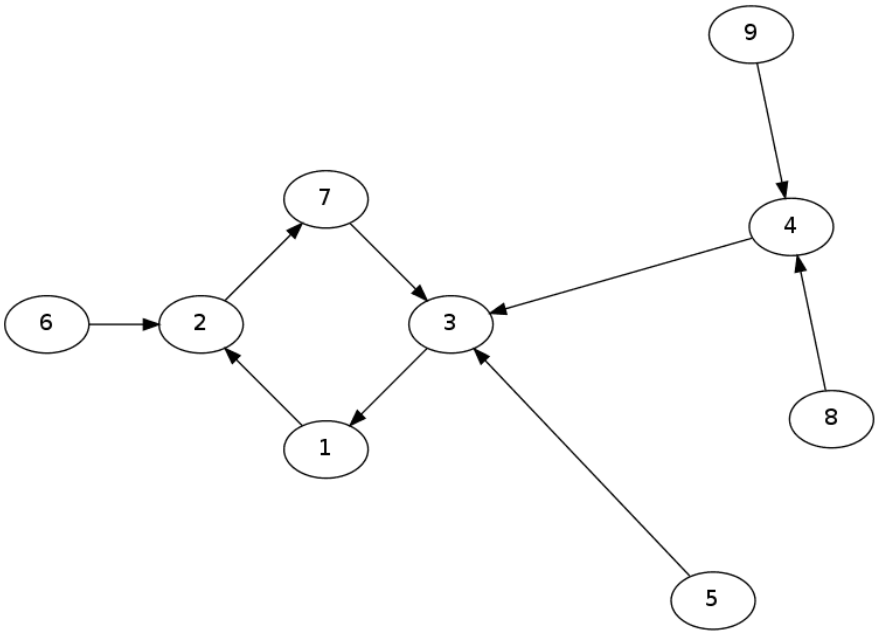
Solution 1: Maximum Cycle in Graph + Longest Chain

How to think about it

Each employee likes exactly one other person, so the graph is a disjoint union of inward rooted cycle-trees. A circular table requires mutual likes between neighbors: either a single cycle, or length-2 mutual pairs with incoming chains attached. Distinct cycles cannot be mixed. A cycle of length at least 3 can contribute only itself, so one candidate is the longest cycle. All 2-cycles may sit together, each extended by the longest incoming chain, which topological peeling computes as distances. We therefore take the maximum of the longest cycle and the sum of distances on all mutual pairs.

We observe that the employee's preference relationship in the problem can be regarded as a directed graph, which can be divided into multiple "base cycle inward trees". Each structure contains a cycle, and each node on the cycle is connected to a tree.

What is a "base cycle inward tree"? First, a base cycle tree is a directed graph with n nodes and n edges, and an inward tree means that in this directed graph, each node has exactly one outgoing edge. In this problem, each employee has exactly one favorite employee, so the constructed directed graph can be composed of multiple "base cycle inward trees".



For this problem, we can find the length of the maximum cycle in the graph. Here we only need to find the length of the largest cycle, because if there are multiple cycles, they are not connected to each other, which does not meet the problem requirements.

In addition, for the size of the cycle equal to 2, that is, there are two employees who like each other, then we can arrange these two employees together. If these two employees are each liked by other employees, then we only need to arrange the employees who like them next to them. If there are multiple such situations, we can arrange them all.

Therefore, the problem is actually equivalent to finding the length of the maximum cycle in the graph, and all cycles of length 2 plus their longest chain. The maximum of these two can be found. To find the longest chain to the cycle of length 2, we can use topological sorting.

The time complexity is O(n), and the space complexity is O(n). Here, n is the length of the array `favorite`.

Python 3

```python
class Solution:
    def maximumInvitations(self, favorite: List[int]) -> int:
        def max_cycle(fa: List[int]) -> int:
            n = len(fa)
            vis = [False] * n
            ans = 0
            for i in range(n):
                if vis[i]:
                    continue
                cycle = []
                j = i
                while not vis[j]:
                    cycle.append(j)
                    vis[j] = True
                    j = fa[j]
                for k, v in enumerate(cycle):
                    if v == j:
                        ans = max(ans, len(cycle) - k)
                        break
            return ans

        def topological_sort(fa: List[int]) -> int:
            n = len(fa)
            indeg = [0] * n
            dist = [1] * n
            for v in fa:
                indeg[v] += 1
            q = deque(i for i, v in enumerate(indeg) if v == 0)
            while q:
                i = q.popleft()
                dist[fa[i]] = max(dist[fa[i]], dist[i] + 1)
                indeg[fa[i]] -= 1
                if indeg[fa[i]] == 0:
                    q.append(fa[i])
            return sum(dist[i] for i, v in enumerate(fa) if i == fa[fa[i]])

        return max(max_cycle(favorite), topological_sort(favorite))
```

1591. Strange Printer II

Hard · Graph, Topological Sort, Array, Directed Acyclic Graph, Matrix

leetcode.com/problems/strange-printer-ii

PROBLEM

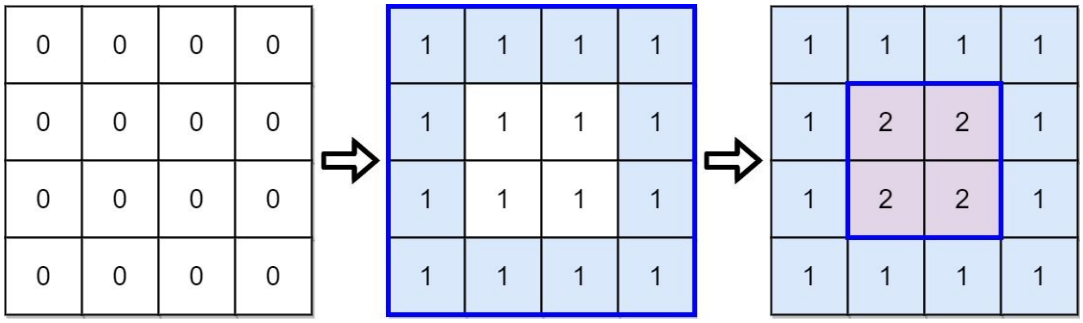
There is a strange printer with the following two special requirements:

- On each turn, the printer will print a solid rectangular pattern of a single color on the grid. This will cover up the existing colors in the rectangle.
- Once the printer has used a color for the above operation, **the same color cannot be used again**.

You are given a `m x n` matrix `targetGrid`, where `targetGrid[row][col]` is the color in the position `(row, col)` of the grid.

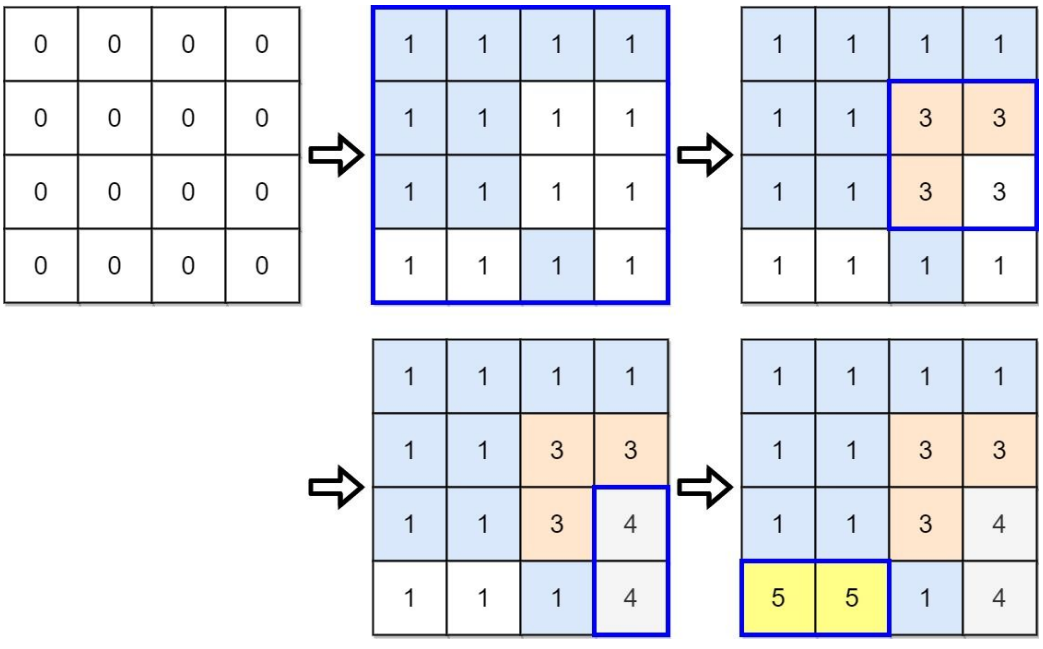
Return `true` *if it is possible to print the matrix* `targetGrid`*, otherwise, return* `false`.

Example 1:



```
Input: targetGrid = [[1,1,1,1],[1,2,2,1],[1,2,2,1],[1,1,1,1]]
Output: true
```

Example 2:



```
Input: targetGrid = [[1,1,1,1],[1,1,3,3],[1,1,3,4],[5,5,1,4]]
Output: true
```

Example 3:

```
Input: targetGrid = [[1,2,1],[2,1,2],[1,2,1]]
Output: false
Explanation: It is impossible to form targetGrid because it is not allowed to print the same color in
different turns.
```

Constraints:

- `m == targetGrid.length`
- `n == targetGrid[i].length`
- `1 <= m, n <= 60`
- `1 <= targetGrid[row][col] <= 60`

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Each print lays down a fresh color as a rectangle that cannot be reused. The same color must occupy its bounding box, and later colors overwrite cells inside that box. For every color take the min/max row and column. Any other color c' inside that rectangle must have been printed later, so we add an edge c→ c'. The instance is printable iff this constraint graph is acyclic, which a topological sort decides.

Python 3 (written for this guide: the doocs page has an empty Python tab)

```python
class Solution:
    def isPrintable(self, targetGrid: List[List[int]]) -> bool:
        m, n = len(targetGrid), len(targetGrid[0])
        # bounding rectangle of every colour: [top, left, bottom, right]
        box = {}
        for i in range(m):
            for j in range(n):
                c = targetGrid[i][j]
                if c not in box:
                    box[c] = [i, j, i, j]
                else:
                    b = box[c]
                    b[0] = min(b[0], i)
                    b[1] = min(b[1], j)
                    b[2] = max(b[2], i)
                    b[3] = max(b[3], j)
        # edge a -> b: colour b appears inside the rectangle of a, so a must be printed BEFORE b
        after = {c: set() for c in box}
        indeg = {c: 0 for c in box}
        for a, (top, left, bottom, right) in box.items():
            for i in range(top, bottom + 1):
                for j in range(left, right + 1):
                    b = targetGrid[i][j]
                    if b != a and b not in after[a]:
                        after[a].add(b)
                        indeg[b] += 1
        # Kahn's algorithm: the order exists exactly when there is no cycle
        queue = [c for c in box if indeg[c] == 0]
        taken = 0
        while queue:
            a = queue.pop()
            taken += 1
            for b in after[a]:
                indeg[b] -= 1
                if indeg[b] == 0:
                    queue.append(b)
        return taken == len(box)
```

Complexity. Time: O(C * m * n), C = number of colours. Space: O(C^2).

2360. Longest Cycle in a Graph

Hard · Depth-First Search, Breadth-First Search, Graph, Topological Sort, Kosaraju, Tarjan

leetcode.com/problems/longest-cycle-in-a-graph

PROBLEM

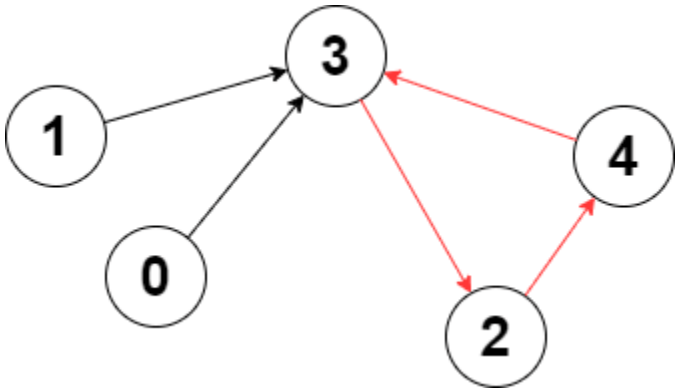
You are given a **directed** graph of `n` nodes numbered from `0` to `n - 1`, where each node has **at most one** outgoing edge.

The graph is represented with a given **0-indexed** array `edges` of size `n`, indicating that there is a directed edge from node `i` to node `edges[i]`. If there is no outgoing edge from node `i`, then `edges[i] == -1`.

Return *the length of the **longest** cycle in the graph*. If no cycle exists, return `-1`.

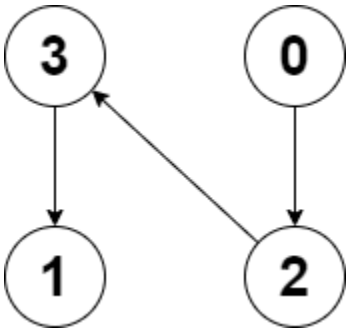
A cycle is a path that starts and ends at the **same** node.

Example 1:



```
Input: edges = [3,3,4,2,3]
Output: 3
Explanation: The longest cycle in the graph is the cycle: 2 -> 4 -> 3 -> 2.
The length of this cycle is 3, so 3 is returned.
```

Example 2:



```
Input: edges = [2,-1,3,1]
Output: -1
Explanation: There are no cycles in this graph.
```

Constraints:

- `n == edges.length`
- `2 <= n <= 10^5`
- `-1 <= edges[i] < n`
- `edges[i] != i`

SOLUTION (PYTHON 3)

Solution 1: Traverse Starting Points

> **How to think about it**
>
> Each node has at most one outgoing edge, so the graph is paths into cycles. n ≤ 10^5; walk the unique successor from every unvisited node. Mark nodes and record the path. Stopping at -1 means no cycle; stopping on a node of this path yields a cycle from that index to the end. Track the longest such length.

We can traverse each node in the range [0,..,n-1]. If a node has not been visited, we start from this node and search for adjacent nodes until we encounter a cycle or a node that has already been visited. If we encounter a cycle, we update the answer.

The time complexity is O(n) and the space complexity is O(n), where n is the number of nodes.

PATTERN 31 OF 41

Union-Find (Disjoint Set)

20 problems · 1 Easy · 13 Medium · 6 Hard

THE IDEA

Merge pairs into groups and ask who is together, in almost O(1) per operation, using path compression and union by size.

Signals: number of provinces, redundant connection, accounts merge, connected components with edges arriving, smallest string with swaps.

A TEMPLATE TO KEEP IN YOUR HANDS (PYTHON)

```
parent = list(range(n))
def find(x):
    while parent[x] != x:
        parent[x] = parent[parent[x]]      # path halving
        x = parent[x]
    return x
def union(a, b):
    ra, rb = find(a), find(b)
    if ra == rb:
        return False                       # already together (a cycle)
    parent[ra] = rb
    return True
```

PATTERN 31 · UNION-FIND (DISJOINT SET) · PROBLEM 1 OF 20

1971. Find if Path Exists in Graph

Easy · Depth-First Search, Breadth-First Search, Union Find, Graph

leetcode.com/problems/find-if-path-exists-in-graph

★ **TOP 10 PROBLEM** in Union-Find (Disjoint Set): master this one first

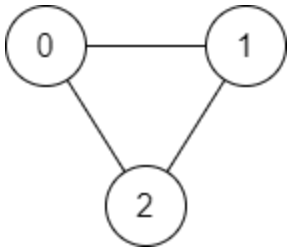
PROBLEM

There is a **bi-directional** graph with `n` vertices, where each vertex is labeled from `0` to `n - 1` (**inclusive**). The edges in the graph are represented as a 2D integer array `edges`, where each `edges[i] = [u_i, v_i]` denotes a bi-directional edge between vertex `u_i` and vertex `v_i`. Every vertex pair is connected by **at most one** edge, and no vertex has an edge to itself.

You want to determine if there is a **valid path** that exists from vertex `source` to vertex `destination`.

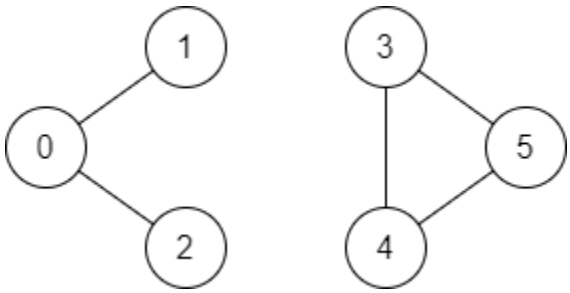
Given `edges` and the integers `n`, `source`, and `destination`, return `true` *if there is a* ***valid path*** *from* `source` *to* `destination`*, or* `false` *otherwise.*

Example 1:



```
Input: n = 3, edges = [[0,1],[1,2],[2,0]], source = 0, destination = 2
Output: true
Explanation: There are two paths from vertex 0 to vertex 2:
- 0 → 1 → 2
- 0 → 2
```

Example 2:



```
Input: n = 6, edges = [[0,1],[0,2],[3,5],[5,4],[4,3]], source = 0, destination = 5
Output: false
Explanation: There is no path from vertex 0 to vertex 5.
```

Constraints:

- `1 <= n <= 2 * 10^5`
- `0 <= edges.length <= 2 * 10^5`
- `edges[i].length == 2`
- `0 <= u_i, v_i <= n - 1`
- `u_i != v_i`
- `0 <= source, destination <= n - 1`
- There are no duplicate edges.

- There are no self edges.

SOLUTIONS (PYTHON 3)

Solution 1: DFS

> **How to think about it**
>
> We only need connectivity between two vertices. After building the adjacency lists, DFS with a visited set reports success on reaching the destination, in linear time.

We first convert edges into an adjacency list g, then use DFS to determine whether there is a path from source to destination.

During the process, we use an array vis to record the vertices that have already been visited to avoid revisiting them.

The time complexity is O(n + m), and the space complexity is O(n + m). Here, n and m are the number of nodes and edges, respectively.

Python 3

```
class Solution:
    def validPath(
        self, n: int, edges: List[List[int]], source: int, destination: int
    ) -> bool:
        def dfs(i: int) -> bool:
            if i == destination:
                return True
            vis.add(i)
            for j in g[i]:
                if j not in vis and dfs(j):
                    return True
            return False

        g = [[] for _ in range(n)]
        for u, v in edges:
            g[u].append(v)
            g[v].append(u)
        vis = set()
        return dfs(source)
```

Solution 2: BFS

> **How to think about it**
>
> Method 1 expands with an explicit stack in depth-first order. A queue expands level by level with the same visited marks: the source is enqueued, and a dequeued vertex that is the destination succeeds. Unvisited neighbors are enqueued. An empty queue means the destination is unreachable.

We can also use BFS to determine whether there is a path from source to destination.

Specifically, we define a queue q, initially adding source to the queue. Additionally, we use a set vis to record the vertices that have already been visited to avoid revisiting them.

Next, we continuously take vertices i from the queue. If i = destination, it means there is a path from source to destination, and we return true. Otherwise, we traverse all adjacent vertices j of i. If j has not been visited, we add j to the queue q and mark j as visited.

Finally, if the queue is empty, it means there is no path from source to destination, and we return false.

The time complexity is O(n + m), and the space complexity is O(n + m). Here, n and m are the number of nodes and edges, respectively.

Python 3

```python
class Solution:
    def validPath(
        self, n: int, edges: List[List[int]], source: int, destination: int
    ) -> bool:
        g = [[] for _ in range(n)]
        for u, v in edges:
            g[u].append(v)
            g[v].append(u)
        q = deque([source])
        vis = {source}
        while q:
            i = q.popleft()
            if i == destination:
                return True
            for j in g[i]:
                if j not in vis:
                    vis.add(j)
                    q.append(j)
        return False
```

Solution 3: Union-Find

> **How to think about it**
>
> When the path itself is unused, union-find merges every edge and compares the two roots. There is no walk over the graph.

Union-Find is a tree-like data structure that, as the name suggests, is used to handle some disjoint set **merge** and **query** problems. It supports two operations:

1. Find: Determine which subset an element belongs to. The time complexity of a single operation is O(α(n)).
2. Union: Merge two subsets into one set. The time complexity of a single operation is O(α(n)).

For this problem, we can use the Union-Find set to merge the edges in `edges`, and then determine whether `source` and `destination` are in the same set.

The time complexity is O(n log n + m) or O(n α(n) + m), and the space complexity is O(n). Where n and m are the number of nodes and edges, respectively.

Python 3

```python
class UnionFind:
    def __init__(self, n):
        self.p = list(range(n))
        self.size = [1] * n

    def find(self, x):
        if self.p[x] != x:
            self.p[x] = self.find(self.p[x])
        return self.p[x]

    def union(self, a, b):
        pa, pb = self.find(a), self.find(b)
        if pa == pb:
            return False
        if self.size[pa] > self.size[pb]:
            self.p[pb] = pa
            self.size[pa] += self.size[pb]
        else:
            self.p[pa] = pb
            self.size[pb] += self.size[pa]
        return True

class Solution:
    def validPath(
        self, n: int, edges: List[List[int]], source: int, destination: int
    ) -> bool:
        uf = UnionFind(n)
        for u, v in edges:
            uf.union(u, v)
        return uf.find(source) == uf.find(destination)
```

Solution 4: Explicit Stack

How to think about it

We only need connectivity between two vertices. With $n \le 2 \times 10^5$, an adjacency-list walk with a visited mark reports success on reaching the destination, in linear time. Recursing from the source into each neighbor reaches depth n on a chain and overflows the call stack. Connectivity does not depend on the order of neighbors. An explicit stack therefore returns immediately when the source is the destination. Otherwise a vertex is marked when it is pushed. After a pop, a neighbor that is the destination succeeds, and only unmarked neighbors are pushed. An empty stack means the destination is unreachable.

We first convert edges into an adjacency list g. If source is destination, we return true immediately. Otherwise an explicit stack starts at the source: a vertex is recorded in vis when it is pushed, a neighbor that is the destination returns true, and only unmarked neighbors are pushed. An empty stack means there is no path.

The time complexity is O(n + m), and the space complexity is O(n + m). Here, n and m are the number of nodes and edges, respectively.

Python 3

```
class Solution:
    def validPath(
        self, n: int, edges: List[List[int]], source: int, destination: int
    ) -> bool:
        if source == destination:
            return True
        g = [[] for _ in range(n)]
        for u, v in edges:
            g[u].append(v)
            g[v].append(u)
        vis = [False] * n
        vis[source] = True
        stk = [source]
        while stk:
            i = stk.pop()
            for j in g[i]:
                if j == destination:
                    return True
                if not vis[j]:
                    vis[j] = True
                    stk.append(j)
        return False
```

                queue.append(nxt)
    return -1
```

PATTERN 31 · UNION-FIND (DISJOINT SET) · PROBLEM 3 OF 20

684. Redundant Connection

Medium · Depth-First Search, Breadth-First Search, Union Find, Graph

leetcode.com/problems/redundant-connection

★ **TOP 10 PROBLEM** in Union-Find (Disjoint Set): master this one first

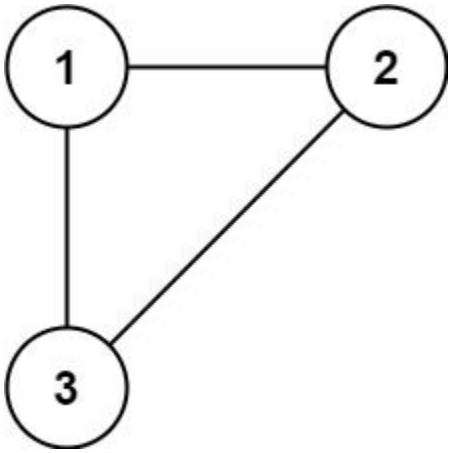
PROBLEM

In this problem, a tree is an **undirected graph** that is connected and has no cycles.

You are given a graph that started as a tree with `n` nodes labeled from `1` to `n`, with one additional edge added. The added edge has two **different** vertices chosen from `1` to `n`, and was not an edge that already existed. The graph is represented as an array `edges` of length `n` where `edges[i] = [a_i, b_i]` indicates that there is an edge between nodes a_i and b_i in the graph.

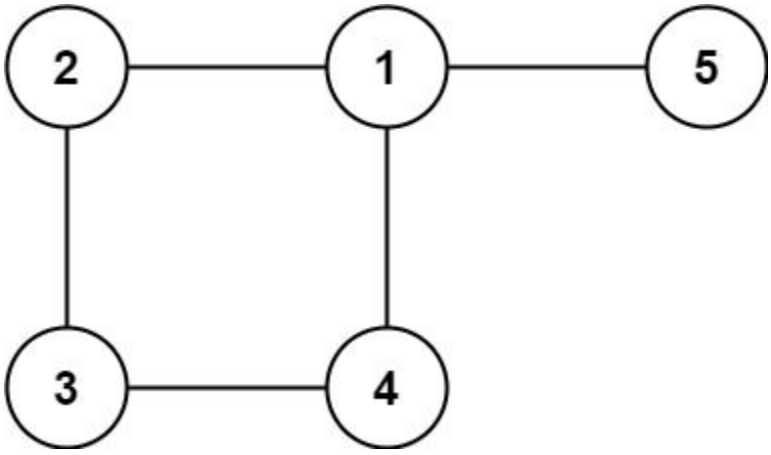
Return *an edge that can be removed so that the resulting graph is a tree of* `n` *nodes*. If there are multiple answers, return the answer that occurs last in the input.

Example 1:



```
Input: edges = [[1,2],[1,3],[2,3]]
Output: [2,3]
```

Example 2:



```
Input: edges = [[1,2],[2,3],[3,4],[1,4],[1,5]]
Output: [1,4]
```

Constraints:

- `n == edges.length`
- `3 <= n <= 1000`
- `edges[i].length == 2`
- `1 <= a_i < b_i <= edges.length`
- `a_i != b_i`
- There are no repeated edges.
- The given graph is connected.

SOLUTIONS (PYTHON 3)

Solution 1: Union-Find

> **How to think about it**
>
> An undirected tree plus one extra edge; delete the last extra edge in the input. Finding the cycle and ranking edges is heavier than needed. Union-Find the edges in order. The first pair already in one component is the redundant edge.

According to the problem description, we need to find an edge that can be removed so that the remaining part is a tree with n nodes. We can traverse each edge and determine whether the two nodes of this edge are in the same connected component. If they are in the same connected component, it means this edge is redundant and can be removed, so we directly return this edge. Otherwise, we merge the two nodes connected by this edge into the same connected component.

The time complexity is O(n log n), and the space complexity is O(n). Here, n is the number of edges.

Python 3

```
class Solution:
    def findRedundantConnection(self, edges: List[List[int]]) -> List[int]:
        def find(x: int) -> int:
            if p[x] != x:
                p[x] = find(p[x])
            return p[x]

        p = list(range(len(edges)))
        for a, b in edges:
            pa, pb = find(a - 1), find(b - 1)
            if pa == pb:
                return [a, b]
            p[pa] = pb
```

Solution 2: Union-Find (Template Approach)

> **How to think about it**
>
> Method 1 inlines `find`. A `UnionFind` with union-by-size returns success/failure; the first failed union is the same edge, with slightly better constants.

Here is a template approach using Union-Find for your reference.

The time complexity is O(n α(n)), and the space complexity is O(n). Here, n is the number of edges, and α(n) is the inverse Ackermann function, which can be considered a very small constant.

Python 3

```python
class UnionFind:
    __slots__ = "p", "size"

    def __init__(self, n: int):
        self.p: List[int] = list(range(n))
        self.size: List[int] = [1] * n

    def find(self, x: int) -> int:
        if self.p[x] != x:
            self.p[x] = self.find(self.p[x])
        return self.p[x]

    def union(self, a: int, b: int) -> bool:
        pa, pb = self.find(a), self.find(b)
        if pa == pb:
            return False
        if self.size[pa] > self.size[pb]:
            self.p[pb] = pa
            self.size[pa] += self.size[pb]
        else:
            self.p[pa] = pb
            self.size[pb] += self.size[pa]
        return True

class Solution:
    def findRedundantConnection(self, edges: List[List[int]]) -> List[int]:
        uf = UnionFind(len(edges))
        for a, b in edges:
            if not uf.union(a - 1, b - 1):
                return [a, b]
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

Built on the solutions above: helper functions, then the function for each follow-up. No tests and no restating of the question.

```python
# FOLLOW-UPS (answered below, in this order):

# are there
# ============================================================

# ---- follow-up 2: function ----
# Answer: Start with n groups and subtract one for each
# union that really joins two groups.
# Time: O(n + e * alpha(n)).  Space: O(n).
def groups_after_each_edge(n, edges):
    parent = list(range(n + 1))

    def find(x):
        while parent[x] != x:
            parent[x] = parent[parent[x]]
            x = parent[x]
        return x

    groups = n
    result = []
    for a, b in edges:
        ra, rb = find(a), find(b)
        if ra != rb:
            parent[ra] = rb
            groups -= 1
        result.append(groups)
    return result
```

721. Accounts Merge

Medium · Depth-First Search, Breadth-First Search, Union Find, Array, Hash Table, String, Sorting

leetcode.com/problems/accounts-merge

★ **TOP 10 PROBLEM** in Union-Find (Disjoint Set): master this one first

PROBLEM

Given a list of `accounts` where each element `accounts[i]` is a list of strings, where the first element `accounts[i][0]` is a name, and the rest of the elements are **emails** representing emails of the account.

Now, we would like to merge these accounts. Two accounts definitely belong to the same person if there is some common email to both accounts. Note that even if two accounts have the same name, they may belong to different people as people could have the same name. A person can have any number of accounts initially, but all of their accounts definitely have the same name.

After merging the accounts, return the accounts in the following format: the first element of each account is the name, and the rest of the elements are emails **in sorted order**. The accounts themselves can be returned in **any order**.

Example 1:

```
Input: accounts = [["John","johnsmith@mail.com","john_newyork@mail.com"],["John","johnsmith@mail.com",
"john00@mail.com"],["Mary","mary@mail.com"],["John","johnnybravo@mail.com"]]
Output: [["John","john00@mail.com","john_newyork@mail.com","johnsmith@mail.com"],["Mary","mary@mail.co
m"],["John","johnnybravo@mail.com"]]
Explanation:
The first and second John's are the same person as they have the common email "johnsmith@mail.com".
The third John and Mary are different people as none of their email addresses are used by other
accounts.
We could return these lists in any order, for example the answer [['Mary', 'mary@mail.com'], ['John',
'johnnybravo@mail.com'],
['John', 'john00@mail.com', 'john_newyork@mail.com', 'johnsmith@mail.com']] would still be accepted.
```

Example 2:

```
Input: accounts = [["Gabe","Gabe0@m.co","Gabe3@m.co","Gabe1@m.co"],["Kevin","Kevin3@m.co","Kevin5@m.co
","Kevin0@m.co"],["Ethan","Ethan5@m.co","Ethan4@m.co","Ethan0@m.co"],["Hanzo","Hanzo3@m.co","Hanzo1@m.
co","Hanzo0@m.co"],["Fern","Fern5@m.co","Fern1@m.co","Fern0@m.co"]]
Output: [["Ethan","Ethan0@m.co","Ethan4@m.co","Ethan5@m.co"],["Gabe","Gabe0@m.co","Gabe1@m.co","Gabe3@
m.co"],["Hanzo","Hanzo0@m.co","Hanzo1@m.co","Hanzo3@m.co"],["Kevin","Kevin0@m.co","Kevin3@m.co","Kevin
5@m.co"],["Fern","Fern0@m.co","Fern1@m.co","Fern5@m.co"]]
```

Constraints:

- `1 <= accounts.length <= 1000`
- `2 <= accounts[i].length <= 10`
- `1 <= accounts[i][j].length <= 30`
- `accounts[i][0]` consists of English letters.
- `accounts[i][j] (for j > 0)` is a valid email.

SOLUTION (PYTHON 3)

Solution 1: Union-Find + Hash Table

> **How to think about it**
>
> Accounts of the same person share emails and must be merged, then sorted. About 1000 accounts makes pairwise set comparison awkward, and names must stay attached. The connectivity is among accounts: two indices join if they share an email. Union-find on account ids, plus a map from email to the first account that used it, finds those edges. Group emails by root, take the root account's name, and sort. Path compression keeps the cost near linearithmic.

Based on the problem description, we can use a union-find data structure to merge accounts with the same email address. The specific steps are as follows:

First, we iterate through all the accounts. For the ith account, we iterate through all its email addresses. If an email address appears in the hash table d, we use the union-find to merge the account's index i with the previously appeared account's index; otherwise, we map this email address to the account's index i.

Next, we iterate through all the accounts again. For the ith account, we use the union-find to find its root node, and then add all the email addresses of that account to the hash table g, where the key is the root node, and the value is the account's email addresses.

The time complexity is O(n × log n), and the space complexity is O(n). Here, n is the number of accounts.

Python 3

```python
class UnionFind:
    def __init__(self, n):
        self.p = list(range(n))
        self.size = [1] * n

    def find(self, x):
        if self.p[x] != x:
            self.p[x] = self.find(self.p[x])
        return self.p[x]

    def union(self, a, b):
        pa, pb = self.find(a), self.find(b)
        if pa == pb:
            return False
        if self.size[pa] > self.size[pb]:
            self.p[pb] = pa
            self.size[pa] += self.size[pb]
        else:
            self.p[pa] = pb
            self.size[pb] += self.size[pa]
        return True

class Solution:
    def accountsMerge(self, accounts: List[List[str]]) -> List[List[str]]:
        uf = UnionFind(len(accounts))
        d = {}
        for i, (_, *emails) in enumerate(accounts):
            for email in emails:
                if email in d:
                    uf.union(i, d[email])
                else:
                    d[email] = i
        g = defaultdict(set)
        for i, (_, *emails) in enumerate(accounts):
            root = uf.find(i)
            g[root].update(emails)
        return [[accounts[root][0]] + sorted(emails) for root, emails in g.items()]
```

PATTERN 31 · UNION-FIND (DISJOINT SET) · PROBLEM 6 OF 20

1319. Number of Operations to Make Network Connected

Medium · Depth-First Search, Breadth-First Search, Union Find, Graph

leetcode.com/problems/number-of-operations-to-make-network-connected

★ **TOP 10 PROBLEM** in Union-Find (Disjoint Set): master this one first

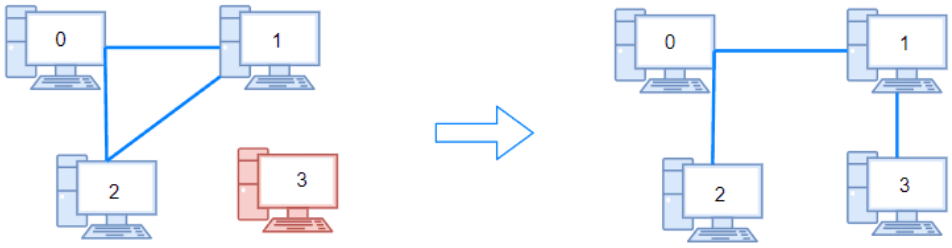
PROBLEM

There are `n` computers numbered from `0` to `n - 1` connected by ethernet cables `connections` forming a network where `connections[i] = [a_i, b_i]` represents a connection between computers `a_i` and `b_i`. Any computer can reach any other computer directly or indirectly through the network.

You are given an initial computer network `connections`. You can extract certain cables between two directly connected computers, and place them between any pair of disconnected computers to make them directly connected.

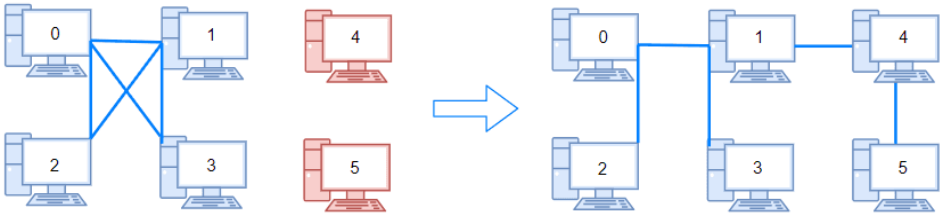
Return *the minimum number of times you need to do this in order to make all the computers connected*. If it is not possible, return `-1`.

Example 1:



```
Input: n = 4, connections = [[0,1],[0,2],[1,2]]
Output: 1
Explanation: Remove cable between computer 1 and 2 and place between computers 1 and 3.
```

Example 2:



```
Input: n = 6, connections = [[0,1],[0,2],[0,3],[1,2],[1,3]]
Output: 2
```

Example 3:

```
Input: n = 6, connections = [[0,1],[0,2],[0,3],[1,2]]
Output: -1
Explanation: There are not enough cables.
```

Constraints:

- `1 <= n <= 10^5`
- `1 <= connections.length <= min(n * (n - 1) / 2, 10^5)`
- `connections[i].length == 2`

- $0 <= a_i, b_i < n$
- $a_i != b_i$
- There are no repeated connections.
- No two computers are connected by more than one cable.

SOLUTION (PYTHON 3)

Solution 1: Union-Find

> **How to think about it**
>
> We may move existing cables so n machines become one network. With n,m up to 10^5, rebuilding the graph is the wrong tool. k components need at least k-1 spare edges to become a tree. Union-find over the edges: a link inside one component is redundant, otherwise we merge and decrease k. If the spare count is below k-1 the answer is -1; otherwise it is k-1.

We can use a union-find data structure to maintain the connectivity between computers. Traverse all connections, and for each connection (a, b), if a and b are already connected, then this connection is redundant, and we increment the count of redundant connections. Otherwise, we connect a and b, and decrement the number of connected components.

Finally, if the number of connected components minus one is greater than the number of redundant connections, it means we cannot connect all computers, so we return -1. Otherwise, we return the number of connected components minus one.

The time complexity is O(m × log n), and the space complexity is O(n). Here, n and m are the number of computers and the number of connections, respectively.

Python 3

```python
class Solution:
    def makeConnected(self, n: int, connections: List[List[int]]) -> int:
        def find(x: int) -> int:
            if p[x] != x:
                p[x] = find(p[x])
            return p[x]

        cnt = 0
        p = list(range(n))
        for a, b in connections:
            pa, pb = find(a), find(b)
            if pa == pb:
                cnt += 1
            else:
                p[pa] = pb
                n -= 1
        return -1 if n - 1 > cnt else n - 1
```

```

990. Satisfiability of Equality Equations

Medium · Union Find, Graph, Array, String

leetcode.com/problems/satisfiability-of-equality-equations

PROBLEM

You are given an array of strings `equations` that represent relationships between variables where each string `equations[i]` is of length `4` and takes one of two different forms: "x_i==y_i" or "x_i!=y_i".Here, x_i and y_i are lowercase letters (not necessarily different) that represent one-letter variable names.

Return `true` *if it is possible to assign integers to variable names so as to satisfy all the given equations, or* `false` *otherwise*.

Example 1:

```
Input: equations = ["a==b","b!=a"]
Output: false
Explanation: If we assign say, a = 1 and b = 1, then the first equation is satisfied, but not the second.
There is no way to assign the variables to satisfy both equations.
```

Example 2:

```
Input: equations = ["b==a","a==b"]
Output: true
Explanation: We could assign a = 1 and b = 1 to satisfy both equations.
```

Constraints:

- `1 <= equations.length <= 500`
- `equations[i].length == 4`
- `equations[i][0]` is a lowercase letter.
- `equations[i][1]` is either `'='` or `'!'`.
- `equations[i][2]` is `'='`.
- `equations[i][3]` is a lowercase letter.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

A set of a==b / a!=b equations must be simultaneously possible. Equality is transitive, so those edges should be united first. Union-find merges every `==`, then each `!=` is checked; if both sides share a component, the system is impossible.

Python 3

```
class Solution:
    def equationsPossible(self, equations: List[str]) -> bool:
        def find(x):
            if p[x] != x:
                p[x] = find(p[x])
            return p[x]

        p = list(range(26))
        for e in equations:
            a, b = ord(e[0]) - ord('a'), ord(e[-1]) - ord('a')
            if e[1] == '=':
                p[find(a)] = find(b)
        for e in equations:
            a, b = ord(e[0]) - ord('a'), ord(e[-1]) - ord('a')
            if e[1] == '!' and find(a) == find(b):
                return False
        return True
```

Complexity. Time: O(n * alpha(26)), essentially O(n). Space: O(1) (26 letters).

PATTERN 31 · UNION-FIND (DISJOINT SET) · PROBLEM 8 OF 20

1202. Smallest String With Swaps

Medium · Depth-First Search, Breadth-First Search, Union Find, Array, Hash Table, String, Sorting

leetcode.com/problems/smallest-string-with-swaps

★ **TOP 10 PROBLEM** in Union-Find (Disjoint Set): master this one first

PROBLEM

You are given a string `s`, and an array of pairs of indices in the string `pairs` where `pairs[i] = [a, b]` indicates 2 indices(0-indexed) of the string.

You can swap the characters at any pair of indices in the given `pairs` **any number of times**.

Return the lexicographically smallest string that `s` can be changed to after using the swaps.

Example 1:

```
Input: s = "dcab", pairs = [[0,3],[1,2]]
Output: "bacd"
Explaination:
Swap s[0] and s[3], s = "bcad"
Swap s[1] and s[2], s = "bacd"
```

Example 2:

```
Input: s = "dcab", pairs = [[0,3],[1,2],[0,2]]
Output: "abcd"
Explaination:
Swap s[0] and s[3], s = "bcad"
Swap s[0] and s[2], s = "acbd"
Swap s[1] and s[2], s = "abcd"
```

Example 3:

```
Input: s = "cba", pairs = [[0,1],[1,2]]
Output: "abc"
Explaination:
Swap s[0] and s[1], s = "bca"
Swap s[1] and s[2], s = "bac"
Swap s[0] and s[1], s = "abc"
```

Constraints:

- `1 <= s.length <= 10^5`
- `0 <= pairs.length <= 10^5`
- `0 <= pairs[i][0], pairs[i][1] < s.length`
- `s` only contains lower case English letters.

SOLUTION (PYTHON 3)

Solution 1: Union-Find

How to think about it

Trying all permutations of each swap is infeasible when both n and |pairs| reach 10^5. Swaps are transitive: indices form connected components, and characters inside a component may be rearranged freely. The lexicographically smallest string fills each component's indices with its characters in increasing order. Union-find builds the components; we collect characters by root, sort them in reverse, then pop the smallest character back to each index. Union-find identifies the groups; sorting supplies the optimal fill order.

We notice that the index pairs have transitivity, i.e., if a and b can be swapped, and b and c can be swapped, then a and c can also be swapped. Therefore, we can consider using a union-find data structure to maintain the connectivity of these index pairs, and sort the characters belonging to the same connected component in lexicographical order.

Finally, we traverse the string. For the character at the current position, we replace it with the smallest character in the connected component, then remove this character from the connected component, and continue to traverse the string.

The time complexity is O(n × log n + m × α(m)), and the space complexity is O(n). Here, n and m are the length of the string and the number of index pairs, respectively, and α is the inverse Ackermann function.

Python 3

```
class Solution:
    def smallestStringWithSwaps(self, s: str, pairs: List[List[int]]) -> str:
        def find(x: int) -> int:
            if p[x] != x:
                p[x] = find(p[x])
            return p[x]

        n = len(s)
        p = list(range(n))
        for a, b in pairs:
            p[find(a)] = find(b)
        d = defaultdict(list)
        for i, c in enumerate(s):
            d[find(i)].append(c)
        for i in d.keys():
            d[i].sort(reverse=True)
        return "".join(d[find(i)].pop() for i in range(n))
```

1061. Lexicographically Smallest Equivalent String

Medium · Union Find, String

leetcode.com/problems/lexicographically-smallest-equivalent-string

PROBLEM

You are given two strings of the same length `s1` and `s2` and a string `baseStr`.

We say `s1[i]` and `s2[i]` are equivalent characters.

- For example, if `s1 = "abc"` and `s2 = "cde"`, then we have `'a' == 'c'`, `'b' == 'd'`, and `'c' == 'e'`.

Equivalent characters follow the usual rules of any equivalence relation:

- **Reflexivity:** `'a' == 'a'`.
- **Symmetry:** `'a' == 'b'` implies `'b' == 'a'`.
- **Transitivity:** `'a' == 'b'` and `'b' == 'c'` implies `'a' == 'c'`.

For example, given the equivalency information from `s1 = "abc"` and `s2 = "cde"`, `"acd"` and `"aab"` are equivalent strings of `baseStr = "eed"`, and `"aab"` is the lexicographically smallest equivalent string of `baseStr`.

Return *the lexicographically smallest equivalent string of* `baseStr` *by using the equivalency information from* `s1` *and* `s2`.

Example 1:

```
Input: s1 = "parker", s2 = "morris", baseStr = "parser"
Output: "makkek"
Explanation: Based on the equivalency information in s1 and s2, we can group their characters as
[m,p], [a,o], [k,r,s], [e,i].
The characters in each group are equivalent and sorted in lexicographical order.
So the answer is "makkek".
```

Example 2:

```
Input: s1 = "hello", s2 = "world", baseStr = "hold"
Output: "hdld"
Explanation: Based on the equivalency information in s1 and s2, we can group their characters as
[h,w], [d,e,o], [l,r].
So only the second letter 'o' in baseStr is changed to 'd', the answer is "hdld".
```

Example 3:

```
Input: s1 = "leetcode", s2 = "programs", baseStr = "sourcecode"
Output: "aauaaaaada"
Explanation: We group the equivalent characters in s1 and s2 as [a,o,e,r,s,c], [l,p], [g,t] and [d,m],
thus all letters in baseStr except 'u' and 'd' are transformed to 'a', the answer is "aauaaaaada".
```

Constraints:

- `1 <= s1.length, s2.length, baseStr <= 1000`
- `s1.length == s2.length`
- `s1`, `s2`, and `baseStr` consist of lowercase English letters.

SOLUTION (PYTHON 3)

Solution 1: Union Find

How to think about it

Equivalence is transitive. Each letter of baseStr should become the smallest letter in its class. Twenty-six letters fit in a disjoint-set union. When uniting s1[i] and s2[i] we attach the larger root to the smaller one, so the representative is the lexicographically smallest character. Each character of baseStr is replaced by its root.

We can use Union Find (Disjoint Set Union, DSU) to handle the equivalence relations between characters. Each character can be regarded as a node, and the equivalence relations can be seen as edges connecting these nodes. With Union Find, we can group all equivalent characters together and quickly find the representative element for each character during queries. When performing union operations, we always set the representative element to be the lexicographically smallest character. This ensures that the final string is the lexicographically smallest equivalent string.

The time complexity is $O((n + m) \times \log |\Sigma|)$ and the space complexity is $O(|\Sigma|)$, where n is the length of strings s1 and s2, m is the length of baseStr, and $|\Sigma|$ is the size of the character set, which is 26 in this problem.

Python 3

```
class Solution:
    def smallestEquivalentString(self, s1: str, s2: str, baseStr: str) -> str:
        def find(x: int) -> int:
            if p[x] != x:
                p[x] = find(p[x])
            return p[x]

        p = list(range(26))
        for a, b in zip(s1, s2):
            x, y = ord(a) - ord("a"), ord(b) - ord("a")
            px, py = find(x), find(y)
            if px < py:
                p[py] = px
            else:
                p[px] = py
        return "".join(chr(find(ord(c) - ord("a")) + ord("a")) for c in baseStr)
```

2316. Count Unreachable Pairs of Nodes in an Undirected Graph

Medium · Depth-First Search, Breadth-First Search, Union Find, Graph

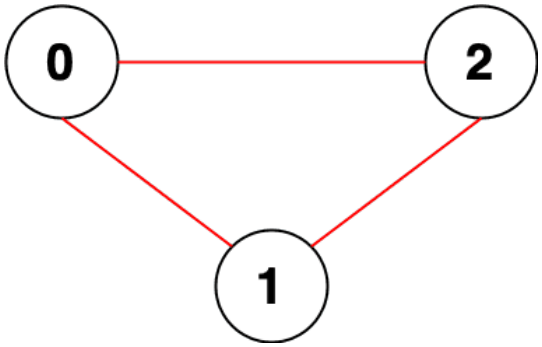
leetcode.com/problems/count-unreachable-pairs-of-nodes-in-an-undirected-graph

PROBLEM

You are given an integer `n`. There is an **undirected** graph with `n` nodes, numbered from `0` to `n - 1`. You are given a 2D integer array `edges` where `edges[i] = [a_i, b_i]` denotes that there exists an **undirected** edge connecting nodes `a_i` and `b_i`.

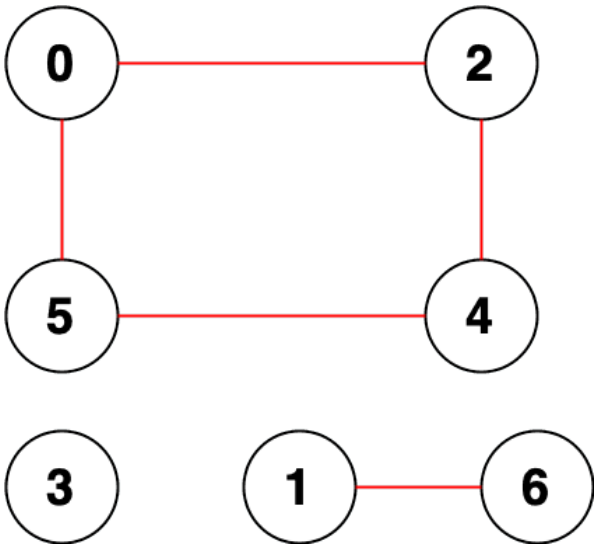
Return *the **number of pairs** of different nodes that are **unreachable** from each other*.

Example 1:



```
Input: n = 3, edges = [[0,1],[0,2],[1,2]]
Output: 0
Explanation: There are no pairs of nodes that are unreachable from each other. Therefore, we return 0.
```

Example 2:



```
Input: n = 7, edges = [[0,2],[0,5],[2,4],[1,6],[5,4]]
Output: 14
Explanation: There are 14 pairs of nodes that are unreachable from each other:
[[0,1],[0,3],[0,6],[1,2],[1,3],[1,4],[1,5],[2,3],[2,6],[3,4],[3,5],[3,6],[4,6],[5,6]].
Therefore, we return 14.
```

Constraints:

- $1 <= n <= 10^5$
- $0 <= edges.length <= 2 * 10^5$
- $edges[i].length == 2$
- $0 <= a_i, b_i < n$
- $a_i != b_i$
- There are no repeated edges.

SOLUTIONS (PYTHON 3)

Solution 1: DFS

How to think about it

Unreachable pairs sit in different components. $n \le 10^5$, so we cannot enumerate pairs. The count is the product of component sizes. DFS yields each component size t. Multiply by the sum s of earlier sizes, then add t into s. Each vertex and edge is visited once.

For any two nodes in an undirected graph, if there is a path between them, then they are mutually reachable.

Therefore, we can use depth-first search to find the number of nodes t in each connected component, and then multiply the current number of nodes t in the connected component by the number of nodes s in all previous connected components to obtain the number of unreachable node pairs in the current connected component, which is s × t. Then, we add t to s and continue to search for the next connected component until all connected components have been searched, and we can obtain the final answer.

The time complexity is O(n + m), and the space complexity is O(n + m). Here, n and m are the number of nodes and edges, respectively.

Python 3

```python
class Solution:
    def countPairs(self, n: int, edges: List[List[int]]) -> int:
        def dfs(i: int) -> int:
            if vis[i]:
                return 0
            vis[i] = True
            return 1 + sum(dfs(j) for j in g[i])

        g = [[] for _ in range(n)]
        for a, b in edges:
            g[a].append(b)
            g[b].append(a)
        vis = [False] * n
        ans = s = 0
        for i in range(n):
            t = dfs(i)
            ans += s * t
            s += t
        return ans
```

Solution 2: Explicit Stack

How to think about it

Unreachable pairs sit in different components. With $n \le 10^5$ we cannot enumerate pairs. The count is the product of component sizes. Recursing from a node into each neighbor reaches depth equal to the component size on a chain. In Python the generator inside `sum` adds another frame, so a few hundred nodes already overflow the call stack. A component's size does not depend on visit order. Each component therefore uses an explicit stack: a node is marked when it is pushed, counted when it is popped, and only unmarked neighbors are pushed. Multiply the size t by the sum s of earlier sizes, then add t into s.

For any two nodes in an undirected graph, if there is a path between them, then they are mutually reachable.

An explicit stack finds the number of nodes t in each connected component. Starting from an unvisited node, we mark a node when pushing it, count it when popping it, and push only unmarked neighbors. Multiply t by the number of nodes s in all previous components to obtain the unreachable pairs s × t, then add t to s. Repeat until every node has been visited.

The time complexity is O(n + m), and the space complexity is O(n + m). Here, n and m are the number of nodes and edges, respectively.

Python 3

```python
class Solution:
    def countPairs(self, n: int, edges: List[List[int]]) -> int:
        def dfs(i: int) -> int:
            if vis[i]:
                return 0
            vis[i] = True
            stk = [i]
            cnt = 0
            while stk:
                u = stk.pop()
                cnt += 1
                for j in g[u]:
                    if not vis[j]:
                        vis[j] = True
                        stk.append(j)
            return cnt

        g = [[] for _ in range(n)]
        for a, b in edges:
            g[a].append(b)
            g[b].append(a)
        vis = [False] * n
        ans = s = 0
        for i in range(n):
            t = dfs(i)
            ans += s * t
            s += t
        return ans
```

```

924. Minimize Malware Spread

Hard · Depth-First Search, Breadth-First Search, Union Find, Graph, Array, Hash Table

leetcode.com/problems/minimize-malware-spread

PROBLEM

You are given a network of `n` nodes represented as an `n x n` adjacency matrix `graph`, where the i^{th} node is directly connected to the j^{th} node if `graph[i][j] == 1`.

Some nodes `initial` are initially infected by malware. Whenever two nodes are directly connected, and at least one of those two nodes is infected by malware, both nodes will be infected by malware. This spread of malware will continue until no more nodes can be infected in this manner.

Suppose `M(initial)` is the final number of nodes infected with malware in the entire network after the spread of malware stops. We will remove **exactly one node** from `initial`.

Return the node that, if removed, would minimize `M(initial)`. If multiple nodes could be removed to minimize `M(initial)`, return such a node with **the smallest index**.

Note that if a node was removed from the `initial` list of infected nodes, it might still be infected later due to the malware spread.

Example 1:

```
Input: graph = [[1,1,0],[1,1,0],[0,0,1]], initial = [0,1]
Output: 0
```

Example 2:

```
Input: graph = [[1,0,0],[0,1,0],[0,0,1]], initial = [0,2]
Output: 0
```

Example 3:

```
Input: graph = [[1,1,1],[1,1,1],[1,1,1]], initial = [1,2]
Output: 1
```

Constraints:

- `n == graph.length`
- `n == graph[i].length`
- `2 <= n <= 300`
- `graph[i][j]` is `0` or `1`.
- `graph[i][j] == graph[j][i]`
- `graph[i][i] == 1`
- `1 <= initial.length <= n`
- `0 <= initial[i] <= n - 1`
- All the integers in `initial` are **unique**.

SOLUTION (PYTHON 3)

Solution 1: Union Find

How to think about it

Remove one initially infected node to minimize the final infection. Infection fills a whole component: if a component has two or more initial nodes, removing one still leaves it infected; only a component with a single initial node can be saved entirely. Union-find gives component sizes and the number of initials per root. Among nodes with cnt[root]=1, pick the one that saves the most nodes (smallest index on ties). If none exist, return the minimum of initial.

According to the problem description, if there are several nodes in the same connected component initially, there can be three situations:

1. None of these nodes are infected.
2. Only one node among these nodes is infected.
3. Multiple nodes among these nodes are infected.

What we need to consider is to minimize the number of infected nodes left after removing a certain infected node.

For situation 1, there are no infected nodes, so we don't need to consider it; for situation 2, only one node is infected, so after removing this node, the other nodes in this connected component will not be infected; for situation 3, multiple nodes are infected, so after removing any infected node, the other nodes in this connected component will still be infected. Therefore, we only need to consider situation 2.

We use a union find set uf to maintain the connectivity of nodes, a variable ans to record the answer, and a variable mx to record the maximum number of infections that can be reduced currently. Initially, ans = n, mx = 0.

Then we traverse the array initial, use a hash table or an array of length n named cnt to count the number of infected nodes in each connected component.

Next, we traverse the array initial again. For each node x, we find the root node root of its connected component. If there is only one infected node in this connected component, i.e., cnt[root] = 1, we update the answer. The update condition is that the number of nodes sz in this connected component is greater than mx or sz equals mx and the value of x is less than ans.

Finally, if ans has not been updated, it means that there are multiple infected nodes in all connected components, so we return the minimum value in initial, otherwise, we return ans.

The time complexity is $O(n^2 \times \alpha(n))$, and the space complexity is $O(n)$. Where n is the number of nodes, and $\alpha(n)$ is the inverse of the Ackermann function.

Python 3

```python
class UnionFind:
    __slots__ = "p", "size"

    def __init__(self, n: int):
        self.p = list(range(n))
        self.size = [1] * n

    def find(self, x: int) -> int:
        if self.p[x] != x:
            self.p[x] = self.find(self.p[x])
        return self.p[x]

    def union(self, a: int, b: int) -> bool:
        pa, pb = self.find(a), self.find(b)
        if pa == pb:
            return False
        if self.size[pa] > self.size[pb]:
            self.p[pb] = pa
            self.size[pa] += self.size[pb]
        else:
            self.p[pa] = pb
            self.size[pb] += self.size[pa]
        return True

    def get_size(self, root: int) -> int:
        return self.size[root]

class Solution:
    def minMalwareSpread(self, graph: List[List[int]], initial: List[int]) -> int:
        n = len(graph)
        uf = UnionFind(n)
        for i in range(n):
            for j in range(i + 1, n):
                graph[i][j] and uf.union(i, j)
        cnt = Counter(uf.find(x) for x in initial)
        ans, mx = n, 0
        for x in initial:
            root = uf.find(x)
            if cnt[root] > 1:
                continue
            sz = uf.get_size(root)
            if sz > mx or (sz == mx and x < ans):
                ans = x
                mx = sz
        return min(initial) if ans == n else ans
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

    return saved
```

959. Regions Cut By Slashes

Medium · Depth-First Search, Breadth-First Search, Union Find, Array, Hash Table, Matrix, Planar Graph

leetcode.com/problems/regions-cut-by-slashes

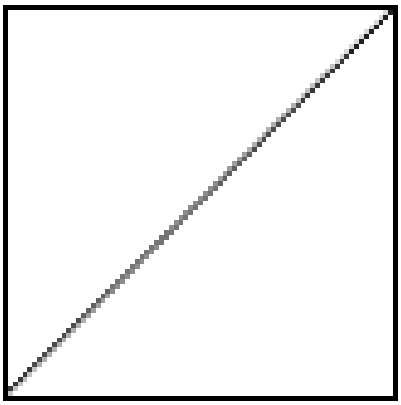
PROBLEM

An `n x n` grid is composed of `1 x 1` squares where each `1 x 1` square consists of a `'/'`, `'\'`, or blank space `' '`. These characters divide the square into contiguous regions.

Given the grid `grid` represented as a string array, return *the number of regions*.

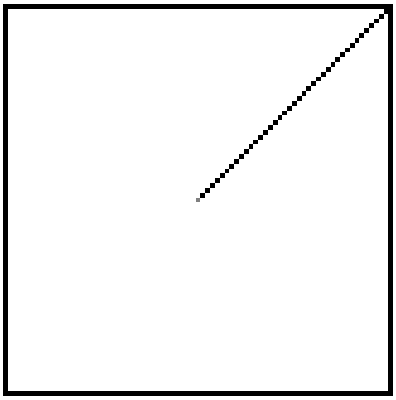
Note that backslash characters are escaped, so a `'\'` is represented as `'\\'`.

Example 1:



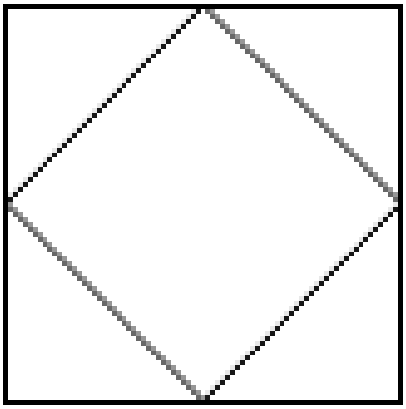
```
Input: grid = [" /","/ "]
Output: 2
```

Example 2:



```
Input: grid = [" /"," "]
Output: 1
```

Example 3:



```
Input: grid = ["/\\","\\/"]
Output: 5
Explanation: Recall that because \ characters are escaped, "\\/" refers to \/, and "/\\" refers to /\.
```

Constraints:

- `n == grid.length == grid[i].length`
- `1 <= n <= 30`
- `grid[i][j]` is either `'/'`, `'\'`, or `' '`.

SOLUTIONS (PYTHON 3)

Solution 1: Union-Find

How to think about it

Slashes cut the grid into regions, n≤ 30. Split each cell into four triangles. Merge pieces that share an open edge: inside a cell according to `'/'`, `'\\'`, or a blank, and between cells along the shared side. Union-find starts at $4n^2$ pieces and decreases on each successful union.

Python 3

```python
class Solution:
    def regionsBySlashes(self, grid: List[str]) -> int:
        def find(x):
            if p[x] != x:
                p[x] = find(p[x])
            return p[x]

        def union(a, b):
            pa, pb = find(a), find(b)
            if pa != pb:
                p[pa] = pb
                nonlocal size
                size -= 1

        n = len(grid)
        size = n * n * 4
        p = list(range(size))
        for i, row in enumerate(grid):
            for j, v in enumerate(row):
                k = i * n + j
                if i < n - 1:
                    union(4 * k + 2, (k + n) * 4)
                if j < n - 1:
                    union(4 * k + 1, (k + 1) * 4 + 3)
                if v == '/':
                    union(4 * k, 4 * k + 3)
                    union(4 * k + 1, 4 * k + 2)
                elif v == '\\':
                    union(4 * k, 4 * k + 1)
                    union(4 * k + 2, 4 * k + 3)
                else:
                    union(4 * k, 4 * k + 1)
                    union(4 * k + 1, 4 * k + 2)
                    union(4 * k + 2, 4 * k + 3)
        return size
```

Complexity. Time: O(n^2 * alpha(n^2)), essentially O(n^2). Space: O(n^2).

Solution 2: DFS

> **How to think about it**
>
> Union-find treats a region as a set. We can instead refine each cell into a 2× 2 and DFS the empty squares; slashes become walls, and diagonal empties are entered only through a slash opening. The number of components is the answer.

Python 3 (written for this guide: the doocs page has no Python 3 version of this solution)

```
class Solution:
    def regionsBySlashes(self, grid: List[str]) -> int:
        # every square becomes 2 x 2 cells; 0 = open, 1 and 2 mark the two diagonal directions, -1 =
visited
        size = len(grid)
        n = size * 2
        g = [[0] * n for _ in range(n)]
        for i in range(size):
            for j in range(size):
                y, x = i * 2, j * 2
                if grid[i][j] == "/":
                    g[y][x + 1] = g[y + 1][x] = 1
                elif grid[i][j] == "\\":
                    g[y][x] = g[y + 1][x + 1] = 2

        def valid(v: int) -> bool:
            return 0 <= v < n

        def dfs(i: int, j: int) -> None:
            if not valid(i) or not valid(j) or g[i][j]:
                return
            g[i][j] = -1
            dirs = [-1, 0, 1, 0, -1]
            neighbours = []
            for d in range(4):
                y, x = i + dirs[d], j + dirs[d + 1]
                if valid(y) and valid(x):
                    dfs(y, x)
                    neighbours.append(g[y][x])
                else:
                    neighbours.append(-1)
            top, right, bottom, left = neighbours
            if top == 1 and right == 1:
                dfs(i - 1, j + 1)
            if bottom == 1 and left == 1:
                dfs(i + 1, j - 1)
            if top == 2 and left == 2:
                dfs(i - 1, j - 1)
            if bottom == 2 and right == 2:
                dfs(i + 1, j + 1)

        regions = 0
        for i in range(n):
            for j in range(n):
                if g[i][j] == 0:
                    dfs(i, j)
                    regions += 1
        return regions
```

Complexity. Time: O(n^2). Space: O(n^2).

1101. The Earliest Moment When Everyone Become Friends

Medium · Union Find, Array, Sorting

leetcode.com/problems/the-earliest-moment-when-everyone-become-friends

PROBLEM

There are n people in a social group labeled from `0` to `n - 1`. You are given an array `logs` where `logs[i] = [timestamp`$_i$`, x`$_i$`, y`$_i$`]` indicates that x_i and y_i will be friends at the time $timestamp_i$.

Friendship is **symmetric**. That means if `a` is friends with `b`, then `b` is friends with `a`. Also, person `a` is acquainted with a person `b` if `a` is friends with `b`, or `a` is a friend of someone acquainted with `b`.

Return *the earliest time for which every person became acquainted with every other person*. If there is no such earliest time, return `-1`.

Example 1:

```
Input: logs = [[20190101,0,1],[20190104,3,4],[20190107,2,3],[20190211,1,5],[20190224,2,4],[20190301,0,3],[20190312,1,2],[20190322,4,5]], n = 6
Output: 20190301
Explanation:
The first event occurs at timestamp = 20190101, and after 0 and 1 become friends, we have the following friendship groups [0,1], [2], [3], [4], [5].
The second event occurs at timestamp = 20190104, and after 3 and 4 become friends, we have the following friendship groups [0,1], [2], [3,4], [5].
The third event occurs at timestamp = 20190107, and after 2 and 3 become friends, we have the following friendship groups [0,1], [2,3,4], [5].
The fourth event occurs at timestamp = 20190211, and after 1 and 5 become friends, we have the following friendship groups [0,1,5], [2,3,4].
The fifth event occurs at timestamp = 20190224, and as 2 and 4 are already friends, nothing happens.
The sixth event occurs at timestamp = 20190301, and after 0 and 3 become friends, we all become friends.
```

Example 2:

```
Input: logs = [[0,2,0],[1,0,1],[3,0,3],[4,1,2],[7,3,1]], n = 4
Output: 3
Explanation: At timestamp = 3, all the persons (i.e., 0, 1, 2, and 3) become friends.
```

Constraints:

- `2 <= n <= 100`
- `1 <= logs.length <=` 10^4
- `logs[i].length == 3`
- `0 <=` $timestamp_i$ `<=` 10^9
- `0 <=` x_i`, `y_i `<= n - 1`
- x_i `!=` y_i
- All the values $timestamp_i$ are **unique**.
- All the pairs (x_i, y_i) occur at most one time in the input.

SOLUTIONS (PYTHON 3)

Solution 1: Sorting + Union-Find

How to think about it

We need the earliest time when all n people lie in one connected component. Logs arrive unordered, so sort them by timestamp and process in order. If the two people are still in different sets, union them and decrement the component count. Union-find makes the find/merge step nearly constant. When the count reaches 1, everyone is connected and that timestamp is the answer; if logs run out first, return -1.

We sort all the logs in ascending order by timestamp, then traverse the sorted logs. Using a union-find set, we check whether the two people in the current log are already friends. If they are not friends, we merge them into one friend circle, until everyone is in one friend circle, then return the timestamp of the current log.

If we have traversed all the logs and not everyone is in one friend circle, then return -1.

The time complexity is O(n × log n), and the space complexity is O(n). Here, n is the number of logs.

Python 3

```python
class Solution:
    def earliestAcq(self, logs: List[List[int]], n: int) -> int:
        def find(x):
            if p[x] != x:
                p[x] = find(p[x])
            return p[x]

        p = list(range(n))
        for t, x, y in sorted(logs):
            if find(x) == find(y):
                continue
            p[find(x)] = find(y)
            n -= 1
            if n == 1:
                return t
        return -1
```

Solution 2

How to think about it

Method 1 inlines path compression and does not union by size. Method 2 wraps a `UnionFind` with path compression and union-by-size; `union` reports whether a merge happened, and the main loop only tracks the component count. The moment everyone becomes friends is unchanged, with shallower trees.

Python 3

```python
class UnionFind:
    __slots__ = ('p', 'size')

    def __init__(self, n):
        self.p = list(range(n))
        self.size = [1] * n

    def find(self, x: int) -> int:
        if self.p[x] != x:
            self.p[x] = self.find(self.p[x])
        return self.p[x]

    def union(self, a: int, b: int) -> bool:
        pa, pb = self.find(a), self.find(b)
        if pa == pb:
            return False
        if self.size[pa] > self.size[pb]:
            self.p[pb] = pa
            self.size[pa] += self.size[pb]
        else:
            self.p[pa] = pb
            self.size[pb] += self.size[pa]
        return True

class Solution:
    def earliestAcq(self, logs: List[List[int]], n: int) -> int:
        uf = UnionFind(n)
        for t, x, y in sorted(logs):
            if uf.union(x, y):
                n -= 1
                if n == 1:
                    return t
        return -1
```

Complexity. Time: O(m log m + m * alpha(n)), m = number of logs. Space: O(n).

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

    return -1
```

685. Redundant Connection II

Hard · Depth-First Search, Breadth-First Search, Union Find, Graph

leetcode.com/problems/redundant-connection-ii

★ **TOP 10 PROBLEM** in Union-Find (Disjoint Set): master this one first

PROBLEM

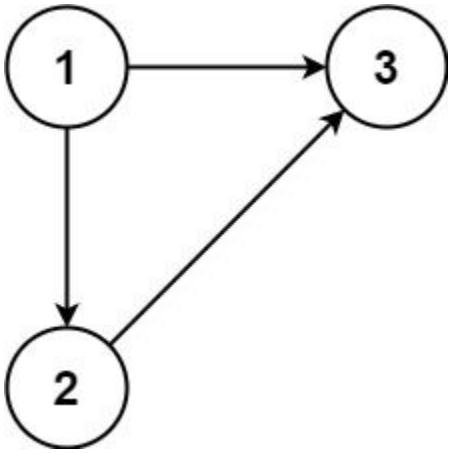
In this problem, a rooted tree is a **directed** graph such that, there is exactly one node (the root) for which all other nodes are descendants of this node, plus every node has exactly one parent, except for the root node which has no parents.

The given input is a directed graph that started as a rooted tree with `n` nodes (with distinct values from `1` to `n`), with one additional directed edge added. The added edge has two different vertices chosen from `1` to `n`, and was not an edge that already existed.

The resulting graph is given as a 2D-array of `edges`. Each element of `edges` is a pair $[u_i, v_i]$ that represents a **directed** edge connecting nodes u_i and v_i, where u_i is a parent of child v_i.

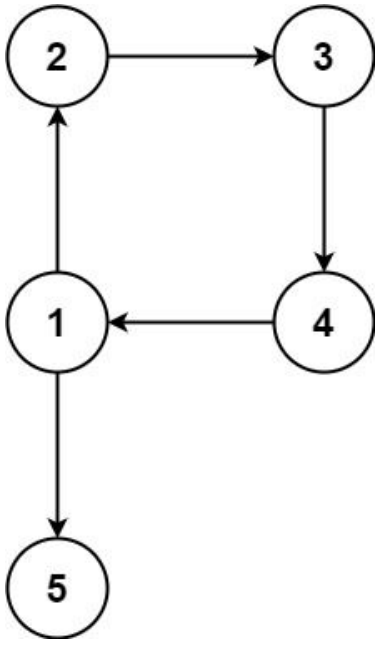
Return *an edge that can be removed so that the resulting graph is a rooted tree of* `n` *nodes*. If there are multiple answers, return the answer that occurs last in the given 2D-array.

Example 1:



```
Input: edges = [[1,2],[1,3],[2,3]]
Output: [2,3]
```

Example 2:



```
Input: edges = [[1,2],[2,3],[3,4],[4,1],[1,5]]
Output: [4,1]
```

Constraints:

- `n == edges.length`
- `3 <= n <= 1000`
- `edges[i].length == 2`
- `1 <= u_i, v_i <= n`
- `u_i != v_i`

SOLUTIONS (PYTHON 3)

Solution 1: Union-Find

How to think about it

A rooted tree plus one directed edge may create a node of in-degree 2, a cycle into the root, or both. Undirected union-find alone misses the double-parent case. Collect the two edges into an in-degree-2 node. Skip the later one and union-find: a cycle means the earlier edge must go. With no double parent, delete the first edge that closes a cycle.

According to the problem description, for a rooted tree, the in-degree of the root node is 0, and the in-degree of other nodes is 1. After adding an edge to the tree, there can be the following three scenarios:

1. The added edge points to a non-root node, and the in-degree of that node becomes 2. In this case, there is no directed cycle in the graph:

```
  1
 / \
v   v
2-->3
```

2. The added edge points to a non-root node, and the in-degree of that node becomes 2. In this case, there is a directed cycle in the graph:

```
  1
  |
  v
  2 <--> 3
```

3. The added edge points to the root node, and the in-degree of the root node becomes 1. In this case, there is a directed cycle in the graph, but there are no nodes with an in-degree of 2.

```
  1
  /^
v  \
2-->3
```

Therefore, we first calculate the in-degree of each node. If there exists a node with an in-degree of 2, we identify the two edges corresponding to that node, denoted as dup[0] and dup[1]. If deleting dup[1] results in the remaining edges not forming a tree, then dup[0] is the edge that needs to be deleted; otherwise, dup[1] is the edge that needs to be deleted.

If there are no nodes with an in-degree of 2, we traverse the array edges. For each edge (u, v), we use the union-find data structure to maintain connectivity between nodes. If u and v are already connected, it indicates that there is a directed cycle in the graph, and the current edge is the one that needs to be deleted.

The time complexity is O(n log n), and the space complexity is O(n), where n is the number of edges.

Python 3

```python
class Solution:
    def findRedundantDirectedConnection(self, edges: List[List[int]]) -> List[int]:
        def find(x: int) -> int:
            if p[x] != x:
                p[x] = find(p[x])
            return p[x]

        n = len(edges)
        ind = [0] * n
        for _, v in edges:
            ind[v - 1] += 1
        dup = [i for i, (_, v) in enumerate(edges) if ind[v - 1] == 2]
        p = list(range(n))
        if dup:
            for i, (u, v) in enumerate(edges):
                if i == dup[1]:
                    continue
                pu, pv = find(u - 1), find(v - 1)
                if pu == pv:
                    return edges[dup[0]]
                p[pu] = pv
            return edges[dup[1]]
        for i, (u, v) in enumerate(edges):
            pu, pv = find(u - 1), find(v - 1)
            if pu == pv:
                return edges[i]
            p[pu] = pv
```

Solution 2: Union-Find (Template Approach)

> **How to think about it**
>
> The same case split, with path compression and union-by-size in a `UnionFind` class. The driver only handles `dup` and a failed union.

Here is a template approach using Union-Find for your reference.

The time complexity is O(n α(n)), and the space complexity is O(n). Here, n is the number of edges, and α(n) is the inverse Ackermann function, which can be considered a very small constant.

Python 3

```python
class UnionFind:
    __slots__ = "p", "size"

    def __init__(self, n: int):
        self.p: List[int] = list(range(n))

1627. Graph Connectivity With Threshold

Hard · Union Find, Array, Math, Number Theory

leetcode.com/problems/graph-connectivity-with-threshold

PROBLEM

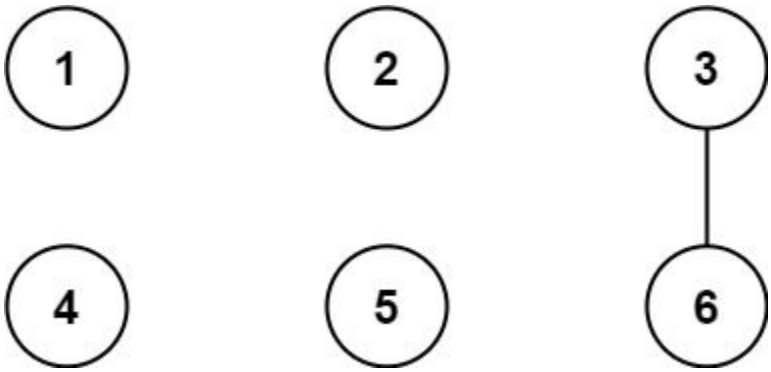
We have `n` cities labeled from `1` to `n`. Two different cities with labels `x` and `y` are directly connected by a bidirectional road if and only if `x` and `y` share a common divisor **strictly greater** than some `threshold`. More formally, cities with labels `x` and `y` have a road between them if there exists an integer `z` such that all of the following are true:

- `x % z == 0`,
- `y % z == 0`, and
- `z > threshold`.

Given the two integers, `n` and `threshold`, and an array of `queries`, you must determine for each `queries[i] = [a_i, b_i]` if cities `a_i` and `b_i` are connected directly or indirectly. (i.e. there is some path between them).

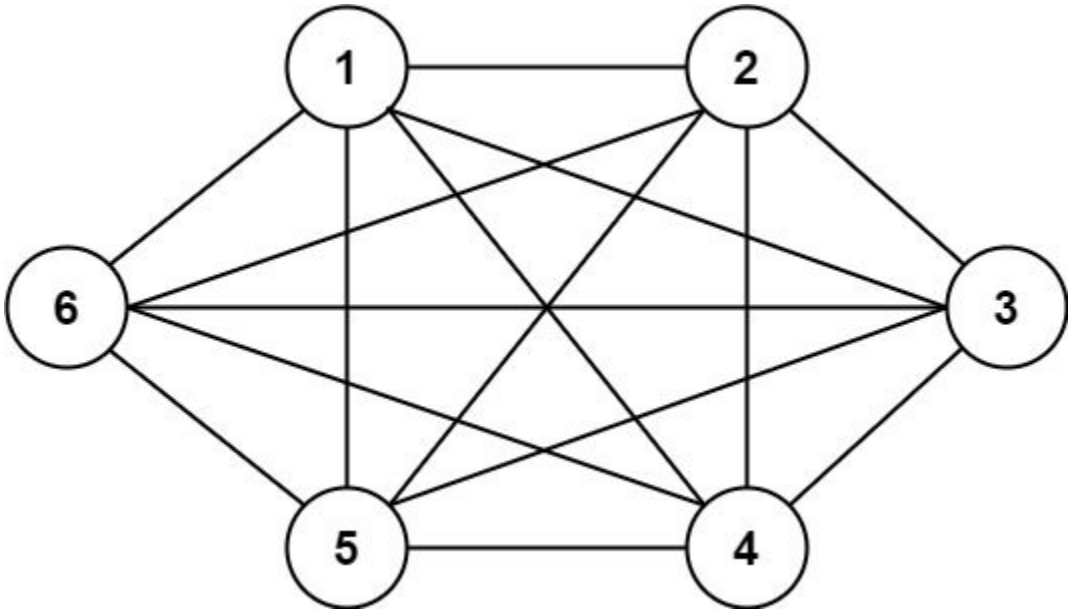
Return *an array* `answer`*, where* `answer.length == queries.length` *and* `answer[i]` *is* `true` *if for the* `i^th` *query, there is a path between* `a_i` *and* `b_i`*, or* `answer[i]` *is* `false` *if there is no path.*

Example 1:



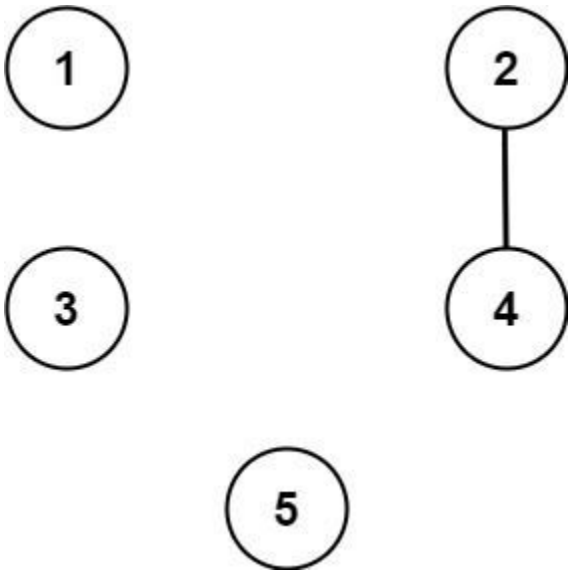
```
Input: n = 6, threshold = 2, queries = [[1,4],[2,5],[3,6]]
Output: [false,false,true]
Explanation: The divisors for each number:
1: 1
2: 1, 2
3: 1, 3
4: 1, 2, 4
5: 1, 5
6: 1, 2, 3, 6
Using the underlined divisors above the threshold, only cities 3 and 6 share a common divisor, so they
are the
only ones directly connected. The result of each query:
[1,4] 1 is not connected to 4
[2,5] 2 is not connected to 5
[3,6] 3 is connected to 6 through path 3--6
```

Example 2:



Input: n = 6, threshold = 0, queries = [[4,5],[3,4],[3,2],[2,6],[1,3]]
Output: [true,true,true,true,true]
Explanation: The divisors for each number are the same as the previous example. However, since the threshold is 0,
all divisors can be used. Since all numbers share 1 as a divisor, all cities are connected.

Example 3:



Input: n = 5, threshold = 1, queries = [[4,5],[4,5],[3,2],[2,3],[3,4]]
Output: [false,false,false,false,false]
Explanation: Only cities 2 and 4 share a common divisor 2 which is strictly greater than the threshold 1, so they are the only ones directly connected.
Please notice that there can be multiple queries for the same pair of nodes [x, y], and that the query [x, y] is equivalent to the query [y, x].

Constraints:

- $2 <= n <= 10^4$
- $0 <= threshold <= n$
- $1 <= queries.length <= 10^5$
- $queries[i].length == 2$

- $1 <= a_i, b_i <= cities$
- $a_i != b_i$

SOLUTION (PYTHON 3)

Solution 1: Union-Find

> **How to think about it**
>
> Two cities are connected if a path exists using edges whose gcd exceeds threshold. Testing gcd on every pair is too slow when both n and the number of queries are large. Each z above the threshold links all of its multiples, so unioning along multiples covers every direct edge. A disjoint-set unions z,2z,3z,… for z ∈ (threshold, n], and each query tests whether the two cities share a root.

We can enumerate z and its multiples, and use union-find to connect them. In this way, for each query [a, b], we only need to determine whether a and b are in the same connected component.

The time complexity is O(n × log n × (α(n) + q)), and the space complexity is O(n). Here, n and q are the number of nodes and queries, respectively, and α is the inverse function of the Ackermann function.

Python 3

```python
class UnionFind:
    def __init__(self, n):
        self.p = list(range(n))
        self.size = [1] * n

    def find(self, x):
        if self.p[x] != x:
            self.p[x] = self.find(self.p[x])
        return self.p[x]

    def union(self, a, b):
        pa, pb = self.find(a), self.find(b)
        if pa == pb:
            return False
        if self.size[pa] > self.size[pb]:
            self.p[pb] = pa
            self.size[pa] += self.size[pb]
        else:
            self.p[pa] = pb
            self.size[pb] += self.size[pa]
        return True

class Solution:
    def areConnected(
        self, n: int, threshold: int, queries: List[List[int]]
    ) -> List[bool]:
        uf = UnionFind(n + 1)
        for a in range(threshold + 1, n + 1):
            for b in range(a + a, n + 1, a):
                uf.union(a, b)
        return [uf.find(a) == uf.find(b) for a, b in queries]
```

1697. Checking Existence of Edge Length Limited Paths

Hard · Union Find, Graph, Array, Two Pointers, Sorting

leetcode.com/problems/checking-existence-of-edge-length-limited-paths

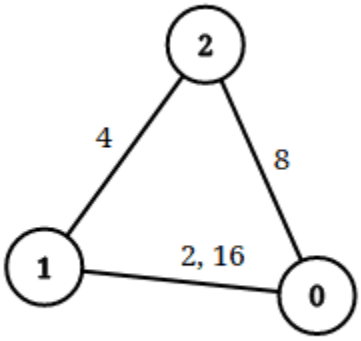
PROBLEM

An undirected graph of `n` nodes is defined by `edgeList`, where `edgeList[i] = [u_i, v_i, dis_i]` denotes an edge between nodes `u_i` and `v_i` with distance `dis_i`. Note that there may be **multiple** edges between two nodes.

Given an array `queries`, where `queries[j] = [p_j, q_j, limit_j]`, your task is to determine for each `queries[j]` whether there is a path between `p_j` and `q_j` such that each edge on the path has a distance **strictly less than** `limit_j`.

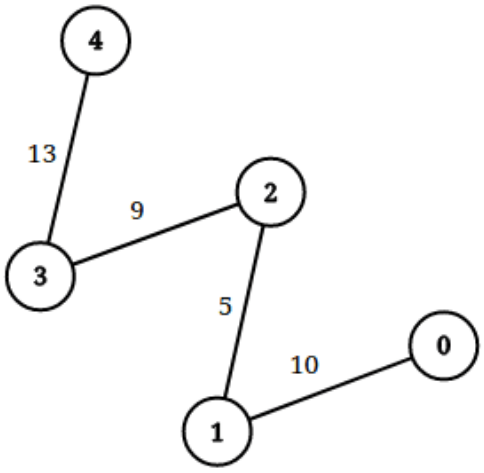
Return *a **boolean array*** `answer`*, where* `answer.length == queries.length` *and the* `j^th` *value of* `answer` *is* `true` *if there is a path for* `queries[j]` *is* `true`*, and* `false` *otherwise*.

Example 1:



```
Input: n = 3, edgeList = [[0,1,2],[1,2,4],[2,0,8],[1,0,16]], queries = [[0,1,2],[0,2,5]]
Output: [false,true]
Explanation: The above figure shows the given graph. Note that there are two overlapping edges between
0 and 1 with distances 2 and 16.
For the first query, between 0 and 1 there is no path where each distance is less than 2, thus we
return false for this query.
For the second query, there is a path (0 -> 1 -> 2) of two edges with distances less than 5, thus we
return true for this query.
```

Example 2:



```
Input: n = 5, edgeList = [[0,1,10],[1,2,5],[2,3,9],[3,4,13]], queries = [[0,4,14],[1,4,13]]
Output: [true,false]
Explanation: The above figure shows the given graph.
```

Constraints:

- $2 <= n <= 10^5$
- $1 <= edgeList.length, queries.length <= 10^5$
- $edgeList[i].length == 3$
- $queries[j].length == 3$
- $0 <= u_i, v_i, p_j, q_j <= n - 1$
- $u_i != v_i$
- $p_j != q_j$
- $1 <= dis_i, limit_j <= 10^9$
- There may be **multiple** edges between two nodes.

SOLUTION (PYTHON 3)

Solution 1: Offline Queries + Union-Find

> **How to think about it**
>
> Each query asks whether two vertices are connected by a path whose edges are all strictly below limit. Rebuilding a graph per query is too slow; queries are independent, so we go offline. Sort edges and queries by weight/limit. A two-pointer union-find adds every edge lighter than the current limit, then tests whether the two vertices share a root. Remember original query indices when writing the answer array.

According to the problem requirements, we need to judge each query queries[i], that is, to determine whether there is a path with edge weight less than or equal to limit between the two points a and b of the current query.

The connectivity of two points can be determined by a union-find set. Moreover, since the order of queries does not affect the result, we can sort all queries in ascending order by limit, and also sort all edges in ascending order by edge weight.

Then for each query, we start from the edge with the smallest weight, add all edges with weights strictly less than limit to the union-find set, and then use the query operation of the union-find set to determine whether the two points are connected.

The time complexity is O(m × log m + q × log q), where m and q are the number of edges and queries, respectively.

Python 3

```python
class Solution:
    def distanceLimitedPathsExist(
        self, n: int, edgeList: List[List[int]], queries: List[List[int]]
    ) -> List[bool]:
        def find(x):
            if p[x] != x:
                p[x] = find(p[x])
            return p[x]

        p = list(range(n))
        edgeList.sort(key=lambda x: x[2])
        j = 0
        ans = [False] * len(queries)
        for i, (a, b, limit) in sorted(enumerate(queries), key=lambda x: x[1][2]):
            while j < len(edgeList) and edgeList[j][2] < limit:
                u, v, _ = edgeList[j]
                p[find(u)] = find(v)
                j += 1
            ans[i] = find(a) == find(b)
        return ans
```

Union-Find is a tree-like data structure that, as the name suggests, is used to handle some disjoint set **merge** and **query** problems. It supports two operations:

1. Find: Determine which subset an element belongs to. The time complexity of a single operation is O(α(n)).
2. Union: Merge two subsets into one set. The time complexity of a single operation is O(α(n)).

Here, α is the inverse Ackermann function, which grows extremely slowly. In other words, the average running time of its single operation can be considered a very small constant.

Below is a common template for Union-Find, which needs to be mastered proficiently. Where:

- `n` represents the number of nodes.
- `p` stores the parent node of each point. Initially, the parent node of each point is itself.
- `size` only makes sense when the node is an ancestor node, indicating the number of points in the set where the ancestor node is located.
- `find(x)` function is used to find the ancestor node of the set where x is located.
- `union(a, b)` function is used to merge the sets where a and b are located.

Python 3

```python
p = list(range(n))
size = [1] * n

def find(x):
    if p[x] != x:
        p[x] = find(p[x])
    return p[x]

def union(a, b):
    pa, pb = find(a), find(b)
    if pa == pb:
        return
    p[pa] = pb
    size[pb] += size[pa]
```

952. Largest Component Size by Common Factor

Hard · Union Find, Array, Hash Table, Math, Number Theory, Prime Factorization

leetcode.com/problems/largest-component-size-by-common-factor

PROBLEM

You are given an integer array of unique positive integers `nums`. Consider the following graph:

- There are `nums.length` nodes, labeled `nums[0]` to `nums[nums.length - 1]`,
- There is an undirected edge between `nums[i]` and `nums[j]` if `nums[i]` and `nums[j]` share a common factor greater than `1`.

Return *the size of the largest connected component in the graph*.

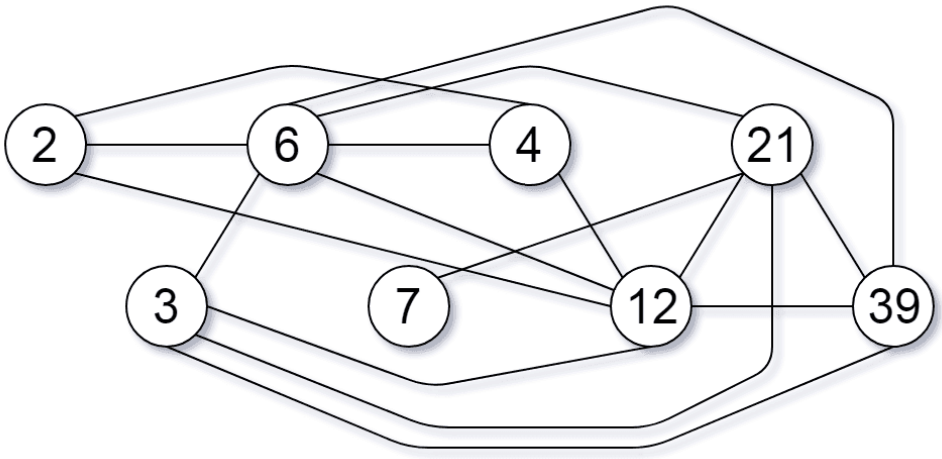
Example 1:

```
Input: nums = [4,6,15,35]
Output: 4
```

Example 2:

```
Input: nums = [20,50,9,63]
Output: 2
```

Example 3:



```
Input: nums = [2,3,6,7,4,12,21,39]
Output: 8
```

Constraints:

- `1 <= nums.length <= 2 * 10^4`
- `1 <= nums[i] <= 10^5`
- All the values of `nums` are **unique**.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Numbers sharing a factor greater than 1 are connected; we want the largest component. Pairwise gcd is quadratic and too slow for n≤ 2× 10^4. Union each value with all of its factors so numbers that share a factor meet. The answer is the highest frequency among the roots of the input values.

Python 3

```
class UnionFind:
    def __init__(self, n):
        self.p = list(range(n))

    def union(self, a, b):
        pa, pb = self.find(a), self.find(b)
        if pa != pb:
            self.p[pa] = pb

    def find(self, x):
        if self.p[x] != x:
            self.p[x] = self.find(self.p[x])
        return self.p[x]

class Solution:
    def largestComponentSize(self, nums: List[int]) -> int:
        uf = UnionFind(max(nums) + 1)
        for v in nums:
            i = 2
            while i <= v // i:
                if v % i == 0:
                    uf.union(v, i)
                    uf.union(v, v // i)
                i += 1
        return max(Counter(uf.find(v) for v in nums).values())
```

Complexity. Time: O(n * sqrt(M)), M = largest number. Space: O(M).

        if x > 1:
            parent[find(number)] = find(x)
    return find(first) == find(second)
```

1579. Remove Max Number of Edges to Keep Graph Fully Traversable

Hard · Union Find, Graph

leetcode.com/problems/remove-max-number-of-edges-to-keep-graph-fully-traversable

PROBLEM

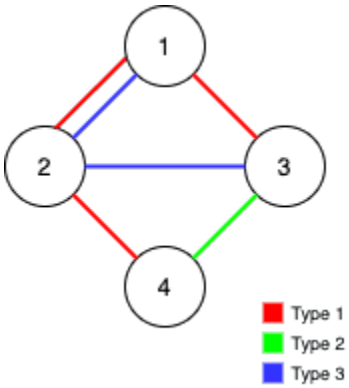
Alice and Bob have an undirected graph of `n` nodes and three types of edges:

- Type 1: Can be traversed by Alice only.
- Type 2: Can be traversed by Bob only.
- Type 3: Can be traversed by both Alice and Bob.

Given an array `edges` where `edges[i] = [type`$_i$`, u`$_i$`, v`$_i$`]` represents a bidirectional edge of type `type`$_i$ between nodes u_i and v_i, find the maximum number of edges you can remove so that after removing the edges, the graph can still be fully traversed by both Alice and Bob. The graph is fully traversed by Alice and Bob if starting from any node, they can reach all other nodes.

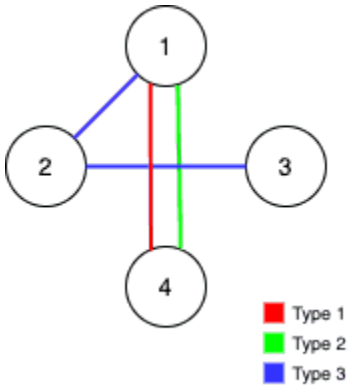
Return *the maximum number of edges you can remove, or return* `-1` *if Alice and Bob cannot fully traverse the graph.*

Example 1:



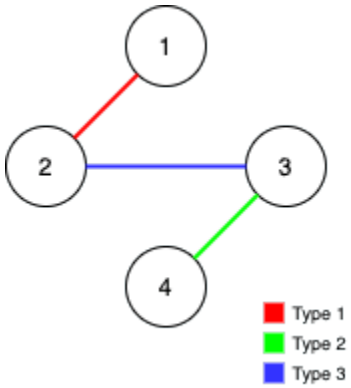
```
Input: n = 4, edges = [[3,1,2],[3,2,3],[1,1,3],[1,2,4],[1,1,2],[2,3,4]]
Output: 2
Explanation: If we remove the 2 edges [1,1,2] and [1,1,3]. The graph will still be fully traversable
by Alice and Bob. Removing any additional edge will not make it so. So the maximum number of edges we
can remove is 2.
```

Example 2:



```
Input: n = 4, edges = [[3,1,2],[3,2,3],[1,1,4],[2,1,4]]
Output: 0
Explanation: Notice that removing any edge will not make the graph fully traversable by Alice and Bob.
```

Example 3:



```
Input: n = 4, edges = [[3,2,3],[1,1,2],[2,3,4]]
Output: -1
Explanation: In the current graph, Alice cannot reach node 4 from the other nodes. Likewise, Bob
cannot reach 1. Therefore it's impossible to make the graph fully traversable.
```

Constraints:

- $1 <= n <= 10^5$
- $1 <= edges.length <= min(10^5, 3 * n * (n - 1) / 2)$
- $edges[i].length == 3$
- $1 <= type_i <= 3$
- $1 <= u_i < v_i <= n$
- All tuples $(type_i, u_i, v_i)$ are distinct.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Delete as many edges as possible while both Alice and Bob can still traverse the graph. n and the edge count reach 10^5. Type-3 edges serve both and should be kept first; exclusive edges only patch each person's graph. Two disjoint-set forests track the two reachability relations. Add type 3 first and discard a shared edge that would close a cycle. Then add types 1 and 2 the same way. A solution exists only when both forests have a single component.

Python 3

```
class UnionFind:
    def __init__(self, n):
        self.p = list(range(n))
        self.size = [1] * n
        self.cnt = n

    def find(self, x):
        if self.p[x] != x:
            self.p[x] = self.find(self.p[x])
        return self.p[x]

    def union(self, a, b):
        pa, pb = self.find(a - 1), self.find(b - 1)
        if pa == pb:
            return False
        if self.size[pa] > self.size[pb]:
            self.p[pb] = pa
            self.size[pa] += self.size[pb]
        else:
            self.p[pa] = pb
            self.size[pb] += self.size[pa]
        self.cnt -= 1
        return True

class Solution:
    def maxNumEdgesToRemove(self, n: int, edges: List[List[int]]) -> int:
        ufa = UnionFind(n)
        ufb = UnionFind(n)
        ans = 0
        for t, u, v in edges:
            if t == 3:
                if ufa.union(u, v):
                    ufb.union(u, v)
                else:
                    ans += 1
        for t, u, v in edges:
            if t == 1:
                ans += not ufa.union(u, v)
            if t == 2:
                ans += not ufb.union(u, v)
        return ans if ufa.cnt == 1 and ufb.cnt == 1 else -1
```

Complexity. Time: O(E * alpha(n)), essentially O(E). Space: O(n).

PATTERN 32 OF 41

Trie (Prefix Tree)

20 problems · 2 Easy · 11 Medium · 7 Hard

THE IDEA

A tree of characters where each path from the root spells a prefix. Lookups cost the length of the word, and shared prefixes are stored once.

Signals: implement a trie, word search II, autocomplete, longest common prefix, replace words, maximum XOR of two numbers.

A TEMPLATE TO KEEP IN YOUR HANDS (PYTHON)

```
root = {}
def insert(word):
    node = root
    for ch in word:
        node = node.setdefault(ch, {})
    node["$"] = True                # end of a word
def starts_with(prefix):
    node = root
    for ch in prefix:
        if ch not in node:
            return False
        node = node[ch]
    return True
```

PATTERN 32 · TRIE (PREFIX TREE) · PROBLEM 1 OF 20

720. Longest Word in Dictionary

Medium · Trie, Array, Hash Table, String, Sorting

leetcode.com/problems/longest-word-in-dictionary

★ **TOP 10 PROBLEM** in Trie (Prefix Tree): master this one first

PROBLEM

Given an array of strings `words` representing an English Dictionary, return *the longest word in* `words` *that can be built one character at a time by other words in* `words`.

If there is more than one possible answer, return the longest word with the smallest lexicographical order. If there is no answer, return the empty string.

Note that the word should be built from left to right with each additional character being added to the end of a previous word.

Example 1:

```
Input: words = ["w","wo","wor","worl","world"]
Output: "world"
Explanation: The word "world" can be built one character at a time by "w", "wo", "wor", and "worl".
```

Example 2:

```
Input: words = ["a","banana","app","appl","ap","apply","apple"]
Output: "apple"
Explanation: Both "apply" and "apple" can be built from other words in the dictionary. However,
"apple" is lexicographically smaller than "apply".
```

Constraints:

- `1 <= words.length <= 1000`
- `1 <= words[i].length <= 30`
- `words[i]` consists of lowercase English letters.

SOLUTION (PYTHON 3)

Solution 1: Trie

How to think about it

We want the longest word that can be built by adding one letter at a time from other dictionary words, breaking ties lexicographically. The input is small, but checking every prefix in a set is easy to get messy. That condition is exactly: every prefix of the word is itself in the dictionary. After inserting all words into a trie, a walk that requires every node to be a word-end decides it in one pass. Build the trie, then scan each word with search, keeping the longer word or the lexicographically smaller one of equal length. Time is linear in the total number of characters.

We can use a trie to store all the words, then traverse all the words to determine if the current word can be formed by adding one letter at a time from other words in the trie. Find the longest word that meets the condition and has the smallest lexicographical order.

The time complexity is O(L), and the space complexity is O(L), where L is the sum of the lengths of all words.

Python 3

```python
class Trie:
    def __init__(self):
        self.children: List[Optional[Trie]] = [None] * 26
        self.is_end = False

    def insert(self, w: str):
        node = self
        for c in w:
            idx = ord(c) - ord("a")
            if node.children[idx] is None:
                node.children[idx] = Trie()
            node = node.children[idx]
        node.is_end = True

    def search(self, w: str) -> bool:
        node = self
        for c in w:
            idx = ord(c) - ord("a")
            if node.children[idx] is None:
                return False
            node = node.children[idx]
            if not node.is_end:
                return False
        return True

class Solution:
    def longestWord(self, words: List[str]) -> str:
        trie = Trie()
        for w in words:
            trie.insert(w)
        ans = ""
        for w in words:
            if trie.search(w) and (
                len(ans) < len(w) or (len(ans) == len(w) and ans > w)
            ):
                ans = w
        return ans
```

    return count
```

PATTERN 32 · TRIE (PREFIX TREE) · PROBLEM 5 OF 20

1804. Implement Trie II (Prefix Tree)

Medium · Design, Trie, Hash Table, String

leetcode.com/problems/implement-trie-ii-prefix-tree

PROBLEM

A **trie** (pronounced as "try") or **prefix tree** is a tree data structure used to efficiently store and retrieve keys in a dataset of strings. There are various applications of this data structure, such as autocomplete and spellchecker.

Implement the Trie class:

- `Trie()` Initializes the trie object.
- `void insert(String word)` Inserts the string `word` into the trie.
- `int countWordsEqualTo(String word)` Returns the number of instances of the string `word` in the trie.
- `int countWordsStartingWith(String prefix)` Returns the number of strings in the trie that have the string `prefix` as a prefix.
- `void erase(String word)` Erases the string `word` from the trie.

Example 1:

```
Input
["Trie", "insert", "insert", "countWordsEqualTo", "countWordsStartingWith", "erase",
"countWordsEqualTo", "countWordsStartingWith", "erase", "countWordsStartingWith"]
[[], ["apple"], ["apple"], ["apple"], ["app"], ["apple"], ["apple"], ["app"], ["apple"], ["app"]]
Output
[null, null, null, 2, 2, null, 1, 1, null, 0]

Explanation
Trie trie = new Trie();
trie.insert("apple"); // Inserts "apple".
trie.insert("apple"); // Inserts another "apple".
trie.countWordsEqualTo("apple"); // There are two instances of "apple" so return 2.
trie.countWordsStartingWith("app"); // "app" is a prefix of "apple" so return 2.
trie.erase("apple"); // Erases one "apple".
trie.countWordsEqualTo("apple"); // Now there is only one instance of "apple" so return 1.
trie.countWordsStartingWith("app"); // return 1
trie.erase("apple"); // Erases "apple". Now the trie is empty.
trie.countWordsStartingWith("app"); // return 0
```

Constraints:

- `1 <= word.length, prefix.length <= 2000`
- `word` and `prefix` consist only of lowercase English letters.
- At most $3 * 10^4$ calls **in total** will be made to `insert`, `countWordsEqualTo`, `countWordsStartingWith`, and `erase`.
- It is guaranteed that for any function call to `erase`, the string `word` will exist in the trie.

SOLUTION (PYTHON 3)

Solution 1: Implement Trie with Array

> **How to think about it**
>
> A standard trie only answers existence. Here we also need the count of a word, the count of words with a given prefix, and deletion. Scanning every inserted string on each query would be too slow given the operation limits. Store two counters on every node: v for words ending here and pv for words that pass through. Insertion increments pv along the path and v at the end; queries walk to the node and read the corresponding counter; erasure decrements along the same path. Each operation stays linear in the word length.

Each node in the Trie includes three parts:

1. An array of pointers `children` pointing to child nodes. For this problem, the array length is 26, which is the number of lowercase English letters. `children[0]` corresponds to the lowercase letter a, ..., `children[25]` corresponds to the lowercase letter z.
1. An int variable `v`, representing the number of strings ending with this node.
1. An int variable `pv`, representing the number of strings with this node as the prefix node.

1. Insert String

We start from the root of the Trie and insert the string. For the child node corresponding to the current character, there are two cases:

- The child node exists. Move to the child node along the pointer and continue to process the next character.
- The child node does not exist. Create a new child node, record it in the corresponding position of the `children` array, then move to the child node along the pointer, and increase the `pv` value of the child node by 1. Continue to search for the next character.

Repeat the above steps until the last character of the string is processed, then increase the `v` value of the current node by 1.

The time complexity is O(n), where n is the length of the string.

2. Search Prefix

We start from the root of the Trie and search for the prefix. For the child node corresponding to the current character, there are two cases:

- The child node exists. Move to the child node along the pointer and continue to search for the next character.
- The child node does not exist. This means that the Trie does not contain this prefix, return a null pointer.

Repeat the above steps until a null pointer is returned or the last character of the prefix is searched.

The time complexity is O(n), where n is the length of the string.

3. Remove String

We start from the root node of the Trie, and sequentially reduce the `pv` value of the corresponding child node by 1, until the last character of the string is searched. Then reduce the `v` value of the current node by 1.

The time complexity is O(n), where n is the length of the string.

Python 3

```python
class Trie:
    def __init__(self):
        self.children = [None] * 26
        self.v = self.pv = 0

    def insert(self, word: str) -> None:
        node = self
        for c in word:
            idx = ord(c) - ord('a')
            if node.children[idx] is None:
                node.children[idx] = Trie()
            node = node.children[idx]
            node.pv += 1
        node.v += 1

    def countWordsEqualTo(self, word: str) -> int:
        node = self.search(word)
        return 0 if node is None else node.v

    def countWordsStartingWith(self, prefix: str) -> int:
        node = self.search(prefix)
        return 0 if node is None else node.pv

    def erase(self, word: str) -> None:
        node = self
        for c in word:
            idx = ord(c) - ord('a')
            node = node.children[idx]
            node.pv -= 1
        node.v -= 1

    def search(self, word):

648. Replace Words

Medium · Trie, Array, Hash Table, String

leetcode.com/problems/replace-words

★ **TOP 10 PROBLEM** in Trie (Prefix Tree): master this one first

PROBLEM

In English, we have a concept called **root**, which can be followed by some other word to form another longer word - let's call this word **derivative**. For example, when the **root** `"help"` is followed by the word `"ful"`, we can form a derivative `"helpful"`.

Given a `dictionary` consisting of many **roots** and a `sentence` consisting of words separated by spaces, replace all the derivatives in the sentence with the **root** forming it. If a derivative can be replaced by more than one **root**, replace it with the **root** that has **the shortest length**.

Return *the* `sentence` after the replacement.

Example 1:

```
Input: dictionary = ["cat","bat","rat"], sentence = "the cattle was rattled by the battery"
Output: "the cat was rat by the bat"
```

Example 2:

```
Input: dictionary = ["a","b","c"], sentence = "aadsfasf absbs bbab cadsfafs"
Output: "a a b c"
```

Constraints:

- `1 <= dictionary.length <= 1000`
- `1 <= dictionary[i].length <= 100`
- `dictionary[i]` consists of only lower-case letters.
- `1 <= sentence.length <= 10^6`
- `sentence` consists of only lower-case letters and spaces.
- The number of words in `sentence` is in the range `[1, 1000]`
- The length of each word in `sentence` is in the range `[1, 1000]`
- Every two consecutive words in `sentence` will be separated by exactly one space.
- `sentence` does not have leading or trailing spaces.

SOLUTION (PYTHON 3)

Solution 1: Trie

How to think about it

Each sentence word should be replaced by the shortest dictionary root. Testing every root on every word repeats prefixes. Insert roots into a trie and walk each word until the first `is_end`; that prefix is the shortest root.

We can use a trie to store all the roots in the dictionary. Define the trie node class Trie, which contains an array children of length 26 to store child nodes, and a boolean variable is_end to mark whether it is a complete root.

For each root, we insert it into the trie. For each word in the sentence, we search for its shortest root in the trie. If found, we replace the word; otherwise, we keep it unchanged.

The time complexity is O(n × |w| + L), and the space complexity is O(n × |w|), where n and |w| are the number of roots in the dictionary and the average length, respectively, and L is the total length of words in the sentence.

Python 3

```python
class Trie:
    def __init__(self):
        self.children = [None] * 26
        self.is_end = False

    def insert(self, w: str) -> None:
        node = self
        for c in w:
            idx = ord(c) - ord("a")
            if node.children[idx] is None:
                node.children[idx] = Trie()
            node = node.children[idx]
        node.is_end = True

    def search(self, w: str) -> str:
        node = self
        for i, c in enumerate(w, 1):
            idx = ord(c) - ord("a")
            if node.children[idx] is None:
                return w
            node = node.children[idx]
            if node.is_end:
                return w[:i]
        return w

class Solution:
    def replaceWords(self, dictionary: List[str], sentence: str) -> str:
        trie = Trie()
        for w in dictionary:
            trie.insert(w)
        return " ".join(trie.search(w) for w in sentence.split())
```

PATTERN 32 · TRIE (PREFIX TREE) · PROBLEM 7 OF 20

677. Map Sum Pairs

Medium · Design, Trie, Hash Table, String

leetcode.com/problems/map-sum-pairs

★ **TOP 10 PROBLEM** in Trie (Prefix Tree): master this one first

PROBLEM

Design a map that allows you to do the following:

- Maps a string key to a given value.
- Returns the sum of the values that have a key with a prefix equal to a given string.

Implement the `MapSum` class:

- `MapSum()` Initializes the `MapSum` object.
- `void insert(String key, int val)` Inserts the `key-val` pair into the map. If the `key` already existed, the original `key-value` pair will be overridden to the new one.
- `int sum(string prefix)` Returns the sum of all the pairs' value whose `key` starts with the `prefix`.

Example 1:

```
Input
["MapSum", "insert", "sum", "insert", "sum"]
[[], ["apple", 3], ["ap"], ["app", 2], ["ap"]]
Output
[null, null, 3, null, 5]

Explanation
MapSum mapSum = new MapSum();
mapSum.insert("apple", 3);
mapSum.sum("ap"); // return 3 (apple = 3)
mapSum.insert("app", 2);
mapSum.sum("ap"); // return 5 (apple + app = 3 + 2 = 5)
```

Constraints:

- `1 <= key.length, prefix.length <= 50`
- `key` and `prefix` consist of only lowercase English letters.
- `1 <= val <= 1000`
- At most `50` calls will be made to `insert` and `sum`.

SOLUTION (PYTHON 3)

Solution 1: Hash Table + Trie

How to think about it

`sum(prefix)` needs the total of keys with that prefix, and `insert` overwrites. Scanning every key is linear in the map size. Trie nodes store subtree sums. Insert adds Δ=val-old along the path; `sum` returns the node at the prefix. A hash map keeps the previous value.

We use a hash table d to store key-value pairs and a trie t to store the prefix sums of the key-value pairs. Each node in the trie contains two pieces of information:

- `val`: the total sum of the values of the key-value pairs with this node as the prefix
- `children`: an array of length 26 that stores the child nodes of this node

When inserting a key-value pair (key, val), we first check if the key exists in the hash table. If it does, the `val` of each node in the trie needs to subtract the original value of the key and then add the new value. If it does not exist, the `val` of each

node in the trie needs to add the new value.

When querying the prefix sum, we start from the root node of the trie and traverse the prefix string. If the current node's child nodes do not contain the character, it means the prefix does not exist in the trie, and we return 0. Otherwise, we continue to traverse the next character until we finish traversing the prefix string and return the `val` of the current node.

In terms of time complexity, the time complexity of inserting a key-value pair is O(n), where n is the length of the key. The time complexity of querying the prefix sum is O(m), where m is the length of the prefix.

The space complexity is O(n × m × C), where n and m are the number of keys and the maximum length of the keys, respectively; and C is the size of the character set, which is 26 in this problem.

Python 3

```
class Trie:
    def __init__(self):
        self.children: List[Trie | None] = [None] * 26
        self.val: int = 0

    def insert(self, w: str, x: int):
        node = self
        for c in w:
            idx = ord(c) - ord('a')
            if node.children[idx] is None:
                node.children[idx] = Trie()
            node = node.children[idx]
            node.val += x

    def search(self, w: str) -> int:
        node = self
        for c in w:
            idx = ord(c) - ord('a')
            if node.children[idx] is None:
                return 0
            node = node.children[idx]
        return node.val

class MapSum:
    def __init__(self):
        self.d = defaultdict(int)
        self.tree = Trie()

    def insert(self, key: str, val: int) -> None:
        x = val - self.d[key]
        self.d[key] = val
        self.tree.insert(key, x)

    def sum(self, prefix: str) -> int:
        return self.tree.search(prefix)

# Your MapSum object will be instantiated and called as such:
# obj = MapSum()
# obj.insert(key,val)
# param_2 = obj.sum(prefix)
```

PATTERN 32 · TRIE (PREFIX TREE) · PROBLEM 9 OF 20

1268. Search Suggestions System

Medium · Trie, Array, String, Binary Search, Sorting, Heap (Priority Queue)

leetcode.com/problems/search-suggestions-system

★ **TOP 10 PROBLEM** in Trie (Prefix Tree): master this one first

PROBLEM

You are given an array of strings `products` and a string `searchWord`.

Design a system that suggests at most three product names from `products` after each character of `searchWord` is typed. Suggested products should have common prefix with `searchWord`. If there are more than three products with a common prefix return the three lexicographically minimums products.

Return *a list of lists of the suggested products after each character of* `searchWord` *is typed*.

Example 1:

```
Input: products = ["mobile","mouse","moneypot","monitor","mousepad"], searchWord = "mouse"
Output: [["mobile","moneypot","monitor"],["mobile","moneypot","monitor"],["mouse","mousepad"],["mouse"
,"mousepad"],["mouse","mousepad"]]
Explanation: products sorted lexicographically = ["mobile","moneypot","monitor","mouse","mousepad"].
After typing m and mo all products match and we show user ["mobile","moneypot","monitor"].
After typing mou, mous and mouse the system suggests ["mouse","mousepad"].
```

Example 2:

```
Input: products = ["havana"], searchWord = "havana"
Output: [["havana"],["havana"],["havana"],["havana"],["havana"],["havana"]]
Explanation: The only word "havana" will be always suggested while typing the search word.
```

Constraints:

- `1 <= products.length <= 1000`
- `1 <= products[i].length <= 3000`
- `1 <= sum(products[i].length) <= 2 * 10^4`
- All the strings of `products` are **unique**.
- `products[i]` consists of lowercase English letters.
- `1 <= searchWord.length <= 1000`
- `searchWord` consists of lowercase English letters.

SOLUTION (PYTHON 3)

Solution 1: Sorting + Trie

How to think about it

After each extra letter we want the three lexicographically smallest products with that prefix. There are 1000 products: sort, then insert into a trie, each node keeping at most three indices in insertion order — the top three for that prefix. Walking searchWord maps those index lists back to names. Sorting makes insertion order lexicographic; the trie locates prefixes.

The problem requires that after each letter of the input `searchWord`, recommend up to three products from the `products` array that have the same prefix as `searchWord`. If there are more than three products with the same prefix that can be recommended, return the three with the smallest lexicographic order.

To find products with the same prefix, we can use a trie; to return the three products with the smallest lexicographic order, we can first sort the `products` array, and then store the indices of the sorted array in the trie.

Each node of the trie maintains the following information:

- `children`: This is an array of length 26, used to store the child nodes of the current node. `children[i]` represents the node whose character is `i + 'a'` among the child nodes of the current node.
- `v`: This is an array, used to store the indices of the characters in the `products` array among the child nodes of the current node, storing up to three indices.

During the search, we start from the root node of the trie, find the index array corresponding to each prefix, and store it in the result array. Finally, we only need to map each index in the index array to the `products` array.

The time complexity is O(L × log n + m), and the space complexity is O(L). Where L is the sum of the lengths of all strings in the `products` array, and n and m are the lengths of the `products` array and `searchWord`, respectively.

Python 3

```python
class Trie:
    def __init__(self):
        self.children: List[Union[Trie, None]] = [None] * 26
        self.v: List[int] = []

    def insert(self, w, i):
        node = self
        for c in w:
            idx = ord(c) - ord('a')
            if node.children[idx] is None:
                node.children[idx] = Trie()
            node = node.children[idx]
            if len(node.v) < 3:
                node.v.append(i)

    def search(self, w):
        node = self
        ans = [[] for _ in range(len(w))]
        for i, c in enumerate(w):
            idx = ord(c) - ord('a')
            if node.children[idx] is None:
                break
            node = node.children[idx]
            ans[i] = node.v
        return ans

class Solution:
    def suggestedProducts(
        self, products: List[str], searchWord: str
    ) -> List[List[str]]:
        products.sort()
        trie = Trie()
        for i, w in enumerate(products):
            trie.insert(w, i)
        return [[products[i] for i in v] for v in trie.search(searchWord)]
```

PATTERN 32 · TRIE (PREFIX TREE) · PROBLEM 13 OF 20

820. Short Encoding of Words

Medium · Trie, Array, Hash Table, String

leetcode.com/problems/short-encoding-of-words

PROBLEM

A **valid encoding** of an array of `words` is any reference string `s` and array of indices `indices` such that:

- `words.length == indices.length`
- The reference string `s` ends with the `'#'` character.
- For each index `indices[i]`, the **substring** of `s` starting from `indices[i]` and up to (but not including) the next `'#'` character is equal to `words[i]`.

Given an array of `words`, return *the **length of the shortest reference string** `s` possible of any **valid encoding** of* `words`.

Example 1:

```
Input: words = ["time", "me", "bell"]
Output: 10
Explanation: A valid encoding would be s = "time#bell#" and indices = [0, 2, 5].
words[0] = "time", the substring of s starting from indices[0] = 0 to the next '#' is underlined in
"time#bell#"
words[1] = "me", the substring of s starting from indices[1] = 2 to the next '#' is underlined in
"time#bell#"
words[2] = "bell", the substring of s starting from indices[2] = 5 to the next '#' is underlined in
"time#bell#"
```

Example 2:

```
Input: words = ["t"]
Output: 2
Explanation: A valid encoding would be s = "t#" and indices = [0].
```

Constraints:

- `1 <= words.length <= 2000`
- `1 <= words[i].length <= 7`
- `words[i]` consists of only lowercase letters.

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

The encoding concatenates words with `#`. A shorter word that is a suffix of a longer one is already covered. Pairwise suffix checks waste work. Insert the reversed words into a trie so shared suffixes share a path. Only leaves need their own encoding (length plus one); internal nodes are covered by a longer word.

Python 3

```python
class Trie:
    def __init__(self) -> None:
        self.children = [None] * 26

class Solution:
    def minimumLengthEncoding(self, words: List[str]) -> int:
        root = Trie()
        for w in words:
            cur = root
            for c in w[::-1]:
                idx = ord(c) - ord("a")
                if cur.children[idx] == None:
                    cur.children[idx] = Trie()
                cur = cur.children[idx]
        return self.dfs(root, 1)

    def dfs(self, cur: Trie, l: int) -> int:
        isLeaf, ans = True, 0
        for i in range(26):
            if cur.children[i] != None:
                isLeaf = False
                ans += self.dfs(cur.children[i], l + 1)
        if isLeaf:
            ans += l
        return ans
```

Complexity. Time: O(L), L = total number of letters. Space: O(26 * L).

Solution 2

> **How to think about it**
>
> Method 1 builds the full trie, then DFS-counts leaves. Inserting reversed words from long to short lets longer words occupy paths first. If a later word's path already exists, it is a suffix of a longer word and contributes 0; otherwise it contributes length plus one. The answer is accumulated during insertion, so the second DFS is dropped.

Python 3

```python
class Trie:
    def __init__(self):
        self.children = [None] * 26

    def insert(self, w):
        node = self
        pref = True
        for c in w:
            idx = ord(c) - ord("a")
            if node.children[idx] is None:
                node.children[idx] = Trie()
                pref = False
            node = node.children[idx]
        return 0 if pref else len(w) + 1

class Solution:
    def minimumLengthEncoding(self, words: List[str]) -> int:
        words.sort(key=lambda x: -len(x))
        trie = Trie()
        return sum(trie.insert(w[::-1]) for w in words)
```

Complexity. Time: O(L + n log n). Space: O(26 * L).

PATTERN 32 · TRIE (PREFIX TREE) · PROBLEM 14 OF 20

212. Word Search II

Hard · Trie, Array, String, Backtracking, Matrix

leetcode.com/problems/word-search-ii

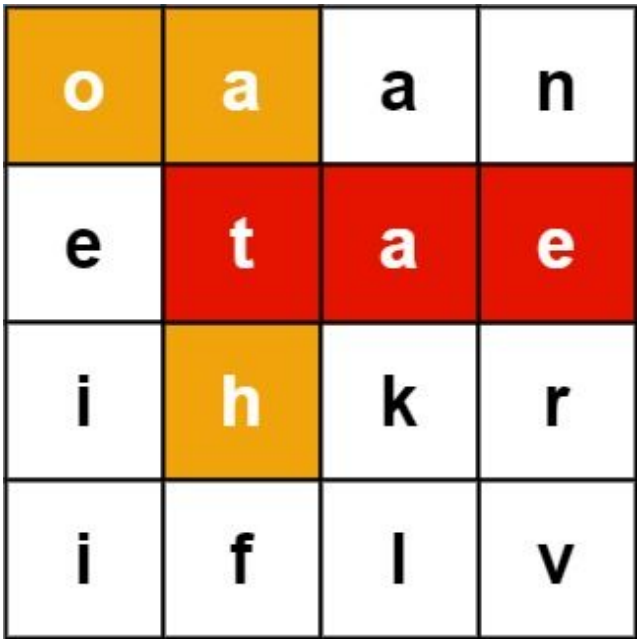
★ **TOP 10 PROBLEM** in Trie (Prefix Tree): master this one first

PROBLEM

Given an `m x n board` of characters and a list of strings `words`, return *all words on the board*.

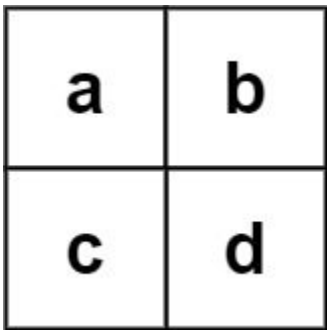
Each word must be constructed from letters of sequentially adjacent cells, where **adjacent cells** are horizontally or vertically neighboring. The same letter cell may not be used more than once in a word.

Example 1:



```
Input: board = [["o","a","a","n"],["e","t","a","e"],["i","h","k","r"],["i","f","l","v"]], words =
["oath","pea","eat","rain"]
Output: ["eat","oath"]
```

Example 2:



```
Input: board = [["a","b"],["c","d"]], words = ["abcb"]
Output: []
```

Constraints:

- `m == board.length`

- `n == board[i].length`
- `1 <= m, n <= 12`
- `board[i][j]` is a lowercase English letter.
- `1 <= words.length <= 3 * 10^4`
- `1 <= words[i].length <= 10`
- `words[i]` consists of lowercase English letters.
- All the strings of `words` are unique.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

A separate DFS per word repeats work on shared prefixes. Building a trie of words lets the board search walk the tree and prune dead branches. From each cell we expand to neighbors whose edge exists in the trie. Reaching a word node records the answer and sets ref to -1 so it is not reported again.

Python 3

```python
class Trie:
    def __init__(self):
        self.children: List[Trie | None] = [None] * 26
        self.ref: int = -1

    def insert(self, w: str, ref: int):
        node = self
        for c in w:
            idx = ord(c) - ord('a')
            if node.children[idx] is None:
                node.children[idx] = Trie()
            node = node.children[idx]
        node.ref = ref

class Solution:
    def findWords(self, board: List[List[str]], words: List[str]) -> List[str]:
        def dfs(node: Trie, i: int, j: int):
            idx = ord(board[i][j]) - ord('a')
            if node.children[idx] is None:
                return
            node = node.children[idx]
            if node.ref >= 0:
                ans.append(words[node.ref])
                node.ref = -1
            c = board[i][j]
            board[i][j] = '#'
            for a, b in pairwise((-1, 0, 1, 0, -1)):
                x, y = i + a, j + b
                if 0 <= x < m and 0 <= y < n and board[x][y] != '#':
                    dfs(node, x, y)
            board[i][j] = c

        tree = Trie()
        for i, w in enumerate(words):
            tree.insert(w, i)
        m, n = len(board), len(board[0])
        ans = []
        for i in range(m):
            for j in range(n):
                dfs(tree, i, j)
        return ans
```

Complexity. Time: O(m * n * 3^l), l = length of the longest word (pruned by the trie). Space: O(W) for the trie, W = total letters.

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

745. Prefix and Suffix Search

Hard · Design, Trie, Array, Hash Table, String

leetcode.com/problems/prefix-and-suffix-search

PROBLEM

Design a special dictionary that searches the words in it by a prefix and a suffix.

Implement the `WordFilter` class:

- `WordFilter(string[] words)` Initializes the object with the `words` in the dictionary.
- `f(string pref, string suff)` Returns *the index of the word in the dictionary,* which has the prefix `pref` and the suffix `suff`. If there is more than one valid index, return **the largest** of them. If there is no such word in the dictionary, return `-1`.

Example 1:

```
Input
["WordFilter", "f"]
[[["apple"]], ["a", "e"]]
Output
[null, 0]
Explanation
WordFilter wordFilter = new WordFilter(["apple"]);
wordFilter.f("a", "e"); // return 0, because the word at index 0 has prefix = "a" and suffix = "e".
```

Constraints:

- `1 <= words.length <= 10^4`
- `1 <= words[i].length <= 7`
- `1 <= pref.length, suff.length <= 7`
- `words[i]`, `pref` and `suff` consist of lowercase English letters only.
- At most `10^4` calls will be made to the function `f`.

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

Return the largest index whose word has a given prefix and suffix. Words are at most length 7, so every prefix–suffix pair of every word can be stored, and a query is O(1). Later words overwrite earlier ones, so the map keeps the largest index. Empty prefix and suffix are stored as well. Keys are (pref,suff). f looks up or returns -1.

Python 3

```python
class WordFilter:
    def __init__(self, words: List[str]):
        self.d = {}
        for k, w in enumerate(words):
            n = len(w)
            for i in range(n + 1):
                a = w[:i]
                for j in range(n + 1):
                    b = w[j:]
                    self.d[(a, b)] = k

    def f(self, pref: str, suff: str) -> int:
        return self.d.get((pref, suff), -1)

# Your WordFilter object will be instantiated and called as such:
# obj = WordFilter(words)
# param_1 = obj.f(pref,suff)
```

Solution 2

How to think about it

Solution 1 stores every prefix–suffix pair. Two tries—one on the word, one on the reverse—record the indices that pass each node. A query fetches the two index lists (increasing by insert order) and walks them from the right for the largest common index. Lists stay short because words are short, without materializing every pair.

Python 3

```
class Trie:
    def __init__(self):
        self.children = [None] * 26
        self.indexes = []

    def insert(self, word, i):
        node = self
        for c in word:
            idx = ord(c) - ord("a")
            if node.children[idx] is None:
                node.children[idx] = Trie()
            node = node.children[idx]
            node.indexes.append(i)

    def search(self, pref):
        node = self
        for c in pref:
            idx = ord(c) - ord("a")
            if node.children[idx] is None:
                return []
            node = node.children[idx]
        return node.indexes

class WordFilter:
    def __init__(self, words: List[str]):
        self.p = Trie()
        self.s = Trie()
        for i, w in enumerate(words):
            self.p.insert(w, i)
            self.s.insert(w[::-1], i)

    def f(self, pref: str, suff: str) -> int:
        a = self.p.search(pref)
        b = self.s.search(suff[::-1])
        if not a or not b:
            return -1
        i, j = len(a) - 1, len(b) - 1
        while ~i and ~j:
            if a[i] == b[j]:
                return a[i]
            if a[i] > b[j]:
                i -= 1
            else:
                j -= 1
        return -1

# Your WordFilter object will be instantiated and called as such:
# obj = WordFilter(words)
# param_1 = obj.f(pref,suff)
```

Complexity. Time: build O(sum of word lengths); f O(p + s + N), p and s = prefix and suffix lengths, N = number of words. Space: O(sum of word lengths).

```

1707. Maximum XOR With an Element From Array

Hard · Bit Manipulation, Trie, Array

leetcode.com/problems/maximum-xor-with-an-element-from-array

PROBLEM

You are given an array `nums` consisting of non-negative integers. You are also given a `queries` array, where `queries[i] = [x_i, m_i]`.

The answer to the `i^th` query is the maximum bitwise `XOR` value of `x_i` and any element of `nums` that does not exceed `m_i`. In other words, the answer is `max(nums[j] XOR x_i)` for all `j` such that `nums[j] <= m_i`. If all elements in `nums` are larger than `m_i`, then the answer is `-1`.

Return *an integer array* `answer` *where* `answer.length == queries.length` *and* `answer[i]` *is the answer to the* `i^th` *query.*

Example 1:

```
Input: nums = [0,1,2,3,4], queries = [[3,1],[1,3],[5,6]]
Output: [3,3,7]
Explanation:
1) 0 and 1 are the only two integers not greater than 1. 0 XOR 3 = 3 and 1 XOR 3 = 2. The larger of the two is 3.
2) 1 XOR 2 = 3.
3) 5 XOR 2 = 7.
```

Example 2:

```
Input: nums = [5,2,4,6,6,3], queries = [[12,4],[8,1],[6,3]]
Output: [15,-1,5]
```

Constraints:

- `1 <= nums.length, queries.length <= 10^5`
- `queries[i].length == 2`
- `0 <= nums[j], x_i, m_i <= 10^9`

SOLUTION (PYTHON 3)

Solution 1: Offline Query + Binary Trie

How to think about it

Each query asks for the maximum x_i xor nums[j] among values ≤ m_i. Scanning the array per query is O(nq) and fails for n,q≤ 10^5. Queries are independent of one another and of the order of nums. Sorting by m_i lets us insert eligible numbers monotonically into one structure. Sort nums and insert values ≤ m_i into a binary trie with a moving pointer. Walking opposite bits on the trie yields the maximum XOR; an empty trie answers -1.

From the problem description, we know that each query is independent and the result of the query is irrelevant to the order of elements in nums. Therefore, we consider sorting all queries in ascending order of m_i, and also sorting nums in ascending order.

Next, we use a binary trie to maintain the elements in nums. We use a pointer j to record the current elements in the trie, initially j=0. For each query $[x_i, m_i]$, we continuously insert elements from nums into the trie until nums[j] > m_i. At this point, we can query all elements not exceeding m_i in the trie, and we take the XOR value of the element with the maximum XOR value with x_i as the answer.

The time complexity is O(m × log m + n × (log n + log M)), and the space complexity is O(n × log M). Where m and n are the lengths of the arrays nums and queries respectively, and M is the maximum value in the array nums. In this problem, M ≤

10^9.

Python 3

```python
class Trie:
    __slots__ = ["children"]

    def __init__(self):
        self.children = [None] * 2

    def insert(self, x: int):
        node = self
        for i in range(30, -1, -1):
            v = x >> i & 1
            if node.children[v] is None:
                node.children[v] = Trie()
            node = node.children[v]

    def search(self, x: int) -> int:
        node = self
        ans = 0
        for i in range(30, -1, -1):
            v = x >> i & 1
            if node.children[v ^ 1]:
                ans |= 1 << i
                node = node.children[v ^ 1]
            elif node.children[v]:
                node = node.children[v]
            else:
                return -1
        return ans

class Solution:
    def maximizeXor(self, nums: List[int], queries: List[List[int]]) -> List[int]:
        trie = Trie()
        nums.sort()
        j, n = 0, len(queries)
        ans = [-1] * n
        for i, (x, m) in sorted(zip(range(n), queries), key=lambda x: x[1][1]):
            while j < len(nums) and nums[j] <= m:
                trie.insert(nums[j])
                j += 1
            ans[i] = trie.search(x)
        return ans
```

    return result
```

2416. Sum of Prefix Scores of Strings

Hard · Trie, Array, String, Counting

leetcode.com/problems/sum-of-prefix-scores-of-strings

PROBLEM

You are given an array `words` of size `n` consisting of **non-empty** strings.

We define the **score** of a string `term` as the **number** of strings `words[i]` such that `term` is a **prefix** of `words[i]`.

- For example, if `words = ["a", "ab", "abc", "cab"]`, then the score of `"ab"` is `2`, since `"ab"` is a prefix of both `"ab"` and `"abc"`.

Return *an array* `answer` *of size* `n` *where* `answer[i]` *is the* ***sum*** *of scores of every* ***non-empty*** *prefix of* `words[i]`.

Note that a string is considered as a prefix of itself.

Example 1:

```
Input: words = ["abc","ab","bc","b"]
Output: [5,4,3,2]
Explanation: The answer for each string is the following:
- "abc" has 3 prefixes: "a", "ab", and "abc".
- There are 2 strings with the prefix "a", 2 strings with the prefix "ab", and 1 string with the prefix
"abc".
The total is answer[0] = 2 + 2 + 1 = 5.
- "ab" has 2 prefixes: "a" and "ab".
- There are 2 strings with the prefix "a", and 2 strings with the prefix "ab".
The total is answer[1] = 2 + 2 = 4.
- "bc" has 2 prefixes: "b" and "bc".
- There are 2 strings with the prefix "b", and 1 string with the prefix "bc".
The total is answer[2] = 2 + 1 = 3.
- "b" has 1 prefix: "b".
- There are 2 strings with the prefix "b".
The total is answer[3] = 2.
```

Example 2:

```
Input: words = ["abcd"]
Output: [4]
Explanation:
"abcd" has 4 prefixes: "a", "ab", "abc", and "abcd".
Each prefix has a score of one, so the total is answer[0] = 1 + 1 + 1 + 1 = 4.
```

Constraints:

- `1 <= words.length <= 1000`
- `1 <= words[i].length <= 1000`
- `words[i]` consists of lowercase English letters.

SOLUTION (PYTHON 3)

Solution 1: Prefix Tree

> **How to think about it**
>
> A word's score is the sum of occurrence counts of all its prefixes. Scanning every word for every prefix is heavy when the total length reaches 10^6. Shared prefixes belong on a trie. Insert every word, incrementing cnt on each node. Then walk each word again and sum cnt. Time is linear in the total number of characters.

We can use a prefix tree to maintain all prefixes of the strings and count the occurrences of each prefix.

Define the prefix tree node structure `Trie`, which includes two properties:

- `children`: An array of length 26 used to store the current node's children.
- `cnt`: The occurrence count of the current node.

Define two methods for the prefix tree:

- `insert`: Inserts a string, adding its prefixes into the prefix tree.
- `search`: Searches for a string and returns the occurrence count of its prefixes.

We traverse all strings, inserting each string into the prefix tree. Then we traverse all strings again, calling the `search` method for each string and summing up the occurrence counts of each prefix.

Time complexity is O(L), and space complexity is O(L), where L is the total length of all strings.

Python 3

```python
class Trie:
    __slots__ = "children", "cnt"

    def __init__(self):
        self.children = [None] * 26
        self.cnt = 0

    def insert(self, w):
        node = self
        for c in w:
            idx = ord(c) - ord("a")
            if node.children[idx] is None:
                node.children[idx] = Trie()
            node = node.children[idx]
            node.cnt += 1

    def search(self, w):
        node = self
        ans = 0
        for c in w:
            idx = ord(c) - ord("a")
            if node.children[idx] is None:
                return ans
            node = node.children[idx]
            ans += node.cnt
        return ans

class Solution:
    def sumPrefixScores(self, words: List[str]) -> List[int]:
        trie = Trie()
        for w in words:
            trie.insert(w)
        return [trie.search(w) for w in words]
```

```

PATTERN 33 OF 41

Cyclic Sort

20 problems · 9 Easy · 9 Medium · 2 Hard

THE IDEA

When the numbers are in the range 1..n (or 0..n), put every number at its own index by swapping; whatever is left in the wrong place is the answer. O(n) time, O(1) extra space.

Signals: missing number, find all duplicates, first missing positive, set mismatch, array of n numbers in range 1..n.

A TEMPLATE TO KEEP IN YOUR HANDS (PYTHON)

```
i = 0
while i < len(nums):
    j = nums[i] - 1                        # where nums[i] belongs
    if 0 <= j < len(nums) and nums[i] != nums[j]:
        nums[i], nums[j] = nums[j], nums[i]
    else:
        i += 1
for i, x in enumerate(nums):
    if x != i + 1:
        return i + 1                       # first misplaced position
```

PATTERN 33 · CYCLIC SORT · PROBLEM 2 OF 20

448. Find All Numbers Disappeared in an Array

Easy · Array, Hash Table

leetcode.com/problems/find-all-numbers-disappeared-in-an-array

★ **TOP 10 PROBLEM** in Cyclic Sort: master this one first

PROBLEM

Given an array `nums` of `n` integers where `nums[i]` is in the range `[1, n]`, return *an array of all the integers in the range* `[1, n]` *that do not appear in* `nums`.

Example 1:

```
Input: nums = [4,3,2,7,8,2,3,1]
Output: [5,6]
```

Example 2:

```
Input: nums = [1,1]
Output: [2]
```

Constraints:

- `n == nums.length`
- `1 <= n <= 10^5`
- `1 <= nums[i] <= n`

Follow up: Could you do it without extra space and in `O(n)` runtime? You may assume the returned list does not count as extra space.

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

Values lie in [1,n]; missing numbers are a set difference. Store seen values in a hash set and scan 1..n. Linear time, O(n) extra space. The follow-up wants constant extra memory; this solution establishes correctness first.

Python 3

```python
class Solution:
    def findDisappearedNumbers(self, nums: List[int]) -> List[int]:
        s = set(nums)
        return [x for x in range(1, len(nums) + 1) if x not in s]
```

Solution 2

How to think about it

Solution 1 uses a set. Value x can negate index |x|-1 to mark “seen”; a still-positive slot i means i+1 is missing. Absolute value before indexing avoids treating a mark as a subscript.

Python 3

```
class Solution:
    def findDisappearedNumbers(self, nums: List[int]) -> List[int]:
        for x in nums:
            i = abs(x) - 1
            if nums[i] > 0:
                nums[i] *= -1
        return [i + 1 for i in range(len(nums)) if nums[i] > 0]
```

Complexity. Time: O(n). Space: O(1) extra.

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

        if nums[i] != i + 1:
            return i + 1
    return n + 1
```

PATTERN 33 · CYCLIC SORT · PROBLEM 3 OF 20

645. Set Mismatch

Easy · Bit Manipulation, Array, Hash Table, Sorting

leetcode.com/problems/set-mismatch

★ **TOP 10 PROBLEM** in Cyclic Sort: master this one first

PROBLEM

You have a set of integers `s`, which originally contains all the numbers from `1` to `n`. Unfortunately, due to some error, one of the numbers in `s` got duplicated to another number in the set, which results in **repetition of one** number and **loss of another** number.

You are given an integer array `nums` representing the data status of this set after the error.

Find the number that occurs twice and the number that is missing and return *them in the form of an array*.

Example 1:

```
Input: nums = [1,2,2,4]
Output: [2,3]
```

Example 2:

```
Input: nums = [1,1]
Output: [1,2]
```

Constraints:

- `2 <= nums.length <= 10^4`
- `1 <= nums[i] <= 10^4`

SOLUTIONS (PYTHON 3)

Solution 1: Mathematics

How to think about it

One number in [1,n] is duplicated and one is missing. Sums identify both at once. Let s be the array sum, s_2 the unique-sum, s_1 the sum 1..n. The duplicate is s-s_2 and the missing is s_1-s_2.

We denote s_1 as the sum of all numbers from [1,..n], s_2 as the sum of the numbers in the array nums after removing duplicates, and s as the sum of the numbers in the array nums.

Then s - s_2 is the duplicate number, and s_1 - s_2 is the missing number.

The time complexity is O(n), and the space complexity is O(n), where n is the length of the array nums. Extra space is needed to store the array after de-duplication.

Python 3

```python
class Solution:
    def findErrorNums(self, nums: List[int]) -> List[int]:
        n = len(nums)
        s1 = (1 + n) * n // 2
        s2 = sum(set(nums))
        s = sum(nums)
        return [s - s2, s1 - s2]
```

Solution 2: Hash Table

> **How to think about it**
> The sum method needs a set. A frequency map makes the duplicate (2) and the missing (0) explicit.

We can also use a more intuitive method, using a hash table cnt to count the occurrence of each number in the array nums.

Next, iterate through $x \in [1, n]$, if cnt[x] = 2, then x is the duplicate number, if cnt[x] = 0, then x is the missing number.

The time complexity is O(n), and the space complexity is O(n), where n is the length of the array nums.

Python 3

```python
class Solution:
    def findErrorNums(self, nums: List[int]) -> List[int]:
        cnt = Counter(nums)
        n = len(nums)
        ans = [0] * 2
        for x in range(1, n + 1):
            if cnt[x] == 2:
                ans[0] = x
            if cnt[x] == 0:
                ans[1] = x
        return ans
```

Solution 3: Bit Operation

> **How to think about it**
> The first two methods use linear extra memory. XOR of nums and 1..n yields axor b; split by the lowest set bit to recover a and b, then see which one appears in the array.

According to the properties of the XOR operation, for integer x, we have x xor x = 0 and x xor 0 = x. Therefore, if we perform the XOR operation on all elements in the array nums and all numbers $i \in [1, n]$, we can eliminate the numbers that appear twice, leaving only the XOR result of the missing number and the duplicate number, i.e., xs = a xor b.

Since these two numbers are not equal, there must be at least one bit in the XOR result that is 1. We find the lowest bit of 1 in the XOR result through the lowbit operation, and then divide all numbers in the array nums and all numbers $i \in [1, n]$ into two groups according to whether this bit is 1. In this way, the two numbers are divided into different groups. The XOR result of one group of numbers is a, and the XOR result of the other group is b. These two numbers are the answers we are looking for.

Next, we only need to determine which of a and b is the duplicate number and which is the missing number. Therefore, iterate through the array nums, for the traversed number x, if x=a, then a is the duplicate number, return [a, b], otherwise, at the end of the iteration, return [b, a].

The time complexity is O(n), where n is the length of the array nums. The space complexity is O(1), only using a constant size of extra space.

Python 3

```python
class Solution:
    def findErrorNums(self, nums: List[int]) -> List[int]:
        xs = 0
        for i, x in enumerate(nums, 1):
            xs ^= i ^ x
        a = 0
        lb = xs & -xs
        for i, x in enumerate(nums, 1):
            if i & lb:
                a ^= i
            if x & lb:
                a ^= x
        b = xs ^ a
        for x in nums:
            if x == a:
                return [a, b]
        return [b, a]
```

PATTERN 33 · CYCLIC SORT · PROBLEM 5 OF 20

697. Degree of an Array

Easy · Array, Hash Table

leetcode.com/problems/degree-of-an-array

PROBLEM

Given a non-empty array of non-negative integers `nums`, the **degree** of this array is defined as the maximum frequency of any one of its elements.

Your task is to find the smallest possible length of a (contiguous) subarray of `nums`, that has the same degree as `nums`.

Example 1:

```
Input: nums = [1,2,2,3,1]
Output: 2
Explanation:
The input array has a degree of 2 because both elements 1 and 2 appear twice.
Of the subarrays that have the same degree:
[1, 2, 2, 3, 1], [1, 2, 2, 3], [2, 2, 3, 1], [1, 2, 2], [2, 2, 3], [2, 2]
The shortest length is 2. So return 2.
```

Example 2:

```
Input: nums = [1,2,2,3,1,4,2]
Output: 6
Explanation:
The degree is 3 because the element 2 is repeated 3 times.
So [2,2,3,1,4,2] is the shortest subarray, therefore returning 6.
```

Constraints:

- `nums.length` will be between 1 and 50,000.
- `nums[i]` will be an integer between 0 and 49,999.

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

The degree is the maximum frequency. A shortest subarray with the same degree must cover the first and last occurrence of some mode. Count frequencies and record endpoints. For values that attain the degree, take the minimum right-left+1.

Python 3

```python
class Solution:
    def findShortestSubArray(self, nums: List[int]) -> int:
        cnt = Counter(nums)
        degree = cnt.most_common()[0][1]
        left, right = {}, {}
        for i, v in enumerate(nums):
            if v not in left:
                left[v] = i
            right[v] = i
        ans = inf
        for v in nums:
            if cnt[v] == degree:
                t = right[v] - left[v] + 1
                if ans > t:
                    ans = t
        return ans
```

Complexity. Time: O(n). Space: O(n).

Solution 2

> **How to think about it**
>
> Method 1 records endpoints in one pass. We can also collect the modes first and scan first/last indices per mode. The helpers are longer, the complexity is the same.

Python 3 (written for this guide: the doocs page has no Python 3 version of this solution)

```
class Solution:
    def findShortestSubArray(self, nums: List[int]) -> int:
        count = Counter(nums)
        degree = max(count.values())
        answer = len(nums)
        for value, c in count.items():
            if c == degree:
                first = nums.index(value)
                last = len(nums) - 1 - nums[::-1].index(value)
                answer = min(answer, last - first + 1)
        return answer
```

Complexity. Time: O(n * c), c = number of values that reach the degree. Space: O(n).

```

1512. Number of Good Pairs

Easy · Array, Hash Table, Math, Counting

leetcode.com/problems/number-of-good-pairs

PROBLEM

Given an array of integers `nums`, return *the number of **good pairs***.

A pair `(i, j)` is called *good* if `nums[i] == nums[j]` and `i < j`.

Example 1:

```
Input: nums = [1,2,3,1,1,3]
Output: 4
Explanation: There are 4 good pairs (0,3), (0,4), (3,4), (2,5) 0-indexed.
```

Example 2:

```
Input: nums = [1,1,1,1]
Output: 6
Explanation: Each pair in the array are good.
```

Example 3:

```
Input: nums = [1,2,3]
Output: 0
```

Constraints:

- `1 <= nums.length <= 100`
- `1 <= nums[i] <= 100`

SOLUTION (PYTHON 3)

Solution 1: Counting

How to think about it

Count index pairs with i<j and nums[i]=nums[j]. A double loop would pass for n≤ 100, but it rescans earlier equals on every step. The current x forms one pair with each previous x. A frequency map of values already seen lets us add that count and then increment, so one pass suffices.

Traverse the array, and for each element x, count how many elements before it are equal to x. This count represents the number of good pairs formed by x and the previous elements. After traversing the entire array, we obtain the answer.

The time complexity is O(n), and the space complexity is O(C). Here, n is the length of the array, and C is the range of values in the array. In this problem, C = 101.

Python 3

```python
class Solution:
    def numIdenticalPairs(self, nums: List[int]) -> int:
        ans = 0
        cnt = Counter()
        for x in nums:
            ans += cnt[x]
            cnt[x] += 1
        return ans
```

# numbers equal nums[j] + k.
# Time: O(n).  Space: O(n).
def pairs_with_difference(nums, k):
    seen = {}
    total = 0
    for x in nums:
        total += seen.get(x + k, 0)
        seen[x] = seen.get(x, 0) + 1
    return total
```

PATTERN 33 · CYCLIC SORT · PROBLEM 7 OF 20

1299. Replace Elements with Greatest Element on Right Side

Easy · Array

leetcode.com/problems/replace-elements-with-greatest-element-on-right-side

PROBLEM

Given an array `arr`, replace every element in that array with the greatest element among the elements to its right, and replace the last element with `-1`.

After doing so, return the array.

Example 1:

```
Input: arr = [17,18,5,4,6,1]
Output: [18,6,6,6,1,-1]
Explanation:
- index 0 --> the greatest element to the right of index 0 is index 1 (18).
- index 1 --> the greatest element to the right of index 1 is index 4 (6).
- index 2 --> the greatest element to the right of index 2 is index 4 (6).
- index 3 --> the greatest element to the right of index 3 is index 4 (6).
- index 4 --> the greatest element to the right of index 4 is index 5 (1).
- index 5 --> there are no elements to the right of index 5, so we put -1.
```

Example 2:

```
Input: arr = [400]
Output: [-1]
Explanation: There are no elements to the right of index 0.
```

Constraints:

- `1 <= arr.length <= 10^4`
- `1 <= arr[i] <= 10^5`

SOLUTION (PYTHON 3)

Solution 1: Reverse Traversal

How to think about it

Each index becomes the maximum to its right; the last is -1. Scanning the suffix from the left repeats work. Walking right to left, we keep a suffix max mx, write the old mx into the cell, then update mx with the original value. One reverse pass, O(1) extra space.

We use a variable mx to record the maximum value to the right of the current position, initially mx = -1.

Then we traverse the array from right to left. For each position i, we denote the current value as x, update the current position's value to mx, and then update mx = max(mx, x).

Finally, return the original array.

The time complexity is O(n), where n is the length of the array. The space complexity is O(1).

Python 3

```python
class Solution:
    def replaceElements(self, arr: List[int]) -> List[int]:
        mx = -1
        for i in reversed(range(len(arr))):
            x = arr[i]
            arr[i] = mx
            mx = max(mx, x)
        return arr
```

            stack.pop()
        if stack:
            result[i] = stack[-1]
        stack.append(arr[i])
    return result
```

PATTERN 33 · CYCLIC SORT · PROBLEM 10 OF 20

442. Find All Duplicates in an Array

Medium · Array, Hash Table, Sorting

leetcode.com/problems/find-all-duplicates-in-an-array

★ **TOP 10 PROBLEM** in Cyclic Sort: master this one first

PROBLEM

Given an integer array `nums` of length `n` where all the integers of `nums` are in the range `[1, n]` and each integer appears **at most twice**, return *an array of all the integers that appears **twice***.

You must write an algorithm that runs in `O(n)` time and uses only *constant* auxiliary space, excluding the space needed to store the output

Example 1:

```
Input: nums = [4,3,2,7,8,2,3,1]
Output: [2,3]
```

Example 2:

```
Input: nums = [1,1,2]
Output: [1]
```

Example 3:

```
Input: nums = [1]
Output: []
```

Constraints:

- `n == nums.length`
- `1 <= n <= 10^5`
- `1 <= nums[i] <= n`
- Each element in `nums` appears **once** or **twice**.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Values lie in [1,n] and appear at most twice; the follow-up wants linear time and constant extra memory. A hash set finds duplicates but uses O(n) space. Swap v into index v-1 (cycle sort). Afterwards a value that is not i+1 at index i is a leftover duplicate. The swap loop stops when nums[i]=nums[nums[i]-1], so a duplicate collides with the value already in place and never cycles forever.

Python 3

```python
class Solution:
    def findDuplicates(self, nums: List[int]) -> List[int]:
        for i in range(len(nums)):
            while nums[i] != nums[nums[i] - 1]:
                nums[nums[i] - 1], nums[i] = nums[i], nums[nums[i] - 1]
        return [v for i, v in enumerate(nums) if v != i + 1]
```

PATTERN 33 · CYCLIC SORT · PROBLEM 13 OF 20

1963. Minimum Number of Swaps to Make the String Balanced

Medium · Stack, Greedy, Two Pointers, String, Parentheses

leetcode.com/problems/minimum-number-of-swaps-to-make-the-string-balanced

PROBLEM

You are given a **0-indexed** string `s` of **even** length `n`. The string consists of **exactly** `n / 2` opening brackets `'['` and `n / 2` closing brackets `']'`.

A string is called **balanced** if and only if:

- It is the empty string, or
- It can be written as `AB`, where both `A` and `B` are **balanced** strings, or
- It can be written as `[C]`, where `C` is a **balanced** string.

You may swap the brackets at **any** two indices **any** number of times.

Return *the **minimum** number of swaps to make* `s` ***balanced***.

Example 1:

```
Input: s = "][]["
Output: 1
Explanation: You can make the string balanced by swapping index 0 with index 3.
The resulting string is "[[]]".
```

Example 2:

```
Input: s = "]]][[["
Output: 2
Explanation: You can do the following to make the string balanced:
- Swap index 0 with index 4. s = "[]][][".
- Swap index 1 with index 5. s = "[[][]]".
The resulting string is "[[][]]".
```

Example 3:

```
Input: s = "[]"
Output: 0
Explanation: The string is already balanced.
```

Constraints:

- `n == s.length`
- `2 <= n <= 10^6`
- `n` is even.
- `s[i]` is either `'['` or `']'`.
- The number of opening brackets `'['` equals `n / 2`, and the number of closing brackets `']'` equals `n / 2`.

SOLUTION (PYTHON 3)

Solution 1: Greedy

> **How to think about it**
>
> Any two brackets may be swapped. After matching, the leftover is some `]`s followed by `[`s. If x left brackets remain unmatched, each swap of the two ends removes two of them, so floor((x+1)/2) swaps suffice. One counter computes x.

We use a variable x to record the current number of unmatched left brackets. We traverse the string s, for each character c:

- If c is a left bracket, then we increment x by one;

- If c is a right bracket, then we need to check whether x is greater than zero. If it is, we match the current right bracket with the nearest unmatched left bracket on the left, i.e., decrement x by one.

After the traversal, we will definitely get a string of the form `"]]]...[[[..."`. We then greedily swap the brackets at both ends each time, which can eliminate 2 unmatched left brackets at a time. Therefore, the total number of swaps needed is floor((x + 1)/2).

The time complexity is O(n), where n is the length of the string s. The space complexity is O(1).

Python 3

```
class Solution:
    def minSwaps(self, s: str) -> int:
        x = 0
        for c in s:
            if c == "[":
                x += 1
            elif x:
                x -= 1
        return (x + 1) >> 1
```

```

PATTERN 33 · CYCLIC SORT · PROBLEM 14 OF 20

565. Array Nesting

Medium · Depth-First Search, Array

leetcode.com/problems/array-nesting

★ **TOP 10 PROBLEM** in Cyclic Sort: master this one first

PROBLEM

You are given an integer array `nums` of length `n` where `nums` is a permutation of the numbers in the range `[0, n - 1]`.

You should build a set `s[k] = {nums[k], nums[nums[k]], nums[nums[nums[k]]], ... }` subjected to the following rule:

- The first element in `s[k]` starts with the selection of the element `nums[k]` of `index = k`.
- The next element in `s[k]` should be `nums[nums[k]]`, and then `nums[nums[nums[k]]]`, and so on.
- We stop adding right before a duplicate element occurs in `s[k]`.

Return *the longest length of a set* `s[k]`.

Example 1:

```
Input: nums = [5,4,0,3,1,6,2]
Output: 4
Explanation:
nums[0] = 5, nums[1] = 4, nums[2] = 0, nums[3] = 3, nums[4] = 1, nums[5] = 6, nums[6] = 2.
One of the longest sets s[k]:
s[0] = {nums[0], nums[5], nums[6], nums[2]} = {5, 6, 2, 0}
```

Example 2:

```
Input: nums = [0,1,2]
Output: 1
```

Constraints:

- $1 <= nums.length <= 10^5$
- $0 <= nums[i] < nums.length$
- All the values of `nums` are **unique**.

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

A[i] points to A[A[i]], partitioning the array into disjoint cycles. A nest is a cycle. Walking from every index would revisit the same cycle. A visited array marks seen indices; start a walk only from an unseen index and count the cycle. Disjointness visits each index once. The longest cycle is the answer.

Python 3

```python
class Solution:
    def arrayNesting(self, nums: List[int]) -> int:
        n = len(nums)
        vis = [False] * n
        res = 0
        for i in range(n):
            if vis[i]:
                continue
            cur, m = nums[i], 1
            vis[cur] = True
            while nums[cur] != nums[i]:
                cur = nums[cur]
                m += 1
                vis[cur] = True
            res = max(res, m)
        return res
```

Complexity. Time: O(n). Space: O(n).

Solution 2

> **How to think about it**
>
> Solution 1 uses an O(n) visited array. Values already lie in [0,n-1], so the sentinel n can mark a visited cell in place. Walk the cycle, write n into each cell, and count. A stored n means this index was already processed. Extra space becomes constant; the cycles are the same.

Python 3

```python
class Solution:
    def arrayNesting(self, nums: List[int]) -> int:
        ans, n = 0, len(nums)
        for i in range(n):
            cnt = 0
            while nums[i] != n:
                j = nums[i]
                nums[i] = n
                i = j
                cnt += 1
            ans = max(ans, cnt)
        return ans
```

PATTERN 33 · CYCLIC SORT · PROBLEM 15 OF 20

670. Maximum Swap

Medium · Greedy, Math

leetcode.com/problems/maximum-swap

★ **TOP 10 PROBLEM** in Cyclic Sort: master this one first

PROBLEM

You are given an integer `num`. You can swap two digits at most once to get the maximum valued number.

Return *the maximum valued number you can get*.

Example 1:

```
Input: num = 2736
Output: 7236
Explanation: Swap the number 2 and the number 7.
```

Example 2:

```
Input: num = 9973
Output: 9973
Explanation: No swap.
```

Constraints:

- $0 <= num <= 10^8$

SOLUTIONS (PYTHON 3)

Solution 1: Greedy Algorithm

How to think about it

Swap at most two digits to maximize the number. Trying every pair is unnecessary. From the right, record the index of the largest digit to the right (inclusive). From the left, swap at the first s[i]<s[d[i]]. That raises the highest possible place.

First, we convert the number into a string s. Then, we traverse the string s from right to left, using an array or hash table d to record the position of the maximum number to the right of each number (it can be the position of the number itself).

Next, we traverse d from left to right. If s[i] < s[d[i]], we swap them and exit the traversal process.

Finally, we convert the string s back into a number, which is the answer.

The time complexity is O(log M), and the space complexity is O(log M). Here, M is the range of the number num.

Python 3

```python
class Solution:
    def maximumSwap(self, num: int) -> int:
        s = list(str(num))
        n = len(s)
        d = list(range(n))
        for i in range(n - 2, -1, -1):
            if s[i] <= s[d[i + 1]]:
                d[i] = d[i + 1]
        for i, j in enumerate(d):
            if s[i] < s[j]:
                s[i], s[j] = s[j], s[i]
                break
        return int(''.join(s))
```

Solution 2: Space Optimized Greedy

How to think about it

Method 1 stores a right-max index array. One right-to-left scan can keep the best seen digit and the leftmost profitable swap, without the extra array.

Python 3 (written for this guide: the doocs page has no Python 3 version of this solution)

```
class Solution:
    def maximumSwap(self, num: int) -> int:
        digits = list(str(num))
        low = high = maybe_high = -1
        for i in range(len(digits) - 1, -1, -1):
            if maybe_high == -1 or digits[i] > digits[maybe_high]:
                maybe_high = i
            if i < maybe_high and digits[i] < digits[maybe_high]:
                low, high = i, maybe_high
        if low != -1 and high != -1 and low < high:
            digits[low], digits[high] = digits[high], digits[low]
        return int("".join(digits))
```

Complexity. Time: O(d), d = number of digits. Space: O(d).

```

PATTERN 33 · CYCLIC SORT · PROBLEM 16 OF 20

910. Smallest Range II

Medium · Greedy, Array, Math, Sorting

leetcode.com/problems/smallest-range-ii

PROBLEM

You are given an integer array `nums` and an integer `k`.

For each index `i` where `0 <= i < nums.length`, change `nums[i]` to be either `nums[i] + k` or `nums[i] - k`.

The **score** of `nums` is the difference between the maximum and minimum elements in `nums`.

Return *the minimum **score** of* `nums` *after changing the values at each index*.

Example 1:

```
Input: nums = [1], k = 0
Output: 0
Explanation: The score is max(nums) - min(nums) = 1 - 1 = 0.
```

Example 2:

```
Input: nums = [0,10], k = 2
Output: 6
Explanation: Change nums to be [2, 8]. The score is max(nums) - min(nums) = 8 - 2 = 6.
```

Example 3:

```
Input: nums = [1,3,6], k = 3
Output: 3
Explanation: Change nums to be [4, 6, 3]. The score is max(nums) - min(nums) = 6 - 3 = 3.
```

Constraints:

- `1 <= nums.length <= 10^4`
- `0 <= nums[i] <= 10^4`
- `0 <= k <= 10^4`

SOLUTION (PYTHON 3)

Solution 1: Greedy + Enumeration

How to think about it

Each value becomes +k or -k; 2^n assignments are impossible. After sorting, smaller numbers should take +k and larger ones -k, so an optimal split is a prefix of +k and a suffix of -k. For each cut i, the new minimum is min(nums[0]+k, nums[i]-k) and the new maximum is max(nums[i-1]+k, nums[-1]-k). Keep the smallest gap, including the original one.

According to the problem requirements, we need to find the minimum difference between the maximum and minimum values in the array. Each element can be increased or decreased by k, so we can divide the elements in the array into two parts, one part increased by k and the other part decreased by k. Therefore, we should decrease the larger values in the array by k and increase the smaller values by k to ensure the minimum difference between the maximum and minimum values.

Therefore, we can first sort the array, then enumerate each element in the array, divide it into two parts, one part increased by k and the other part decreased by k, and calculate the difference between the maximum and minimum values. Finally, take the minimum value among all differences.

The time complexity is $O(n \times \log n)$, and the space complexity is $O(\log n)$, where n is the length of the array.

Python 3

```python
class Solution:
    def smallestRangeII(self, nums: List[int], k: int) -> int:
        nums.sort()
        ans = nums[-1] - nums[0]
        for i in range(1, len(nums)):
            mi = min(nums[0] + k, nums[i] - k)
            mx = max(nums[i - 1] + k, nums[-1] - k)
            ans = min(ans, mx - mi)
        return ans
```

2554. Maximum Number of Integers to Choose From a Range I

Medium · Greedy, Array, Hash Table, Binary Search, Sorting

leetcode.com/problems/maximum-number-of-integers-to-choose-from-a-range-i

PROBLEM

You are given an integer array `banned` and two integers `n` and `maxSum`. You are choosing some number of integers following the below rules:

- The chosen integers have to be in the range `[1, n]`.
- Each integer can be chosen **at most once**.
- The chosen integers should not be in the array `banned`.
- The sum of the chosen integers should not exceed `maxSum`.

Return *the **maximum** number of integers you can choose following the mentioned rules*.

Example 1:

```
Input: banned = [1,6,5], n = 5, maxSum = 6
Output: 2
Explanation: You can choose the integers 2 and 4.
2 and 4 are from the range [1, 5], both did not appear in banned, and their sum is 6, which did not
exceed maxSum.
```

Example 2:

```
Input: banned = [1,2,3,4,5,6,7], n = 8, maxSum = 1
Output: 0
Explanation: You cannot choose any integer while following the mentioned conditions.
```

Example 3:

```
Input: banned = [11], n = 7, maxSum = 50
Output: 7
Explanation: You can choose the integers 1, 2, 3, 4, 5, 6, and 7.
They are from the range [1, 7], all did not appear in banned, and their sum is 28, which did not exceed
maxSum.
```

Constraints:

- `1 <= banned.length <= 10^4`
- `1 <= banned[i], n <= 10^4`
- `1 <= maxSum <= 10^9`

SOLUTIONS (PYTHON 3)

Solution 1: Greedy + Enumeration

How to think about it

Pick as many distinct integers from [1,n] as possible, skipping banned, with sum at most maxSum. Smaller values leave more room, so take them first. For n≤ 10^4, walk i=1,2,…, skip banned values via a set, and stop when the next i would exceed the remaining sum.

We use the variable s to represent the sum of the currently selected integers, and the variable ans to represent the number of currently selected integers. We convert the array `banned` into a hash table for easy determination of whether a certain integer is not selectable.

Next, we start enumerating the integer i from 1. If s + i ≤ maxSum and i is not in `banned`, then we can select the integer i, and add i and 1 to s and ans respectively.

Finally, we return ans.

The time complexity is O(n), and the space complexity is O(n). Where n is the given integer.

Python 3

```
class Solution:
    def maxCount(self, banned: List[int], n: int, maxSum: int) -> int:
        ans = s = 0
        ban = set(banned)
        for i in range(1, n + 1):
            if s + i > maxSum:
                break
            if i not in ban:
                ans += 1
                s += i
        return ans
```

Solution 2: Greedy + Binary Search

> **How to think about it**
>
> Solution 1 is linear in n and fails when n is huge. Banned values split [1,n] into contiguous gaps whose prefix sums are arithmetic; binary search finds how many we can still afford. Fill gaps from the left until the budget is gone.

If n is very large, the enumeration in Method One will time out.

We can add 0 and n + 1 to the array `banned`, deduplicate the array `banned`, remove elements greater than n+1, and then sort it.

Next, we enumerate every two adjacent elements i and j in the array `banned`. The range of selectable integers is [i + 1, j - 1]. We use binary search to enumerate the number of elements we can select in this range, find the maximum number of selectable elements, and then add it to ans. At the same time, we subtract the sum of these elements from `maxSum`. If `maxSum` is less than 0, we break the loop. Return the answer.

The time complexity is O(n × log n), and the space complexity is O(n). Where n is the length of the array `banned`.

765. Couples Holding Hands

Hard · Greedy, Depth-First Search, Breadth-First Search, Union Find, Graph

leetcode.com/problems/couples-holding-hands

★ **TOP 10 PROBLEM** in Cyclic Sort: master this one first

PROBLEM

There are `n` couples sitting in `2n` seats arranged in a row and want to hold hands.

The people and seats are represented by an integer array `row` where `row[i]` is the ID of the person sitting in the i^{th} seat. The couples are numbered in order, the first couple being `(0, 1)`, the second couple being `(2, 3)`, and so on with the last couple being `(2n - 2, 2n - 1)`.

Return *the minimum number of swaps so that every couple is sitting side by side*. A swap consists of choosing any two people, then they stand up and switch seats.

Example 1:

```
Input: row = [0,2,1,3]
Output: 1
Explanation: We only need to swap the second (row[1]) and third (row[2]) person.
```

Example 2:

```
Input: row = [3,2,0,1]
Output: 0
Explanation: All couples are already seated side by side.
```

Constraints:

- `2n == row.length`
- `2 <= n <= 30`
- `0 <= row[i] < 2n`
- All the elements of `row` are **unique**.

SOLUTION (PYTHON 3)

Solution 1: Union-Find

How to think about it

Seat couples side by side with the fewest swaps. The count equals a permutation of couple-ids. Each sofa maps two people to couple numbers; those couples are unioned. A cycle of y couples needs y-1 swaps. Union-find on n couple ids; the answer is n minus the number of roots.

We can assign a number to each pair of couples. Person with number 0 and 1 corresponds to couple 0, person with number 2 and 3 corresponds to couple 1, and so on. In other words, the person corresponding to row[i] has a couple number of floor(row[i]/2).

If there are k pairs of couples who are seated incorrectly with respect to each other, i.e., if k pairs of couples are in the same permutation cycle, it will take k-1 swaps for all of them to be seated correctly.

Why? Consider the following: we first adjust the positions of a couple to their correct seats. After this, the problem reduces from k couples to k-1 couples. This process continues, and when k = 1, the number of swaps required is 0. Therefore, if k pairs of couples are in the wrong positions, we need k-1 swaps.

Thus, we only need to traverse the array once, use union-find to determine how many permutation cycles there are. Suppose there are x cycles, and the size of each cycle (in terms of couple pairs) is y_1, y_2, …, y_x. The number of swaps required is y_1-1 + y_2-1 + … + y_x-1 = y_1 + y_2 + … + y_x - x = n - x.

The time complexity is O(n × α(n)), and the space complexity is O(n), where α(n) is the inverse Ackermann function, which can be considered a very small constant.

Python 3

```python
class Solution:
    def minSwapsCouples(self, row: List[int]) -> int:
        def find(x: int) -> int:
            if p[x] != x:
                p[x] = find(p[x])
            return p[x]

        n = len(row) >> 1
        p = list(range(n))
        for i in range(0, len(row), 2):
            a, b = row[i] >> 1, row[i + 1] >> 1
            p[find(a)] = find(b)
        return n - sum(i == find(i) for i in range(n))
```

            x = parent[x]
        return x

    for i in range(0, len(row), 2):
        a, b = row[i] // 2, row[i + 1] // 2
        parent[find(a)] = find(b)
    return n - len(set(find(x) for x in range(n)))
```

PATTERN 34 OF 41

Math / Number Theory

20 problems · 10 Easy · 10 Medium · 0 Hard

THE IDEA

Look for a formula, a modular identity, or a number-theory tool: gcd, primes (sieve), powers by squaring, digit tricks.

Signals: count primes, power(x, n), happy number, factorial trailing zeroes, ugly number, excel sheet column, fraction to decimal.

A TEMPLATE TO KEEP IN YOUR HANDS (PYTHON)

```python
def gcd(a, b):
    while b:
        a, b = b, a % b
    return a

def power(x, n):                # fast exponent: O(log n)
    result = 1
    while n:
        if n & 1:
            result *= x
        x *= x
        n >>= 1
    return result
```

PATTERN 34 · MATH / NUMBER THEORY · PROBLEM 1 OF 20

9. Palindrome Number

Easy · Math

leetcode.com/problems/palindrome-number

★ **TOP 10 PROBLEM** in Math / Number Theory: master this one first

PROBLEM

Given an integer `x`, return `true` if `x` is a **palindrome**, and `false` otherwise.

Example 1:

```
Input: x = 121
Output: true
Explanation: 121 reads as 121 from left to right and from right to left.
```

Example 2:

```
Input: x = -121
Output: false
Explanation: From left to right, it reads -121. From right to left, it becomes 121-. Therefore it is
not a palindrome.
```

Example 3:

```
Input: x = 10
Output: false
Explanation: Reads 01 from right to left. Therefore it is not a palindrome.
```

Constraints:

- $-2^{31} <= x <= 2^{31} - 1$

Follow up:

Could you solve it without converting the integer to a string?

SOLUTION (PYTHON 3)

Solution 1: Reverse Half of the Number

How to think about it

Converting to a string and comparing with its reverse is the obvious idea; the follow-up asks us not to. Reversing the whole x and comparing would also overflow 32-bit integers. We only need half: keep appending x's last digit onto y until y is no longer smaller than the remaining prefix. A negative number cannot be a palindrome; a nonzero number ending in 0 would drop that zero when reversed, so those are false as well. The loop stops when the two halves have the same length. Even length compares x with y; odd length leaves the middle digit on y, so we compare x with y/10.

First, we determine special cases:

- If x < 0, then x is not a palindrome, directly return `false`;
- If x > 0 and the last digit of x is 0, then x is not a palindrome, directly return `false`;
- If the last digit of x is not 0, then x might be a palindrome, continue the following steps.

We reverse the second half of x and compare it with the first half. If they are equal, then x is a palindrome, otherwise, x is not a palindrome.

For example, for x = 1221, we can reverse the second half from "21" to "12" and compare it with the first half "12". Since they are equal, we know that x is a palindrome.

Let's see how to reverse the second half.

For the number 1221, if we perform 1221 mod 10, we will get the last digit 1. To get the second last digit, we can first remove the last digit from 1221 by dividing by 10, 1221 / 10 = 122, then get the remainder of the previous result divided by 10, 122 mod 10 = 2, to get the second last digit.

If we continue this process, we will get more reversed digits.

By continuously multiplying the last digit to the variable y, we can get the number in reverse order.

In the code implementation, we can repeatedly "take out" the last digit of x and "add" it to the end of y, loop until y ≥ x. If at this time x = y, or x = y / 10, then x is a palindrome.

The time complexity is $O(\log_{10}(n))$, where n is x. For each iteration, we will divide the input by 10, so the time complexity is $O(\log_{10}(n))$. The space complexity is O(1).

Python 3

```python
class Solution:
    def isPalindrome(self, x: int) -> bool:
        if x < 0 or (x and x % 10 == 0):
            return False
        y = 0
        while y < x:
            y = y * 10 + x % 10
            x //= 10
        return x in (y, y // 10)
```

# Space: O(log x).
def next_palindrome(x):
    while True:
        text = str(x)
        if text == text[::-1]:
            return x
```

```
        x += 1
```

13. Roman to Integer

Easy · Hash Table, Math, String

leetcode.com/problems/roman-to-integer

★ **TOP 10 PROBLEM** in Math / Number Theory: master this one first

PROBLEM

Roman numerals are represented by seven different symbols: `I`, `V`, `X`, `L`, `C`, `D` and `M`.

```
Symbol Value
I 1
V 5
X 10
L 50
C 100
D 500
M 1000
```

For example, `2` is written as `II` in Roman numeral, just two ones added together. `12` is written as `XII`, which is simply `X + II`. The number `27` is written as `XXVII`, which is `XX + V + II`.

Roman numerals are usually written largest to smallest from left to right. However, the numeral for four is not `IIII`. Instead, the number four is written as `IV`. Because the one is before the five we subtract it making four. The same principle applies to the number nine, which is written as `IX`. There are six instances where subtraction is used:

- `I` can be placed before `V` (5) and `X` (10) to make 4 and 9.
- `X` can be placed before `L` (50) and `C` (100) to make 40 and 90.
- `C` can be placed before `D` (500) and `M` (1000) to make 400 and 900.

Given a roman numeral, convert it to an integer.

Example 1:

```
Input: s = "III"
Output: 3
Explanation: III = 3.
```

Example 2:

```
Input: s = "LVIII"
Output: 58
Explanation: L = 50, V= 5, III = 3.
```

Example 3:

```
Input: s = "MCMXCIV"
Output: 1994
Explanation: M = 1000, CM = 900, XC = 90 and IV = 4.
```

Constraints:

- `1 <= s.length <= 15`
- `s` contains only the characters `('I', 'V', 'X', 'L', 'C', 'D', 'M')`.
- It is **guaranteed** that `s` is a valid roman numeral in the range `[1, 3999]`.

SOLUTION (PYTHON 3)

Solution 1: Hash Table + Simulation

How to think about it

The first idea is a scan with special cases for the six subtractive pairs (IV, IX, …) and addition elsewhere. |s|≤ 15, so it would pass, but the exceptions are easy to miss. The annoyance is deciding whether the current character is added or subtracted. A character is subtracted if and only if it is smaller than the next one; the last character is always added. We do not need to list the six pairs. So we store each character's value in a hash table, compare neighbors to choose the sign, and add the last character.

First, we use a hash table d to record the numerical value corresponding to each character. Then, we traverse the string s from left to right. If the numerical value corresponding to the current character is less than the numerical value corresponding to the character on the right, we subtract the numerical value corresponding to the current character. Otherwise, we add the numerical value corresponding to the current character.

The time complexity is O(n), and the space complexity is O(m). Here, n and m are the length of the string s and the size of the character set, respectively.

Python 3

```
class Solution:
    def romanToInt(self, s: str) -> int:
        d = {'I': 1, 'V': 5, 'X': 10, 'L': 50, 'C': 100, 'D': 500, 'M': 1000}
        return sum((-1 if d[a] < d[b] else 1) * d[a] for a, b in pairwise(s)) + d[s[-1]]
```

```

171. Excel Sheet Column Number

Easy · Math, String

leetcode.com/problems/excel-sheet-column-number

★ **TOP 10 PROBLEM** in Math / Number Theory: master this one first

PROBLEM

Given a string `columnTitle` that represents the column title as appears in an Excel sheet, return *its corresponding column number*.

For example:

```
A -> 1
B -> 2
C -> 3
...
Z -> 26
AA -> 27
AB -> 28
...
```

Example 1:

```
Input: columnTitle = "A"
Output: 1
```

Example 2:

```
Input: columnTitle = "AB"
Output: 28
```

Example 3:

```
Input: columnTitle = "ZY"
Output: 701
```

Constraints:

- `1 <= columnTitle.length <= 7`
- `columnTitle` consists only of uppercase English letters.
- `columnTitle` is in the range `["A", "FXSHRXW"]`.

SOLUTION (PYTHON 3)

Solution 1: Base Conversion

How to think about it

Title to number is the inverse of problem 168: each letter is a digit in 1… 26. Fold left to right with ans=ans× 26 + (c-'A'+1), the same pattern as parsing a decimal string.

The column name in Excel is a representation in base 26. For example, "AB" represents the column number 1 × 26 + 2 = 28.

Therefore, we can iterate through the string `columnTitle`, convert each character to its corresponding value, and then calculate the result.

The time complexity is O(n), where n is the length of the string `columnTitle`. The space complexity is O(1).

Python 3

```
class Solution:
    def titleToNumber(self, columnTitle: str) -> int:
        ans = 0
        for c in map(ord, columnTitle):
            ans = ans * 26 + c - ord("A") + 1
        return ans
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

Built on the solutions above: helper functions, then the function for each follow-up. No tests and no restating of the question.

```
# FOLLOW-UPS (answered below, in this order):
# 1. Add two column titles and answer as a title
# 2. List all column titles from one title to another

# ============================================================
# FOLLOW-UP 1: Add two column titles and answer as a title
# ============================================================

# ---- follow-up 1: function ----
# Answer: Convert both to numbers, add, and convert back
# to letters.
# Time: O(n + log value).  Space: O(log value).
def title_to_number(title):
    number = 0
    for ch in title:
        number = number * 26 + (ord(ch) - ord("A") + 1)
    return number

def number_to_title(number):
    letters = []
    while number > 0:
        number -= 1
        letters.append(chr(ord("A") + number % 26))
        number //= 26
    return "".join(reversed(letters))

def add_columns(a, b):
    return number_to_title(title_to_number(a) + title_to_number(b))

# ============================================================
# FOLLOW-UP 2: List all column titles from one title to
# another
# ============================================================

# ---- follow-up 2: function ----
# Answer: Convert both ends to numbers and convert every
# number in between.
# Time: O(k * L), k = columns in the range, L = title
# length.  Space: O(k * L).
def columns_between(first, last):
    return [number_to_title(x) for x in range(title_to_number(first), title_to_number(last) + 1)]
```

PATTERN 34 · MATH / NUMBER THEORY · PROBLEM 5 OF 20

168. Excel Sheet Column Title

Easy · Math, String

leetcode.com/problems/excel-sheet-column-title

PROBLEM

Given an integer `columnNumber`, return *its corresponding column title as it appears in an Excel sheet*.

For example:

```
A -> 1
B -> 2
C -> 3
...
Z -> 26
AA -> 27
AB -> 28
...
```

Example 1:

```
Input: columnNumber = 1
Output: "A"
```

Example 2:

```
Input: columnNumber = 28
Output: "AB"
```

Example 3:

```
Input: columnNumber = 701
Output: "ZY"
```

Constraints:

- `1 <= columnNumber <= 2^31 - 1`

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Map a positive integer to an Excel column title: base 26 with A… Z as 1… 26, and no zero. Ordinary base 26 would emit 0 instead of Z on a zero remainder. Subtract 1 before mod 26, map the remainder to A– Z, continue with the quotient, and reverse.

Python 3

```python
class Solution:
    def convertToTitle(self, columnNumber: int) -> str:
        res = []
        while columnNumber:
            columnNumber -= 1
            res.append(chr(ord('A') + columnNumber % 26))
            columnNumber //= 26
        return ''.join(res[::-1])
```

Complexity. Time: O(log n). Space: O(log n).

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

Built on the solutions above: helper functions, then the function for each follow-up. No tests and no restating of the question.

```
# FOLLOW-UPS (answered below, in this order):
# 1. Use a different alphabet size (for example only the

    base = len(alphabet)
    letters = []
    while number > 0:
        number -= 1
        letters.append(alphabet[number % base])
        number //= base
    return "".join(reversed(letters))

# ============================================================
# FOLLOW-UP 2: Zero based columns (0 is A, 25 is Z, 26 is
# AA)
# ============================================================

# ---- follow-up 2: function ----
# Answer: Add one and use the usual conversion.
# Time: O(log n).  Space: O(log n).
def zero_based_title(index):
    number = index + 1
    letters = []
    while number > 0:
        number -= 1
        letters.append(chr(ord("A") + number % 26))
        number //= 26
    return "".join(reversed(letters))
```

1071. Greatest Common Divisor of Strings

Easy · Math, String, Greatest Common Divisor, Euclidean Algorithm

leetcode.com/problems/greatest-common-divisor-of-strings

PROBLEM

For two strings `s` and `t`, we say "`t` divides `s`" if and only if `s = t + t + t + ... + t + t` (i.e., `t` is concatenated with itself one or more times).

Given two strings `str1` and `str2`, return *the largest string* `x` *such that* `x` *divides both* `str1` *and* `str2`.

Example 1:

Input: str1 = "ABCABC", str2 = "ABC"

Output: "ABC"

Example 2:

Input: str1 = "ABABAB", str2 = "ABAB"

Output: "AB"

Example 3:

Input: str1 = "LEET", str2 = "CODE"

Output: ""

Example 4:

Input: str1 = "AAAAAB", str2 = "AAA"

Output: ""

Constraints:

- `1 <= str1.length, str2.length <= 1000`
- `str1` and `str2` consist of English uppercase letters.

SOLUTIONS (PYTHON 3)

Solution 1: Enumeration

How to think about it

A common divisor string must tile both inputs, so its length divides both lengths. Trying prefixes from the shorter length downward is enough for m,n≤ 1000. Each candidate t=str1[:i] is repeated until it matches the target length and compared. The first t that tiles both strings is the longest; otherwise the answer is empty.

Enumerate candidate prefixes t from the shorter string length downward, and check whether repeating t can produce str1 and str2. The first valid t is the longest gcd string.

The time complexity is O((m + n) × min(m, n)), and the space complexity is O(m + n), where m and n are the lengths of the two strings.

Python 3

```
class Solution:
    def gcdOfStrings(self, str1: str, str2: str) -> str:
        def check(a, b):
            c = ""
            while len(c) < len(b):
                c += a
            return c == b

        for i in range(min(len(str1), len(str2)), 0, -1):
            t = str1[:i]
            if check(t, str1) and check(t, str2):
                return t
        return ''
```

Solution 2: Math

> **How to think about it**
>
> Enumeration still tries many lengths. If a common divisor exists then $s_1+s_2=s_2+s_1$, and the longest length is $\gcd(|s_1|,|s_2|)$. We reject unequal concatenations and otherwise return the prefix of s_1 of that gcd length.

If a gcd string exists, then $s_1+s_2=s_2+s_1$. In that case the length of the longest gcd string is $\gcd(|s_1|,|s_2|)$.

The time complexity is O(m + n), and the space complexity is O(m + n), where m and n are the lengths of the two strings.

Python 3

```
class Solution:
    def gcdOfStrings(self, str1: str, str2: str) -> str:
        if str1 + str2 != str2 + str1:
            return ''
        n = gcd(len(str1), len(str2))
        return str1[:n]
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

```

PATTERN 34 · MATH / NUMBER THEORY · PROBLEM 8 OF 20

258. Add Digits

Easy · Math, Number Theory, Simulation

leetcode.com/problems/add-digits

PROBLEM

Given an integer `num`, repeatedly add all its digits until the result has only one digit, and return it.

Example 1:

```
Input: num = 38
Output: 2
Explanation: The process is
38 --> 3 + 8 --> 11
11 --> 1 + 1 --> 2
Since 2 has only one digit, return it.
```

Example 2:

```
Input: num = 0
Output: 0
```

Constraints:

- $0 <= num <= 2^{31} - 1$

Follow up: Could you do it without any loop/recursion in `O(1)` runtime?

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Repeated digit sums yield the digital root. For a non-negative integer it is 0 when num=0, and (num-1) mod 9+1 otherwise.

Python 3

```python
class Solution:
    def addDigits(self, num: int) -> int:
        return 0 if num == 0 else (num - 1) % 9 + 1
```

Complexity. Time: O(1). Space: O(1).

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

Built on the solutions above: helper functions, then the function for each follow-up. No tests and no restating of the question.

```python
# FOLLOW-UPS (answered below, in this order):
# 1. The number is given as a very long string
# 2. How many steps does it take to reach one digit

# ============================================================
# FOLLOW-UP 1: The number is given as a very long string
# ============================================================

# ---- follow-up 1: function ----
# Answer: The digital root only depends on the number
# modulo 9; add the digits (mod 9) one by one.
# Time: O(n).  Space: O(1).
def digital_root_of_text(text):
```

```
    total = 0
    for ch in text:
        total += int(ch)
    if total == 0:
        return 0
    if total % 9 == 0:
        return 9
    return total % 9

# ============================================================
# FOLLOW-UP 2: How many steps does it take to reach one
# digit
# ============================================================

# ---- follow-up 2: function ----
# Answer: Repeat the digit sum and count the rounds.
# Time: O(log num) per step, and the number shrinks fast.
# Space: O(1).
def steps_to_single_digit(num):
    steps = 0
    while num >= 10:
        total = 0
        while num > 0:
            total += num % 10
            num //= 10
        num = total
        steps += 1
    return steps
```

PATTERN 34 · MATH / NUMBER THEORY · PROBLEM 9 OF 20

263. Ugly Number

Easy · Math

leetcode.com/problems/ugly-number

PROBLEM

An **ugly number** is a *positive* integer which does not have a prime factor other than 2, 3, and 5.

Given an integer `n`, return `true` *if* `n` *is an* ***ugly number***.

Example 1:

```
Input: n = 6
Output: true
Explanation: 6 = 2 × 3
```

Example 2:

```
Input: n = 1
Output: true
Explanation: 1 has no prime factors.
```

Example 3:

```
Input: n = 14
Output: false
Explanation: 14 is not ugly since it includes the prime factor 7.
```

Constraints:

- $-2^{31} <= n <= 2^{31} - 1$

SOLUTION (PYTHON 3)

Solution 1

How to think about it

An ugly number's prime factors are only 2,3,5. Reject non-positives; otherwise divide out those three primes and test whether 1 remains.

Python 3

```python
class Solution:
    def isUgly(self, n: int) -> bool:
        if n < 1:
            return False
        for x in [2, 3, 5]:
            while n % x == 0:
                n //= x
        return n == 1
```

Complexity. Time: O(log n). Space: O(1).

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

        return None
    exponents = []
    for p in (2, 3, 5):
        count = 0
        while n % p == 0:
            n //= p
            count += 1
        exponents.append(count)
    if n != 1:
        return None
    return exponents
```

728. Self Dividing Numbers

Easy · Math

leetcode.com/problems/self-dividing-numbers

PROBLEM

A **self-dividing number** is a number that is divisible by every digit it contains.

- For example, `128` is **a self-dividing number** because `128 % 1 == 0`, `128 % 2 == 0`, and `128 % 8 == 0`.

A **self-dividing number** is not allowed to contain the digit zero.

Given two integers `left` and `right`, return *a list of all the* ***self-dividing numbers*** *in the range* `[left, right]` (both **inclusive**).

Example 1:

```
Input: left = 1, right = 22
Output: [1,2,3,4,5,6,7,8,9,11,12,15,22]
```

Example 2:

```
Input: left = 47, right = 85
Output: [48,55,66,77]
```

Constraints:

- `1 <= left <= right <= 10^4`

SOLUTION (PYTHON 3)

Solution 1: Simulation

> **How to think about it**
>
> The range is at most 10^4, and testing a number against its own digits is a few divisions. Enumerating the interval is fine. A zero digit cannot divide, so those numbers fail immediately; otherwise x must be divisible by each digit. Walk digits of y=x; reject on a 0 or a failed modulo, otherwise keep x.

We define a function check(x) to determine whether x is a self-dividing number. The implementation idea of the function is as follows:

We use y to record the value of x, and then continuously divide y by 10 until y is 0. During this process, we check whether the last digit of y is 0, or whether x cannot be divided by the last digit of y. If either of these conditions is met, then x is not a self-dividing number, and we return false. Otherwise, after traversing all the digits, we return true.

Finally, we traverse all the numbers in the interval [left, right], and for each number, we call check(x). If it returns true, we add this number to the answer array.

The time complexity is $O(n \times \log_{10} M)$, where n is the number of elements in the interval [left, right], and M = right, which is the maximum value in the interval.

Python 3

```python
class Solution:
    def selfDividingNumbers(self, left: int, right: int) -> List[int]:
        def check(x: int) -> bool:
            y = x
            while y:
                if y % 10 == 0 or x % (y % 10):
                    return False
                y //= 10
            return True

        return [x for x in range(left, right + 1) if check(x)]
```

```

7. Reverse Integer

Medium · Math

leetcode.com/problems/reverse-integer

★ **TOP 10 PROBLEM** in Math / Number Theory: master this one first

PROBLEM

Given a signed 32-bit integer `x`, return `x` *with its digits reversed*. If reversing `x` causes the value to go outside the signed 32-bit integer range `[-2^31, 2^31 - 1]`, then return `0`.

Assume the environment does not allow you to store 64-bit integers (signed or unsigned).

Example 1:

```
Input: x = 123
Output: 321
```

Example 2:

```
Input: x = -123
Output: -321
```

Example 3:

```
Input: x = 120
Output: 21
```

Constraints:

- `-2^31 <= x <= 2^31 - 1`

SOLUTION (PYTHON 3)

Solution 1: Mathematics

How to think about it

Reversing via a string is the obvious idea, but the environment is assumed not to hold 64-bit integers. We cannot compute in a wider type and check overflow afterwards. Peeling the last digit and appending it is ans ← 10·ans+y. Before multiplying by 10, we must know whether the next value would leave [-2^{31}, 2^{31}-1]; if it would, return 0. That check collapses to whether ans still lies in [floor(mi/10), floor(mx/10)]. Inside the range, one more digit is safe; outside, it has already overflowed.

Let's denote mi and mx as -2^{31} and 2^{31} - 1 respectively, then the reverse result of x, ans, needs to satisfy mi ≤ ans ≤ mx.

We can continuously take the remainder of x to get the last digit y of x, and add y to the end of ans. Before adding y, we need to check if ans overflows. That is, check whether ans × 10 + y is within the range [mi, mx].

If x > 0, it needs to satisfy ans × 10 + y ≤ mx, that is, ans × 10 + y ≤ floor(mx/10) × 10 + 7. Rearranging gives (ans - floor(mx/10)) × 10 ≤ 7 - y.

Next, we discuss the conditions for the inequality to hold:

- When ans < floor(mx/10), the inequality obviously holds;
- When ans = floor(mx/10), the necessary and sufficient condition for the inequality to hold is y ≤ 7. If ans = floor(mx/10) and we can still add numbers, it means that the number is at the highest digit, that is, y must not exceed 2, therefore, the inequality must hold;
- When ans > floor(mx/10), the inequality obviously does not hold.

In summary, when x > 0, the necessary and sufficient condition for the inequality to hold is ans ≤ floor(mx/10).

Similarly, when x < 0, the necessary and sufficient condition for the inequality to hold is ans ≥ floor(mi/10).

Therefore, we can check whether ans overflows by checking whether ans is within the range [floor(mi/10), floor(mx/10)]. If it overflows, return 0. Otherwise, add y to the end of ans, and then remove the last digit of x, that is, x ← floor(x/10).

The time complexity is O(log |x|), where |x| is the absolute value of x. The space complexity is O(1).

Python 3

```
class Solution:
    def reverse(self, x: int) -> int:
        ans = 0
        mi, mx = -(2**31), 2**31 - 1
        while x:
            if ans < mi // 10 + 1 or ans > mx // 10:
                return 0
            y = x % 10
            if x < 0 and y > 0:
                y -= 10
            ans = ans * 10 + y
            x = (x - y) // 10
        return ans
```

```

12. Integer to Roman

Medium · Hash Table, Math, String

leetcode.com/problems/integer-to-roman

★ **TOP 10 PROBLEM** in Math / Number Theory: master this one first

PROBLEM

Seven different symbols represent Roman numerals with the following values:

Symbol	Value
I	1
V	5
X	10
L	50
C	100
D	500
M	1000

Roman numerals are formed by appending the conversions of decimal place values from highest to lowest. Converting a decimal place value into a Roman numeral has the following rules:

- If the value does not start with 4 or 9, select the symbol of the maximal value that can be subtracted from the input, append that symbol to the result, subtract its value, and convert the remainder to a Roman numeral.
- If the value starts with 4 or 9 use the **subtractive form** representing one symbol subtracted from the following symbol, for example, 4 is 1 (`I`) less than 5 (`V`): `IV` and 9 is 1 (`I`) less than 10 (`X`): `IX`. Only the following subtractive forms are used: 4 (`IV`), 9 (`IX`), 40 (`XL`), 90 (`XC`), 400 (`CD`) and 900 (`CM`).
- Only powers of 10 (`I`, `X`, `C`, `M`) can be appended consecutively at most 3 times to represent multiples of 10. You cannot append 5 (`V`), 50 (`L`), or 500 (`D`) multiple times. If you need to append a symbol 4 times use the **subtractive form**.

Given an integer, convert it to a Roman numeral.

Example 1:

Input: num = 3749

Output: "MMMDCCXLIX"

Explanation:

```
3000 = MMM as 1000 (M) + 1000 (M) + 1000 (M)
 700 = DCC as 500 (D) + 100 (C) + 100 (C)
  40 = XL as 10 (X) less of 50 (L)
   9 = IX as 1 (I) less of 10 (X)
Note: 49 is not 1 (I) less of 50 (L) because the conversion is based on decimal places
```

Example 2:

Input: num = 58

Output: "LVIII"

Explanation:

```
50 = L
 8 = VIII
```

Example 3:

Input: num = 1994

Output: "MCMXCIV"

Explanation:

```
1000 = M
 900 = CM
  90 = XC
   4 = IV
```

Constraints:

- `1 <= num <= 3999`

SOLUTION (PYTHON 3)

Solution 1: Greedy

How to think about it

The first idea is a per-place lookup (thousands, hundreds, tens, ones), with extra branches for 4 and 9. 1 ≤ num ≤ 3999, so it would pass, but the special cases are easy to miss. The mess is keeping “additive” and “subtractive” rules apart. If we treat CM=900, CD=400, XC=90, and so on as first-class denominations, Roman numerals become a fixed list of values from large to small. The representation in this range is unique, so taking the largest denomination that still fits is always legal. We scan that table greedily, subtracting and appending until num becomes 0.

We can first list all possible symbols cs and their corresponding values vs, then enumerate each value vs[i] from large to small. Each time, we use as many symbols cs[i] corresponding to this value as possible, until the number num becomes 0.

The time complexity is O(m), and the space complexity is O(m). Here, m is the number of symbols.

Python 3

```python
class Solution:
    def intToRoman(self, num: int) -> str:
        cs = ('M', 'CM', 'D', 'CD', 'C', 'XC', 'L', 'XL', 'X', 'IX', 'V', 'IV', 'I')
        vs = (1000, 900, 500, 400, 100, 90, 50, 40, 10, 9, 5, 4, 1)
        ans = []
        for c, v in zip(cs, vs):
            while num >= v:
                num -= v
                ans.append(c)
        return ''.join(ans)
```

PATTERN 34 · MATH / NUMBER THEORY · PROBLEM 14 OF 20

204. Count Primes

Medium · Array, Math, Enumeration, Number Theory, Primality Test, Sieve, Sieve of Eratosthenes

leetcode.com/problems/count-primes

★ **TOP 10 PROBLEM** in Math / Number Theory: master this one first

PROBLEM

Given an integer `n`, return *the number of prime numbers that are strictly less than* `n`.

Example 1:

```
Input: n = 10
Output: 4
Explanation: There are 4 prime numbers less than 10, they are 2, 3, 5, 7.
```

Example 2:

```
Input: n = 0
Output: 0
```

Example 3:

```
Input: n = 1
Output: 0
```

Constraints:

- `0 <= n <= 5 * 10^6`

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Trial division up to √x counts primes, but n can be 5× 10^6, so repeated tests are slow. If x is prime, its multiples 2x,3x,… are composite. The Sieve of Eratosthenes marks those multiples as we scan upward, then counts unmarked values. Each composite is crossed off by a factor, in about O(nloglog n) time.

Python 3

```python
class Solution:
    def countPrimes(self, n: int) -> int:
        primes = [True] * n
        ans = 0
        for i in range(2, n):
            if primes[i]:
                ans += 1
                for j in range(i + i, n, i):
                    primes[j] = False
        return ans
```

172. Factorial Trailing Zeroes

Medium · Math

leetcode.com/problems/factorial-trailing-zeroes

★ **TOP 10 PROBLEM** in Math / Number Theory: master this one first

PROBLEM

Given an integer `n`, return *the number of trailing zeroes in* `n!`.

Note that `n! = n * (n - 1) * (n - 2) * ... * 3 * 2 * 1`.

Example 1:

```
Input: n = 3
Output: 0
Explanation: 3! = 6, no trailing zero.
```

Example 2:

```
Input: n = 5
Output: 1
Explanation: 5! = 120, one trailing zero.
```

Example 3:

```
Input: n = 0
Output: 0
```

Constraints:

- `0 <= n <= 10^4`

Follow up: Could you write a solution that works in logarithmic time complexity?

SOLUTION (PYTHON 3)

Solution 1: Mathematics

How to think about it

Trailing zeros of n! come from factors 10=2× 5. There are always more twos than fives, so the count is the number of factors 5 in [1,n]. Computing n! overflows even at n≤ 10^4. The follow-up wants logarithmic time: repeatedly replace n by floor(n/5) to add the contributions of $5,5^2,5^3,\ldots$.

The problem is actually asking how many factors of 5 are there in [1,n].

Let's take 130 as an example for analysis:

1. Divide by 5 for the first time, get 26, indicating that there are 26 numbers containing the factor 5;
2. Divide by 5 for the second time, get 5, indicating that there are 5 numbers containing the factor 5^2;
3. Divide by 5 for the third time, get 1, indicating that there is 1 number containing the factor 5^3;
4. Sum up to get the count of all factors of 5 in [1,n].

The time complexity is O(log n), and the space complexity is O(1).

Python 3

```
class Solution:
    def trailingZeroes(self, n: int) -> int:
        ans = 0
        while n:
            n //= 5
            ans += n
        return ans
```

166. Fraction to Recurring Decimal

Medium · Hash Table, Math, String

leetcode.com/problems/fraction-to-recurring-decimal

★ **TOP 10 PROBLEM** in Math / Number Theory: master this one first

PROBLEM

Given two integers representing the `numerator` and `denominator` of a fraction, return *the fraction in string format*.

If the fractional part is repeating, enclose the repeating part in parentheses

If multiple answers are possible, return **any of them**.

It is **guaranteed** that the length of the answer string is less than 10^4 for all the given inputs.

Note that if the fraction can be represented as a *finite length string*, you **must** return it.

Example 1:

```
Input: numerator = 1, denominator = 2
Output: "0.5"
```

Example 2:

```
Input: numerator = 2, denominator = 1
Output: "2"
```

Example 3:

```
Input: numerator = 4, denominator = 333
Output: "0.(012)"
```

Constraints:

- -2^{31} <= numerator, denominator <= 2^{31} - 1
- denominator != 0

SOLUTION (PYTHON 3)

Solution 1: Mathematics + Hash Table

How to think about it

Write a fraction as a decimal and wrap the repeating part. Long division repeats iff a remainder repeats. Handle the sign and the integer part first. During the fraction, map each remainder to the first index it appeared; a repeat inserts parentheses there. Remainder 0 is a terminating decimal.

First, we check if the numerator is 0. If it is, we return `"0"` directly.

Next, we check if the numerator and denominator have different signs. If they do, the result is negative, and we set the first character of the result to `"-"`.

Then we take the absolute values of the numerator and denominator, denoted as a and b. Since the range of the numerator and denominator is [-2^{31}, 2^{31} - 1], taking the absolute value directly may cause overflow, so we convert both a and b to long integers.

Next, we calculate the integer part, which is the integer part of a divided by b, convert it to a string, and add it to the result. Then we take the remainder of a divided by b, denoted as a.

If a is 0, it means the result is an integer, and we return the result directly.

Next, we calculate the decimal part. We use a hash table d to record the length of the result corresponding to each remainder. We continuously multiply a by 10, then add the integer part of a divided by b to the result, then take the remainder of a divided by b, denoted as a. If a is 0, it means the result is a finite decimal, and we return the result directly. If a has appeared in the hash table, it means the result is a recurring decimal. We find the starting position of the cycle, insert the result into parentheses, and then return the result.

The time complexity is O(l), and the space complexity is O(l), where l is the length of the result. In this problem, $l < 10^4$.

Python 3

```
class Solution:
    def fractionToDecimal(self, numerator: int, denominator: int) -> str:
        if numerator == 0:
            return "0"
        ans = []
        neg = (numerator > 0) ^ (denominator > 0)
        if neg:
            ans.append("-")
        a, b = abs(numerator), abs(denominator)
        ans.append(str(a // b))
        a %= b
        if a == 0:
            return "".join(ans)
        ans.append(".")
        d = {}
        while a:
            d[a] = len(ans)
            a *= 10
            ans.append(str(a // b))
            a %= b
            if a in d:
                ans.insert(d[a], "(")
                ans.append(")")
                break
        return "".join(ans)
```

PATTERN 34 · MATH / NUMBER THEORY · PROBLEM 17 OF 20

264. Ugly Number II

Medium · Hash Table, Math, Dynamic Programming, Heap (Priority Queue)

leetcode.com/problems/ugly-number-ii

★ **TOP 10 PROBLEM** in Math / Number Theory, K-way Merge: master this one first

Also appears in pattern 38 K-way Merge

PROBLEM

An **ugly number** is a positive integer whose prime factors are limited to `2`, `3`, and `5`.

Given an integer `n`, return *the* n^{th} ***ugly number***.

Example 1:

```
Input: n = 10
Output: 12
Explanation: [1, 2, 3, 4, 5, 6, 8, 9, 10, 12] is the sequence of the first 10 ugly numbers.
```

Example 2:

```
Input: n = 1
Output: 1
Explanation: 1 has no prime factors, therefore all of its prime factors are limited to 2, 3, and 5.
```

Constraints:

- `1 <= n <= 1690`

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

Testing every integer by division wastes non-ugly values when n is large. Every ugly number is a previous one times 2, 3, or 5. A min-heap pops the next ugly number and pushes its products, with a set to skip duplicates. The n-th pop is the answer.

Python 3

```python
class Solution:
    def nthUglyNumber(self, n: int) -> int:
        h = [1]
        vis = {1}
        ans = 1
        for _ in range(n):
            ans = heappop(h)
            for v in [2, 3, 5]:
                nxt = ans * v
                if nxt not in vis:
                    vis.add(nxt)
                    heappush(h, nxt)
        return ans
```

Complexity. Time: O(n log n). Space: O(n).

Solution 2

How to think about it

The heap plus set uses extra memory and a log factor. Three pointers mark the next candidates times 2,3,5; we write the min into dp and advance every pointer that produced it, avoiding duplicates.

Python 3

```python
class Solution:
    def nthUglyNumber(self, n: int) -> int:
        dp = [1] * n
        p2 = p3 = p5 = 0
        for i in range(1, n):
            next2, next3, next5 = dp[p2] * 2, dp[p3] * 3, dp[p5] * 5
            dp[i] = min(next2, next3, next5)
            if dp[i] == next2:
                p2 += 1
            if dp[i] == next3:
                p3 += 1
            if dp[i] == next5:
                p5 += 1
        return dp[-1]
```

Complexity. Time: O(n). Space: O(n).

            i5 += 1
```

365. Water and Jug Problem

Medium · Depth-First Search, Breadth-First Search, Math, Greatest Common Divisor, Euclidean Algorithm, Extended Euclidean Algorithm, Bézout's Identity

leetcode.com/problems/water-and-jug-problem

PROBLEM

You are given two jugs with capacities `x` liters and `y` liters. You have an infinite water supply. Return whether the total amount of water in both jugs may reach `target` using the following operations:

- Fill either jug completely with water.
- Completely empty either jug.
- Pour water from one jug into another until the receiving jug is full, or the transferring jug is empty.

Example 1:

Input: x = 3, y = 5, target = 4

Output: true

Explanation:

Follow these steps to reach a total of 4 liters:

1. Fill the 5-liter jug (0, 5).
2. Pour from the 5-liter jug into the 3-liter jug, leaving 2 liters (3, 2).
3. Empty the 3-liter jug (0, 2).
4. Transfer the 2 liters from the 5-liter jug to the 3-liter jug (2, 0).
5. Fill the 5-liter jug again (2, 5).
6. Pour from the 5-liter jug into the 3-liter jug until the 3-liter jug is full. This leaves 4 liters in the 5-liter jug (3, 4).
7. Empty the 3-liter jug. Now, you have exactly 4 liters in the 5-liter jug (0, 4).

Reference: The Die Hard example.

Example 2:

Input: x = 2, y = 6, target = 5

Output: false

Example 3:

Input: x = 1, y = 2, target = 3

Output: true

Explanation: Fill both jugs. The total amount of water in both jugs is equal to 3 now.

Constraints:

- `1 <= x, y, target <= 10^3`

SOLUTION (PYTHON 3)

Solution 1: DFS

How to think about it

Two jugs of capacities x,y; can we measure z? Bézout's identity says z must be a multiple of gcd(x,y). A state search also decides it. There are O(xy) states. dfs(i,j) is the current pair. A seen state fails; a jug or their sum equal to z succeeds. Otherwise fill, empty, or pour. Start from (0,0).

Let's denote jug1Capacity as x, jug2Capacity as y, and targetCapacity as z.

Next, we design a function dfs(i, j), which represents whether we can get z liters of water when there are i liters of water in jug1 and j liters of water in jug2.

The execution process of the function dfs(i, j) is as follows:

- If (i, j) has been visited, return false.
- If i = z or j = z or i + j = z, return true.
- If we can get z liters of water by filling jug1 or jug2, or emptying jug1 or jug2, return true.
- If we can get z liters of water by pouring water from jug1 into jug2, or pouring water from jug2 into jug1, return true.

The answer is dfs(0, 0).

The time complexity is O(x + y), and the space complexity is O(x + y). Here, x and y are the sizes of jug1Capacity and jug2Capacity respectively.

Python 3

```
class Solution:
    def canMeasureWater(self, x: int, y: int, z: int) -> bool:
        def dfs(i: int, j: int) -> bool:
            if (i, j) in vis:
                return False
            vis.add((i, j))
            if i == z or j == z or i + j == z:
                return True
            if dfs(x, j) or dfs(i, y) or dfs(0, j) or dfs(i, 0):
                return True
            a = min(i, y - j)
            b = min(j, x - i)
            return dfs(i - a, j + a) or dfs(i + b, j - b)

        vis = set()
        return dfs(0, 0)

PATTERN 34 · MATH / NUMBER THEORY · PROBLEM 20 OF 20

400. Nth Digit

Medium · Math, Binary Search

leetcode.com/problems/nth-digit

PROBLEM

Given an integer `n`, return the n^{th} digit of the infinite integer sequence `[1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, ...]`.

Example 1:

```
Input: n = 3
Output: 3
```

Example 2:

```
Input: n = 11
Output: 0
Explanation: The 11th digit of the sequence 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, ... is a 0, which is part of the number 10.
```

Constraints:

- $1 <= n <= 2^{31} - 1$

SOLUTION (PYTHON 3)

Solution 1: Mathematics

> **How to think about it**
>
> Building the infinite concatenation and indexing the n-th character is impossible: n can reach 2^{31}-1. Numbers with k digits contribute a closed-form count: $9\times 10^{k-1}$ of them, hence $k\times 9\times 10^{k-1}$ digits. Subtract those blocks while increasing k until n lands inside the current length, then recover the integer and the offset inside it. The subtraction must finish before locating a concrete number; otherwise a global rank cannot become an index inside one integer.

The smallest and largest integers with k digits are 10^{k-1} and 10^k-1 respectively, so the total number of digits for k-digit numbers is $k \times 9 \times 10^{k-1}$.

We use k to represent the number of digits of the current number, and cnt to represent the total number of numbers with the current number of digits. Initially, k=1, cnt=9.

Each time we subtract cnt × k from n, when n is less than or equal to cnt × k, it means that the number corresponding to n is within the range of numbers with the current number of digits. At this time, we can calculate the corresponding number.

The specific method is to first calculate which number of the current number of digits corresponds to n, and then calculate which digit of this number it is, so as to get the number on this digit.

The time complexity is $O(\log_{10} n)$.

Python 3

```python
class Solution:
    def findNthDigit(self, n: int) -> int:
        k, cnt = 1, 9
        while k * cnt < n:
            n -= k * cnt
            k += 1
            cnt *= 10
        num = 10 ** (k - 1) + (n - 1) // k
        idx = (n - 1) % k
        return int(str(num)[idx])
```

643. Maximum Average Subarray I

Easy · Array, Sliding Window

leetcode.com/problems/maximum-average-subarray-i

★ **TOP 10 PROBLEM** in Sliding Window Maximum / Minimum (Specific Variants): master this one first

PROBLEM

You are given an integer array `nums` consisting of `n` elements, and an integer `k`.

Find a contiguous subarray whose **length is equal to** `k` that has the maximum average value and return *this value*. Any answer with a calculation error less than 10^{-5} will be accepted.

Example 1:

```
Input: nums = [1,12,-5,-6,50,3], k = 4
Output: 12.75000
Explanation: Maximum average is (12 - 5 - 6 + 50) / 4 = 51 / 4 = 12.75
```

Example 2:

```
Input: nums = [5], k = 1
Output: 5.00000
```

Constraints:

- `n == nums.length`
- `1 <= k <= n <=` 10^5
- -10^4 `<= nums[i] <=` 10^4

SOLUTION (PYTHON 3)

Solution 1: Sliding Window

How to think about it

The maximum average of a window of length k is the maximum sum. Recomputing each window is O(nk) for n≤ 10^5. Slide a length-k sum: add the entering value, drop the leaving one, and divide the best sum by k.

We maintain a sliding window of length k, and for each window, we calculate the sum s of the numbers within the window. We take the maximum sum s as the answer.

The time complexity is O(n), where n is the length of the array nums. The space complexity is O(1).

Python 3

```python
class Solution:
    def findMaxAverage(self, nums: List[int], k: int) -> float:
        ans = s = sum(nums[:k])
        for i in range(k, len(nums)):
            s += nums[i] - nums[i - k]
            ans = max(ans, s)
        return ans / k
```

```

2379. Minimum Recolors to Get K Consecutive Black Blocks

Easy · String, Sliding Window

leetcode.com/problems/minimum-recolors-to-get-k-consecutive-black-blocks

★ **TOP 10 PROBLEM** in Sliding Window Maximum / Minimum (Specific Variants): master this one first

PROBLEM

You are given a **0-indexed** string `blocks` of length `n`, where `blocks[i]` is either `'W'` or `'B'`, representing the color of the i^{th} block. The characters `'W'` and `'B'` denote the colors white and black, respectively.

You are also given an integer `k`, which is the desired number of **consecutive** black blocks.

In one operation, you can **recolor** a white block such that it becomes a black block.

Return *the **minimum** number of operations needed such that there is at least **one** occurrence of* `k` *consecutive black blocks.*

Example 1:

```
Input: blocks = "WBBWWBBWBW", k = 7
Output: 3
Explanation:
One way to achieve 7 consecutive black blocks is to recolor the 0th, 3rd, and 4th blocks
so that blocks = "BBBBBBBWBW".
It can be shown that there is no way to achieve 7 consecutive black blocks in less than 3 operations.
Therefore, we return 3.
```

Example 2:

```
Input: blocks = "WBWBBBW", k = 2
Output: 0
Explanation:
No changes need to be made, since 2 consecutive black blocks already exist.
Therefore, we return 0.
```

Constraints:

- `n == blocks.length`
- `1 <= n <= 100`
- `blocks[i]` is either `'W'` or `'B'`.
- `1 <= k <= n`

SOLUTION (PYTHON 3)

Solution 1: Sliding Window

How to think about it

Painting a window of length k all black costs its number of whites. We only need every window, not a search over colorings. Count whites in the first k cells, then slide, adding and removing the ends, and keep the minimum.

We observe that what the problem actually asks for is the minimum number of white blocks in a sliding window of size k.

Therefore, we only need to traverse the string blocks, use a variable cnt to count the number of white blocks in the current window, and then use a variable ans to maintain the minimum value.

After the traversal ends, we can get the answer.

The time complexity is O(n), where n is the length of the string blocks. The space complexity is O(1).

Python 3

```
class Solution:
    def minimumRecolors(self, blocks: str, k: int) -> int:
        ans = cnt = blocks[:k].count('W')
        for i in range(k, len(blocks)):
            cnt += blocks[i] == 'W'
            cnt -= blocks[i - k] == 'W'
            ans = min(ans, cnt)
        return ans
```

1292. Maximum Side Length of a Square with Sum Less than or Equal to Threshold

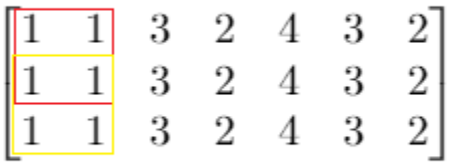
Medium · Array, Binary Search, Matrix, Prefix Sum

leetcode.com/problems/maximum-side-length-of-a-square-with-sum-less-than-or-equal-to-threshold

PROBLEM

Given a `m x n` matrix `mat` and an integer `threshold`, return *the maximum side-length of a square with a sum less than or equal to* `threshold` *or return* `0` *if there is no such square*.

Example 1:



```
Input: mat = [[1,1,3,2,4,3,2],[1,1,3,2,4,3,2],[1,1,3,2,4,3,2]], threshold = 4
Output: 2
Explanation: The maximum side length of square with sum less than or equal to 4 is 2 as shown.
```

Example 2:

```
Input: mat = [[2,2,2,2,2],[2,2,2,2,2],[2,2,2,2,2],[2,2,2,2,2],[2,2,2,2,2]], threshold = 1
Output: 0
```

Constraints:

- `m == mat.length`
- `n == mat[i].length`
- `1 <= m, n <= 300`
- `0 <= mat[i][j] <= 10^4`
- `0 <= threshold <= 10^5`

SOLUTION (PYTHON 3)

Solution 1: 2D Prefix Sum + Binary Search

How to think about it

A square's sum grows with its side (entries are non-negative), so feasibility is monotone. m,n ≤ 300; enumerating sides and corners with an $O(k^2)$ sum is too slow. A 2-D prefix makes every square O(1), and we binary-search the side. The check scans top-left corners and compares the prefix sum to the threshold. The search returns the largest feasible side.

We can precompute a 2D prefix sum array s, where s[i + 1][j + 1] represents the sum of elements in the matrix mat from (0, 0) to (i, j). With this, we can calculate the sum of elements in any square region in O(1) time.

Next, we can use binary search to find the maximum side length. We enumerate the side length k of the square, and then iterate through all possible top-left positions (i, j) of the square. We can calculate the sum of elements v for the square. If v ≤ threshold, it indicates that there exists a square region with side length k whose sum is less than or equal to the threshold;

otherwise, no such square exists for the current k.

The time complexity is O(m × n × log min(m, n)), and the space complexity is O(m × n).

Python 3

```python
class Solution:
    def maxSideLength(self, mat: List[List[int]], threshold: int) -> int:
        def check(k: int) -> bool:
            for i in range(m - k + 1):
                for j in range(n - k + 1):
                    v = s[i + k][j + k] - s[i][j + k] - s[i + k][j] + s[i][j]
                    if v <= threshold:
                        return True
            return False

        m, n = len(mat), len(mat[0])
        s = [[0] * (n + 1) for _ in range(m + 1)]
        for i, row in enumerate(mat, 1):
            for j, x in enumerate(row, 1):
                s[i][j] = s[i - 1][j] + s[i][j - 1] - s[i - 1][j - 1] + x
        l, r = 0, min(m, n)
        while l < r:
            mid = (l + r + 1) >> 1
            if check(mid):
                l = mid
            else:
                r = mid - 1
        return l
```

1438. Longest Continuous Subarray With Absolute Diff Less Than or Equal to Limit

Medium · Queue, Array, Ordered Set, Sliding Window, Monotonic Queue, Heap (Priority Queue)

leetcode.com/problems/longest-continuous-subarray-with-absolute-diff-less-than-or-equal-to-limit

★ **TOP 10 PROBLEM** in Sliding Window Maximum / Minimum (Specific Variants): master this one first

PROBLEM

You are given an array of integers `nums` and an integer `limit`.

Return the size of the **longest non-empty subarray** such that the **absolute** difference between **every pair of elements** in this **subarray** is **less than or equal** to `limit`.

Example 1:

Input: nums = [8,2,4,7], limit = 4

Output: 2

Explanation:

Checking every subarray, where the absolute difference is taken over all pairs of its elements:
`[8]` with maximum absolute diff `|8-8| = 0 <= 4`.
`[8,2]` with maximum absolute diff `|8-2| = 6 > 4`.
`[8,2,4]` with maximum absolute diff `|8-2| = 6 > 4`.
`[8,2,4,7]` with maximum absolute diff `|8-2| = 6 > 4`.
`[2]` with maximum absolute diff `|2-2| = 0 <= 4`.
`[2,4]` with maximum absolute diff `|4-2| = 2 <= 4`.
`[2,4,7]` with maximum absolute diff `|7-2| = 5 > 4`. Note that the pair `(2, 7)` is not adjacent, but it is still compared.
`[4]` with maximum absolute diff `|4-4| = 0 <= 4`.
`[4,7]` with maximum absolute diff `|7-4| = 3 <= 4`.
`[7]` with maximum absolute diff `|7-7| = 0 <= 4`.
Therefore, the size of the longest subarray is 2.

Example 2:

Input: nums = [10,1,2,4,7,2], limit = 5

Output: 4

Explanation:

The subarray `[2,4,7,2]` is valid because every pair of its elements differs by at most `5`, the largest being `|7-2| = 5`.

It cannot be extended to the left, since `[1,2,4,7,2]` contains the pair `(1, 7)` with `|7-1| = 6 > 5`. Therefore, the size of the longest subarray is 4.

Example 3:

Input: nums = [4,2,2,2,4,4,2,2], limit = 0

Output: 3

Explanation:

Since `limit = 0`, every pair of elements in the subarray must be equal, so only runs of identical values qualify.

The longest such run is `[2,2,2]`, of size 3.

Constraints:

- $1 <= nums.length <= 10^5$
- $1 <= nums[i] <= 10^9$

- $0 <= limit <= 10^9$

SOLUTIONS (PYTHON 3)

Solution 1: Ordered Set + Sliding Window

> **How to think about it**
>
> The max–min gap of a subarray does not decrease as the window grows. n≤ 10^5 rules out all intervals. For each right end, move the left end until max-min≤ limit. An ordered multiset exposes the current extrema; remove the leftmost value when the window is illegal. The longest valid window is the answer.

We can enumerate each position as the right endpoint of the subarray, and find the leftmost left endpoint corresponding to it, such that the difference between the maximum and minimum values in the interval does not exceed limit. During the process, we use an ordered set to maintain the maximum and minimum values within the window.

The time complexity is O(n log n), and the space complexity is O(n). Here, n is the length of the array `nums`.

Python 3

```
class Solution:
    def longestSubarray(self, nums: List[int], limit: int) -> int:
        sl = SortedList()
        ans = j = 0
        for i, x in enumerate(nums):
            sl.add(x)
            while sl[-1] - sl[0] > limit:
                sl.remove(nums[j])
                j += 1
            ans = max(ans, i - j + 1)
        return ans
```

Solution 2: Binary Search + Sliding Window

> **How to think about it**
>
> Method 1 shrinks per right end. Length is monotone: if some window of length mid is valid, shorter ones exist. Binary-search the length and test a candidate with two monotonic queues. The time is still O(nlog n); the longest-window search becomes a decision problem.

We notice that if a subarray of length k satisfies the condition, then a subarray of length k' < k also satisfies the condition. This shows a monotonicity, therefore, we can use binary search to find the longest subarray that satisfies the condition.

We define the left boundary of the binary search as l = 0, and the right boundary as r = n. For each mid = (l + r + 1)/2, we check whether there exists a subarray of length mid that satisfies the condition. If it exists, we update l = mid, otherwise we update r = mid - 1. The problem is transformed into whether there exists a subarray of length mid in the array that satisfies the condition, which is actually to find the difference between the maximum and minimum values in the sliding window does not exceed limit. We can use two monotonic queues to maintain the maximum and minimum values in the window respectively.

The time complexity is O(n × log n), and the space complexity is O(n). Where n is the length of the array nums.

Python 3

```python
class Solution:
    def longestSubarray(self, nums: List[int], limit: int) -> int:
        def check(k: int) -> bool:
            min_q = deque()
            max_q = deque()
            for i, x in enumerate(nums):
                if min_q and i - min_q[0] + 1 > k:
                    min_q.popleft()
                if max_q and i - max_q[0] + 1 > k:
                    max_q.popleft()
                while min_q and nums[min_q[-1]] >= x:
                    min_q.pop()
                while max_q and nums[max_q[-1]] <= x:
                    max_q.pop()
                min_q.append(i)
                max_q.append(i)
                if i >= k - 1 and nums[max_q[0]] - nums[min_q[0]] <= limit:
                    return True
            return False

        l, r = 1, len(nums)
        while l < r:
            mid = (l + r + 1) >> 1
            if check(mid):
                l = mid
            else:
                r = mid - 1
        return l
```

Solution 3: Sliding Window + Deque

> **How to think about it**
>
> Methods 1 and 2 pay a logarithmic factor. Two monotonic deques maintain the window max and min in amortized O(1), so expanding the right end and shrinking the left end is linear.

We can use a deque to maintain the maximum and minimum values within the window. We maintain two deques, one for storing the indices of the maximum values and the other for the minimum values within the window. Define two pointers l and r to point to the left and right boundaries of the window, respectively.

Each time we move the right boundary r to the right, we check if the element corresponding to the tail index of the maximum value deque is less than the current element. If it is, we dequeue the tail element until the element corresponding to the tail of the maximum value deque is not less than the current element. Similarly, we check if the element corresponding to the tail index of the minimum value deque is greater than the current element. If it is, we dequeue the tail element until the element corresponding to the tail of the minimum value deque is not greater than the current element. Then, we enqueue the current element's index.

If the difference between the elements at the front of the maximum value deque and the minimum value deque is greater than limit, then we move the left boundary l to the right. If the element at the front of the maximum value deque is less than l, we dequeue the front element of the maximum value deque. Similarly, if the element at the front of the minimum value deque is less than l, we dequeue the front element of the minimum value deque.

The answer is n - l.

The time complexity is O(n), and the space complexity is O(n). Here, n is the length of the array nums.

Python 3

```
class Solution:
    def longestSubarray(self, nums: List[int], limit: int) -> int:
        maxq = deque()
        minq = deque()
        l, n = 0, len(nums)
        for r, x in enumerate(nums):
            while maxq and nums[maxq[-1]] < x:
                maxq.pop()
            while minq and nums[minq[-1]] > x:
                minq.pop()
            maxq.append(r)
            minq.append(r)
            if nums[maxq[0]] - nums[minq[0]] > limit:
                l += 1
                if maxq[0] < l:
                    maxq.popleft()
                if minq[0] < l:
                    minq.popleft()
        return n - l
```

2831. Find the Longest Equal Subarray

Medium · Array, Hash Table, Binary Search, Sliding Window

leetcode.com/problems/find-the-longest-equal-subarray

PROBLEM

You are given a **0-indexed** integer array `nums` and an integer `k`.

A subarray is called **equal** if all of its elements are equal. Note that the empty subarray is an **equal** subarray.

Return *the length of the **longest** possible equal subarray after deleting **at most** `k` elements from* `nums`.

A **subarray** is a contiguous, possibly empty sequence of elements within an array.

Example 1:

```
Input: nums = [1,3,2,3,1,3], k = 3
Output: 3
Explanation: It's optimal to delete the elements at index 2 and index 4.
After deleting them, nums becomes equal to [1, 3, 3, 3].
The longest equal subarray starts at i = 1 and ends at j = 3 with length equal to 3.
It can be proven that no longer equal subarrays can be created.
```

Example 2:

```
Input: nums = [1,1,2,2,1,1], k = 2
Output: 4
Explanation: It's optimal to delete the elements at index 2 and index 3.
After deleting them, nums becomes equal to [1, 1, 1, 1].
The array itself is an equal subarray, so the answer is 4.
It can be proven that no longer equal subarrays can be created.
```

Constraints:

- `1 <= nums.length <= 10^5`
- `1 <= nums[i] <= nums.length`
- `0 <= k <= nums.length`

SOLUTIONS (PYTHON 3)

Solution 1: Hash Table + Two Pointers

> **How to think about it**
>
> An equal subarray may delete at most k other values. A window is illegal once the count of non-majority elements exceeds k. A frequency map tracks the peak count mx; shrink from the left when r-l+1-mx>k. The answer is that peak.

We use two pointers to maintain a monotonically variable length window, and a hash table to maintain the number of occurrences of each element in the window.

The number of all elements in the window minus the number of the most frequently occurring element in the window is the number of elements that need to be deleted from the window.

Each time, we add the element pointed to by the right pointer to the window, then update the hash table, and also update the number of the most frequently occurring element in the window. When the number of elements that need to be deleted from the window exceeds k, we move the left pointer once, and then update the hash table.

After the traversal, return the number of the most frequently occurring element.

The time complexity is O(n), and the space complexity is O(n). Here, n is the length of the array.

Python 3

```python
class Solution:
    def longestEqualSubarray(self, nums: List[int], k: int) -> int:
        cnt = Counter()
        l = 0
        mx = 0
        for r, x in enumerate(nums):
            cnt[x] += 1
            mx = max(mx, cnt[x])
            if r - l + 1 - mx > k:
                cnt[nums[l]] -= 1
                l += 1
        return mx
```

Solution 2: Hash Table + Two Pointers (Method 2)

> **How to think about it**
>
> Method 1 keeps frequencies of every value in one window. Grouping indices by value lets each two-pointer scan count only the gaps between occurrences of that value, with the same linear bound.

We can use a hash table g to maintain the index list of each element.

Next, we enumerate each element as the equal value element. We take out the index list ids of this element from the hash table g. Then we define two pointers l and r to maintain a window, so that the number of elements in the window minus the number of equal value elements does not exceed k. Therefore, we only need to find the largest window that meets the condition.

The time complexity is O(n), and the space complexity is O(n). Where n is the length of the array.

Python 3

```python
class Solution:
    def longestEqualSubarray(self, nums: List[int], k: int) -> int:
        g = defaultdict(list)
        for i, x in enumerate(nums):
            g[x].append(i)
        ans = 0
        for ids in g.values():
            l = 0
            for r in range(len(ids)):
                while ids[r] - ids[l] - (r - l) > k:
                    l += 1
                ans = max(ans, r - l + 1)
        return ans
```

2444. Count Subarrays With Fixed Bounds

Hard · Queue, Array, Sliding Window, Monotonic Queue

leetcode.com/problems/count-subarrays-with-fixed-bounds

★ **TOP 10 PROBLEM** in Sliding Window Maximum / Minimum (Specific Variants): master this one first

PROBLEM

You are given an integer array `nums` and two integers `minK` and `maxK`.

A **fixed-bound subarray** of `nums` is a subarray that satisfies the following conditions:

- The **minimum** value in the subarray is equal to `minK`.
- The **maximum** value in the subarray is equal to `maxK`.

Return *the **number** of fixed-bound subarrays*.

A **subarray** is a **contiguous** part of an array.

Example 1:

```
Input: nums = [1,3,5,2,7,5], minK = 1, maxK = 5
Output: 2
Explanation: The fixed-bound subarrays are [1,3,5] and [1,3,5,2].
```

Example 2:

```
Input: nums = [1,1,1,1], minK = 1, maxK = 1
Output: 10
Explanation: Every subarray of nums is a fixed-bound subarray. There are 10 possible subarrays.
```

Constraints:

- `2 <= nums.length <= 10^5`
- `1 <= nums[i], minK, maxK <= 10^6`

SOLUTION (PYTHON 3)

Solution 1: Enumerate the Right Endpoint

How to think about it

At $n \le 10^5$, a fixed-bound subarray stays inside [minK,maxK] and contains both extrema. For a right end i, the left end must be after the last out-of-range index and at most the earlier of the last minK and maxK. Keep those three indices k, j_1, j_2 and add $\max(0, \min(j_1, j_2) - k)$. Each right end is O(1).

According to the problem description, we know that all elements of a bounded subarray are within the range [minK, maxK], and the minimum value must be minK, while the maximum value must be maxK.

We iterate through the array nums and count the number of bounded subarrays with nums[i] as the right endpoint. Then, we sum up all the counts.

The specific implementation logic is as follows:

1. Maintain the index k of the most recent element that is not within the range [minK, maxK], initialized to -1. The left endpoint of the current element nums[i] must be greater than k.
2. Maintain the most recent index j_1 where the value is minK and the most recent index j_2 where the value is maxK, both initialized to -1. The left endpoint of the current element nums[i] must be less than or equal to $\min(j_1, j_2)$.
3. Based on the above, the number of bounded subarrays with the current element as the right endpoint is $\max(0, \min(j_1, j_2) - k)$. Accumulate all these counts to get the result.

The time complexity is O(n), where n is the length of the array nums. The space complexity is O(1).

Python 3

```python
class Solution:
    def countSubarrays(self, nums: List[int], minK: int, maxK: int) -> int:
        j1 = j2 = k = -1
        ans = 0
        for i, v in enumerate(nums):
            if v < minK or v > maxK:
                k = i
            if v == minK:
                j1 = i
            if v == maxK:
                j2 = i
            ans += max(0, min(j1, j2) - k)
        return ans
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

Built on the solutions above: helper functions, then the function for each follow-up. No tests and no restating of the question.

PATTERN 36 · SIMULATION / ARRAY REARRANGEMENT · PROBLEM 1 OF 20

118. Pascal's Triangle

Easy · Array, Dynamic Programming

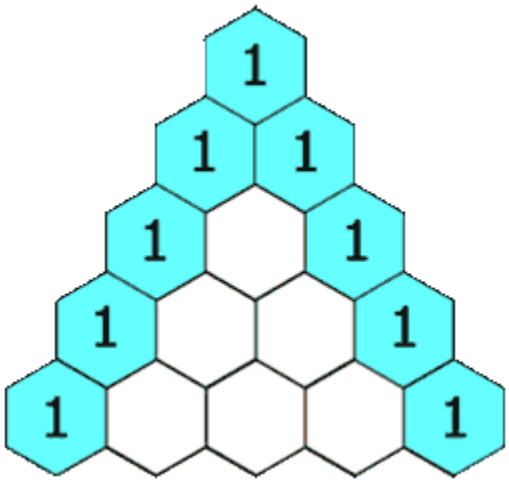
leetcode.com/problems/pascals-triangle

★ **TOP 10 PROBLEM** in Simulation / Array Rearrangement: master this one first

PROBLEM

Given an integer `numRows`, return the first numRows of **Pascal's triangle**.

In **Pascal's triangle**, each number is the sum of the two numbers directly above it as shown:



Example 1:

```
Input: numRows = 5
Output: [[1],[1,1],[1,2,1],[1,3,3,1],[1,4,6,4,1]]
```

Example 2:

```
Input: numRows = 1
Output: [[1]]
```

Constraints:

- `1 <= numRows <= 30`

SOLUTION (PYTHON 3)

Solution 1: Simulation

How to think about it

Row i is formed by adding adjacent entries of row i-1, with 1s on both ends. numRows≤ 30, so building row by row is enough. Each row depends only on the previous one.

We first create an answer array f, then set the first row of f to [1]. Next, starting from the second row, the first and last elements of each row are 1, and for other elements f[i][j] = f[i - 1][j - 1] + f[i - 1][j].

The time complexity is $O(n^2)$, where n is the given number of rows. Ignoring the space consumption of the answer, the space complexity is O(1).

Python 3

```
class Solution:
    def generate(self, numRows: int) -> List[List[int]]:
        f = [[1]]
        for i in range(numRows - 1):
            g = [1] + [a + b for a, b in pairwise(f[-1])] + [1]
            f.append(g)
        return f
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

# 2. How many odd numbers are in row r

# ============================================================
# FOLLOW-UP 1: Only row number r using O(r) memory
# ============================================================

# ---- follow-up 1: function ----
# Answer: Build the row from the previous one in place,
# going from right to left.
# Time: O(r^2).  Space: O(r).
def pascal_row(row_index):
    row = [1] * (row_index + 1)
    for i in range(2, row_index + 1):
        for j in range(i - 1, 0, -1):
            row[j] += row[j - 1]
    return row

# ============================================================
# FOLLOW-UP 2: How many odd numbers are in row r
# ============================================================

# ---- follow-up 2: function ----
# Answer: By Lucas' theorem, the count is 2 to the power
# of the number of one bits in r.
# Time: O(log r).  Space: O(1).
def odd_entries_in_row(row_index):
    ones = 0
    while row_index > 0:
        ones += row_index & 1
        row_index >>= 1
    return 2 ** ones
```

566. Reshape the Matrix

Easy · Array, Matrix, Simulation

leetcode.com/problems/reshape-the-matrix

★ **TOP 10 PROBLEM** in Simulation / Array Rearrangement: master this one first

PROBLEM

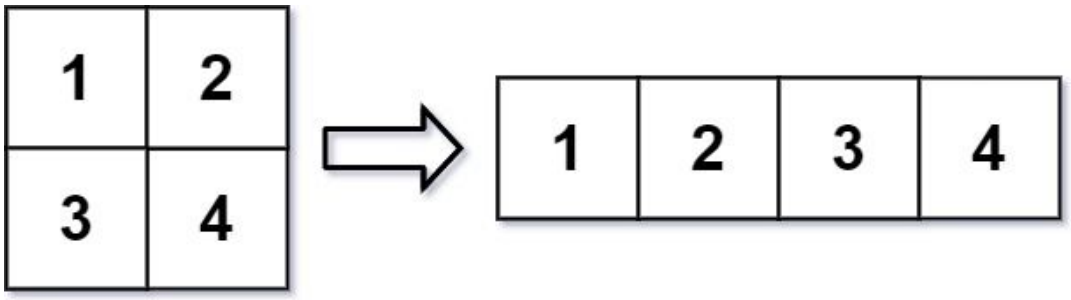
In MATLAB, there is a handy function called `reshape` which can reshape an `m x n` matrix into a new one with a different size `r x c` keeping its original data.

You are given an `m x n` matrix `mat` and two integers `r` and `c` representing the number of rows and the number of columns of the wanted reshaped matrix.

The reshaped matrix should be filled with all the elements of the original matrix in the same row-traversing order as they were.

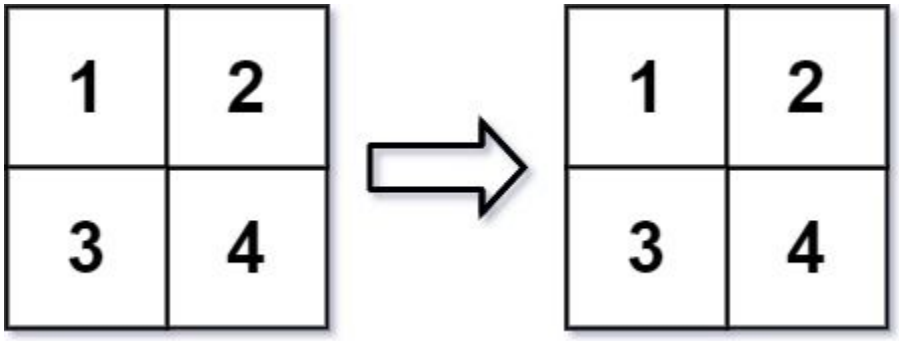
If the `reshape` operation with given parameters is possible and legal, output the new reshaped matrix; Otherwise, output the original matrix.

Example 1:



```
Input: mat = [[1,2],[3,4]], r = 1, c = 4
Output: [[1,2,3,4]]
```

Example 2:



```
Input: mat = [[1,2],[3,4]], r = 2, c = 4
Output: [[1,2],[3,4]]
```

Constraints:

- `m == mat.length`
- `n == mat[i].length`
- `1 <= m, n <= 100`
- `-1000 <= mat[i][j] <= 1000`
- `1 <= r, c <= 300`

SOLUTIONS (PYTHON 3)

Solution 1: Simulation

> **How to think about it**
>
> Reshape is a row-major relayout into r × c. If the product of dimensions differs, return the original matrix. A linear index i reads `mat[i // n][i % n]` and writes `ans[i // c][i % c]`. One pass copies every element.

First, we get the number of rows and columns of the original matrix, denoted as m and n respectively. If m × n ≠ r × c, then the matrix cannot be reshaped, and we return the original matrix directly.

Otherwise, we create a new matrix with r rows and c columns. Starting from the first element of the original matrix, we traverse all elements in row-major order and place the traversed elements into the new matrix in order.

After traversing all elements of the original matrix, we get the answer.

The time complexity is O(m × n), where m and n are the number of rows and columns of the original matrix, respectively. Ignoring the space consumption of the answer, the space complexity is O(1).

Python 3

```python
class Solution:
    def matrixReshape(self, mat: List[List[int]], r: int, c: int) -> List[List[int]]:
        m, n = len(mat), len(mat[0])
        if m * n != r * c:
            return mat
        ans = [[0] * c for _ in range(r)]
        for i in range(m * n):
            ans[i // c][i % c] = mat[i // n][i % n]
        return ans
```

Solution 2

> **How to think about it**
>
> Solution 1 already maps through a linear index. Solution 2 writes the same formula while iterating the destination, so only the loop order changes. The correspondence is identical; there is no new asymptotic gain.

Python 3 (written for this guide: the doocs page has no Python 3 version of this solution)

```python
class Solution:
    def matrixReshape(self, mat: List[List[int]], r: int, c: int) -> List[List[int]]:
        m, n = len(mat), len(mat[0])
        if m * n != r * c:
            return mat
        ans = [[0] * c for _ in range(r)]
        for i in range(r * c):
            ans[i // c][i % c] = mat[i // n][i % n]
        return ans
```

Complexity. Time: O(r * c). Space: O(r * c).

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

        if isinstance(item, list):
            result += flatten(item)
        else:
            result.append(item)
    return result
```

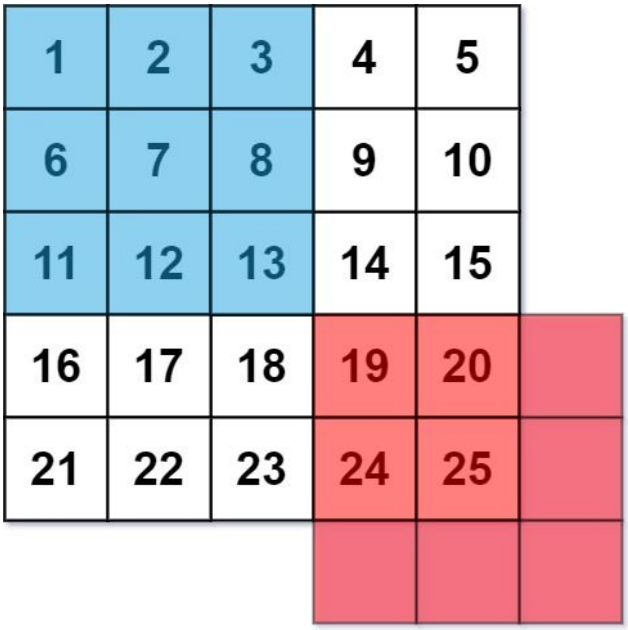
661. Image Smoother

Easy · Array, Matrix

leetcode.com/problems/image-smoother

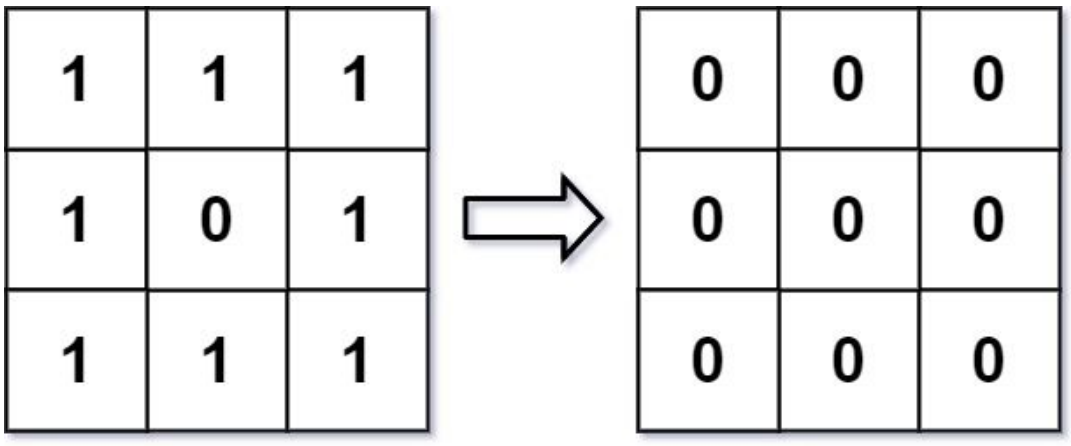
PROBLEM

An **image smoother** is a filter of the size `3 x 3` that can be applied to each cell of an image by rounding down the average of the cell and the eight surrounding cells (i.e., the average of the nine cells in the blue smoother). If one or more of the surrounding cells of a cell is not present, we do not consider it in the average (i.e., the average of the four cells in the red smoother).



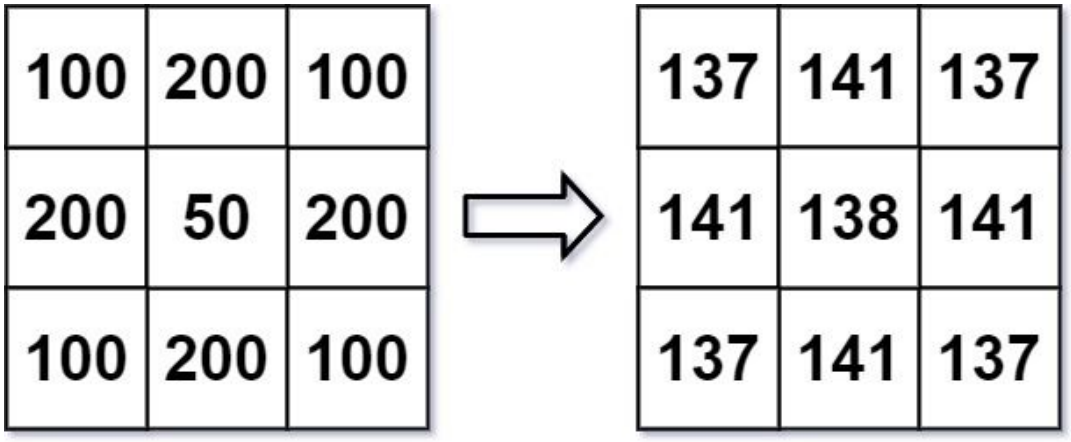
Given an `m x n` integer matrix `img` representing the grayscale of an image, return *the image after applying the smoother on each cell of it*.

Example 1:



```
Input: img = [[1,1,1],[1,0,1],[1,1,1]]
Output: [[0,0,0],[0,0,0],[0,0,0]]
Explanation:
For the points (0,0), (0,2), (2,0), (2,2): floor(3/4) = floor(0.75) = 0
For the points (0,1), (1,0), (1,2), (2,1): floor(5/6) = floor(0.83333333) = 0
For the point (1,1): floor(8/9) = floor(0.88888889) = 0
```

Example 2:



```
Input: img = [[100,200,100],[200,50,200],[100,200,100]]
Output: [[137,141,137],[141,138,141],[137,141,137]]
Explanation:
For the points (0,0), (0,2), (2,0), (2,2): floor((100+200+200+50)/4) = floor(137.5) = 137
For the points (0,1), (1,0), (1,2), (2,1): floor((200+200+50+200+100+100)/6) = floor(141.666667) = 141
For the point (1,1): floor((50+200+200+200+200+100+100+100+100)/9) = floor(138.888889) = 138
```

Constraints:

- `m == img.length`
- `n == img[i].length`
- `1 <= m, n <= 200`
- `0 <= img[i][j] <= 255`

SOLUTION (PYTHON 3)

Solution 1: Direct Traversal

How to think about it

Each cell becomes the floor-average of itself and its (up to eight) neighbors. A 200× 200 grid can be scanned directly. For (i,j) sum the in-bound cells of [i-1,i+1]×[j-1,j+1] into a new matrix so in-place writes do not affect neighbors.

We create a 2D array ans of size m × n, where ans[i][j] represents the smoothed value of the cell in the i-th row and j-th column of the image.

For ans[i][j], we traverse the cell in the i-th row and j-th column of img and its surrounding 8 cells, calculate their sum s and count cnt, then compute the average value s / cnt and store it in ans[i][j].

After the traversal, we return ans.

The time complexity is O(m × n), where m and n are the number of rows and columns of img, respectively. Ignoring the space consumption of the answer array, the space complexity is O(1).

Python 3

```
class Solution:
    def imageSmoother(self, img: List[List[int]]) -> List[List[int]]:
        m, n = len(img), len(img[0])
        ans = [[0] * n for _ in range(m)]
        for i in range(m):
            for j in range(n):
                s = cnt = 0
                for x in range(i - 1, i + 2):
                    for y in range(j - 1, j + 2):
                        if 0 <= x < m and 0 <= y < n:
                            cnt += 1
                            s += img[x][y]
                ans[i][j] = s // cnt
        return ans
```

                    total += img[nr][nc]
                    count += 1
            result[r][c] = total // count
    return result
```

66. Plus One

Easy · Array, Math

leetcode.com/problems/plus-one

★ **TOP 10 PROBLEM** in Simulation / Array Rearrangement: master this one first

PROBLEM

You are given a **large integer** represented as an integer array `digits`, where each `digits[i]` is the i^{th} digit of the integer. The digits are ordered from most significant to least significant in left-to-right order. The large integer does not contain any leading `0`'s.

Increment the large integer by one and return *the resulting array of digits*.

Example 1:

```
Input: digits = [1,2,3]
Output: [1,2,4]
Explanation: The array represents the integer 123.
Incrementing by one gives 123 + 1 = 124.
Thus, the result should be [1,2,4].
```

Example 2:

```
Input: digits = [4,3,2,1]
Output: [4,3,2,2]
Explanation: The array represents the integer 4321.
Incrementing by one gives 4321 + 1 = 4322.
Thus, the result should be [4,3,2,2].
```

Example 3:

```
Input: digits = [9]
Output: [1,0]
Explanation: The array represents the integer 9.
Incrementing by one gives 9 + 1 = 10.
Thus, the result should be [1,0].
```

Constraints:

- `1 <= digits.length <= 100`
- `0 <= digits[i] <= 9`
- `digits` does not contain any leading `0`'s.

SOLUTION (PYTHON 3)

Solution 1: Simulation

How to think about it

The first idea is to join the digits into an integer and add one. n ≤ 100, so the value overflows ordinary integer types. The bottleneck is a carry that may run all the way to the most significant digit. Adding one never produces a carry other than 1: walk from the least significant digit; stop at the first digit that is not 9; only an all-9s array needs a leading 1. So we simulate from right to left and return as soon as a digit does not carry, without converting the whole number into another representation.

We start traversing from the last element of the array, add one to the current element, and then take the modulus by 10. If the result is not 0, it means that there is no carry for the current element, and we can directly return the array. Otherwise, the current element is 0 and needs to be carried over. We continue to traverse the previous element and repeat the above

operation. If we still haven't returned after traversing the array, it means that all elements in the array are 0, and we need to insert a 1 at the beginning of the array.

The time complexity is O(n), where n is the length of the array. Ignoring the space consumption of the answer, the space complexity is O(1).

Python 3

```python
class Solution:
    def plusOne(self, digits: List[int]) -> List[int]:
        n = len(digits)
        for i in range(n - 1, -1, -1):
            digits[i] += 1
            digits[i] %= 10
            if digits[i] != 0:
                return digits
        return [1] + digits
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

Built on the solutions above: helper functions, then the function for each follow-up. No tests and no restating of the question.

```python
# FOLLOW-UPS (answered below, in this order):
# 1. Add one to a number written in base b
# 2. Add two numbers given as digit lists

# ============================================================
# FOLLOW-UP 1: Add one to a number written in base b
# ============================================================

# ---- follow-up 1: function ----
# Answer: The same carry walk, using the base instead of
# 10.
# Time: O(n).  Space: O(n).
def plus_one_in_base(digits, base):
    digits = list(digits)
    for i in range(len(digits) - 1, -1, -1):
        if digits[i] + 1 < base:
            digits[i] += 1
            return digits
        digits[i] = 0
    return [1] + digits

# ============================================================
# FOLLOW-UP 2: Add two numbers given as digit lists
# ============================================================

# ---- follow-up 2: function ----
# Answer: Add from the right with a carry.
# Time: O(max(a, b)).  Space: O(max(a, b)).
def add_digit_lists(a, b):
    result = []
    carry = 0
    i, j = len(a) - 1, len(b) - 1
    while i >= 0 or j >= 0 or carry:
        total = carry
        if i >= 0:
            total += a[i]
            i -= 1
        if j >= 0:
            total += b[j]
            j -= 1
        result.append(total % 10)
        carry = total // 10
    return result[::-1]
```

723. Candy Crush

Medium · Array, Two Pointers, Matrix, Simulation

leetcode.com/problems/candy-crush

★ **TOP 10 PROBLEM** in Simulation / Array Rearrangement: master this one first

PROBLEM

This question is about implementing a basic elimination algorithm for Candy Crush.

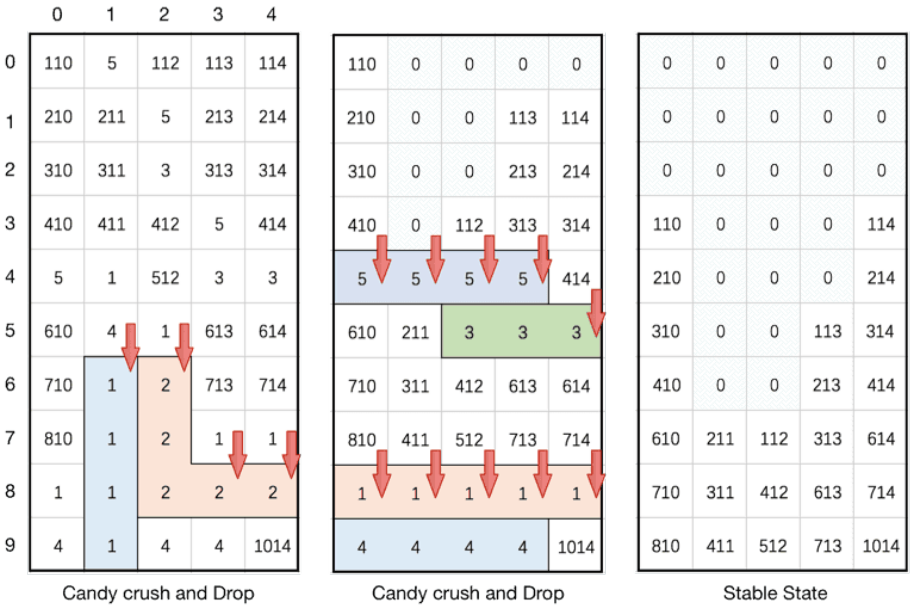
Given an `m x n` integer array `board` representing the grid of candy where `board[i][j]` represents the type of candy. A value of `board[i][j] == 0` represents that the cell is empty.

The given board represents the state of the game following the player's move. Now, you need to restore the board to a stable state by crushing candies according to the following rules:

- If three or more candies of the same type are adjacent vertically or horizontally, crush them all at the same time - these positions become empty.
- After crushing all candies simultaneously, if an empty space on the board has candies on top of itself, then these candies will drop until they hit a candy or bottom at the same time. No new candies will drop outside the top boundary.
- After the above steps, there may exist more candies that can be crushed. If so, you need to repeat the above steps.
- If there does not exist more candies that can be crushed (i.e., the board is stable), then return the current board.

You need to perform the above rules until the board becomes stable, then return *the stable board*.

Example 1:



```
Input: board = [[110,5,112,113,114],[210,211,5,213,214],[310,311,3,313,314],[410,411,412,5,414],[5,1,5
12,3,3],[610,4,1,613,614],[710,1,2,713,714],[810,1,2,1,1],[1,1,2,2,2],[4,1,4,4,1014]]
Output: [[0,0,0,0,0],[0,0,0,0,0],[0,0,0,0,0],[110,0,0,0,114],[210,0,0,0,214],[310,0,0,113,314],[410,0,
0,213,414],[610,211,112,313,614],[710,311,412,613,714],[810,411,512,713,1014]]
```

Example 2:

```
Input: board = [[1,3,5,5,2],[3,4,3,3,1],[3,2,4,5,2],[2,4,4,5,5],[1,4,4,1,1]]
Output: [[1,3,0,0,0],[3,4,0,5,2],[3,2,0,3,1],[2,4,0,5,2],[1,4,3,1,1]]
```

Constraints:

- `m == board.length`
- `n == board[i].length`
- `3 <= m, n <= 50`
- `1 <= board[i][j] <= 2000`

SOLUTION (PYTHON 3)

Solution 1: Simulation

> **How to think about it**
>
> Crush every run of three or more equal candies, drop, and repeat until stable. The board is small enough to simulate. Crushing immediately would disturb other runs that should vanish in the same step. The rule is: mark all current runs, then drop once. Mark doomed cells with a negative value (compare by absolute value) using length-3 windows on rows and columns. If anything was marked, pack positives downward in each column, fill zeros, and repeat.

We can traverse the matrix row by row and column by column to find three consecutive identical elements and mark them as negative numbers. If marking is successful, we need to move the elements in the matrix down until no elements can move down.

The time complexity is $O(m^2 \times n^2)$, where m and n are the number of rows and columns of the matrix, respectively. The space complexity is O(1).

Python 3

```python
class Solution:
    def candyCrush(self, board: List[List[int]]) -> List[List[int]]:
        m, n = len(board), len(board[0])
        run = True
        while run:
            run = False
            for i in range(m):
                for j in range(2, n):
                    if board[i][j] and abs(board[i][j]) == abs(board[i][j - 1]) == abs(
                        board[i][j - 2]
                    ):
                        run = True
                        board[i][j] = board[i][j - 1] = board[i][j - 2] = -abs(

1041. Robot Bounded In Circle

Medium · Math, String, Simulation

leetcode.com/problems/robot-bounded-in-circle

★ **TOP 10 PROBLEM** in Simulation / Array Rearrangement: master this one first

PROBLEM

On an infinite plane, a robot initially stands at `(0, 0)` and faces north. Note that:

- The **north direction** is the positive direction of the y-axis.
- The **south direction** is the negative direction of the y-axis.
- The **east direction** is the positive direction of the x-axis.
- The **west direction** is the negative direction of the x-axis.

The robot can receive one of three instructions:

- `"G"`: go straight 1 unit.
- `"L"`: turn 90 degrees to the left (i.e., anti-clockwise direction).
- `"R"`: turn 90 degrees to the right (i.e., clockwise direction).

The robot performs the `instructions` given in order, and repeats them forever.

Return `true` if and only if there exists a circle in the plane such that the robot never leaves the circle.

Example 1:

```
Input: instructions = "GGLLGG"
Output: true
Explanation: The robot is initially at (0, 0) facing the north direction.
"G": move one step. Position: (0, 1). Direction: North.
"G": move one step. Position: (0, 2). Direction: North.
"L": turn 90 degrees anti-clockwise. Position: (0, 2). Direction: West.
"L": turn 90 degrees anti-clockwise. Position: (0, 2). Direction: South.
"G": move one step. Position: (0, 1). Direction: South.
"G": move one step. Position: (0, 0). Direction: South.
Repeating the instructions, the robot goes into the cycle: (0, 0) --> (0, 1) --> (0, 2) --> (0, 1) --> (0, 0).
Based on that, we return true.
```

Example 2:

```
Input: instructions = "GG"
Output: false
Explanation: The robot is initially at (0, 0) facing the north direction.
"G": move one step. Position: (0, 1). Direction: North.
"G": move one step. Position: (0, 2). Direction: North.
Repeating the instructions, keeps advancing in the north direction and does not go into cycles.
Based on that, we return false.
```

Example 3:

```
Input: instructions = "GL"
Output: true
Explanation: The robot is initially at (0, 0) facing the north direction.
"G": move one step. Position: (0, 1). Direction: North.
"L": turn 90 degrees anti-clockwise. Position: (0, 1). Direction: West.
"G": move one step. Position: (-1, 1). Direction: West.
"L": turn 90 degrees anti-clockwise. Position: (-1, 1). Direction: South.
"G": move one step. Position: (-1, 0). Direction: South.
"L": turn 90 degrees anti-clockwise. Position: (-1, 0). Direction: East.
"G": move one step. Position: (0, 0). Direction: East.
"L": turn 90 degrees anti-clockwise. Position: (0, 0). Direction: North.
Repeating the instructions, the robot goes into the cycle: (0, 0) --> (0, 1) --> (-1, 1) --> (-1, 0)
--> (0, 0).
Based on that, we return true.
```

Constraints:

- `1 <= instructions.length <= 100`
- `instructions[i]` is `'G'`, `'L'` or, `'R'`.

SOLUTION (PYTHON 3)

Solution 1: Simulation

How to think about it

The program repeats forever, so we cannot simulate infinitely many steps. One cycle's net displacement and heading decide boundedness: back at the origin, or no longer facing north, later cycles stay in a loop. k∈[0,3] is the heading and dist counts steps on the four axes. Left adds one, right adds three, and a go increments the current axis. After one cycle we accept if north equals south and east equals west, or if k≠ 0.

We can simulate the robot's movement. Use a variable k to represent the robot's direction, initialized to 0, which means the robot is facing north. The variable k can take values in the range [0, 3], representing the robot facing north, west, south, and east, respectively. Additionally, we use an array dist of length 4 to record the distance the robot travels in the four directions, initialized to [0, 0, 0, 0].

Traverse the instruction string instructions. If the current instruction is `'L'`, the robot turns west, i.e., k = (k + 1) mod 4; if the instruction is `'R'`, the robot turns east, i.e., k = (k + 3) mod 4; otherwise, the robot moves one step in the current direction, i.e., dist[k]++.

If the given instruction string instructions is executed once and the robot returns to the origin, i.e., dist[0] = dist[2] and dist[1] = dist[3], then the robot will definitely enter a loop. This is because no matter how many times the instructions are repeated, the robot always returns to the origin, so it must enter a loop.

If the given instruction string instructions is executed once and the robot does not return to the origin, suppose the robot is at (x, y) and its direction is k.

- If k=0, i.e., the robot is facing north, then after executing the instructions a second time, the coordinate change is (x, y); after executing the instructions a third time, the coordinate change is still (x, y)... Accumulating these changes, the robot will eventually reach (n × x, n × y), where n is a positive integer. Since the robot does not return to the origin, i.e., x ≠ 0 or y ≠ 0, it follows that n × x ≠ 0 or n × y ≠ 0, so the robot will not enter a loop;
- If k=1, i.e., the robot is facing west, then after executing the instructions a second time, the coordinate change is (-y, x); after executing the instructions a third time, the coordinate change is (-x, -y); after executing the instructions a fourth time, the coordinate change is (y, -x). Accumulating these coordinate changes, we find that the robot will eventually return to the origin (0, 0);
- If k=2, i.e., the robot is facing south, then after executing the instructions a second time, the coordinate change is (-x, -y). Accumulating these two coordinate changes, we find that the robot will eventually return to the origin (0, 0);
- If k=3, i.e., the robot is facing east, then after executing the instructions a second time, the coordinate change is (y, -x); after executing the instructions a third time, the coordinate change is (-x, -y); after executing the instructions a fourth time, the coordinate change is (-y, x). Accumulating these coordinate changes, we find that the robot will eventually

return to the origin (0, 0).

In conclusion, if the given instruction string instructions is executed once and the robot returns to the origin, or if the robot's direction is different from the initial direction, then the robot will definitely enter a loop.

The time complexity is O(n), and the space complexity is O(1), where n is the length of the instruction string instructions.

Python 3

```
class Solution:
    def isRobotBounded(self, instructions: str) -> bool:
        k = 0
        dist = [0] * 4
        for c in instructions:
            if c == 'L':
                k = (k + 1) % 4
            elif c == 'R':
                k = (k + 3) % 4
            else:
                dist[k] += 1
        return (dist[0] == dist[2] and dist[1] == dist[3]) or k != 0
```

PATTERN 36 · SIMULATION / ARRAY REARRANGEMENT · PROBLEM 10 OF 20

885. Spiral Matrix III

Medium · Array, Matrix, Simulation

leetcode.com/problems/spiral-matrix-iii

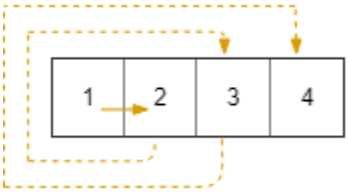
PROBLEM

You start at the cell `(rStart, cStart)` of an `rows x cols` grid facing east. The northwest corner is at the first row and column in the grid, and the southeast corner is at the last row and column.

You will walk in a clockwise spiral shape to visit every position in this grid. Whenever you move outside the grid's boundary, we continue our walk outside the grid (but may return to the grid boundary later.). Eventually, we reach all `rows * cols` spaces of the grid.

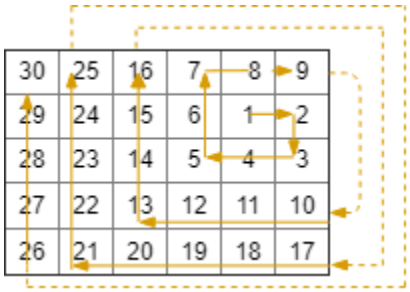
Return *an array of coordinates representing the positions of the grid in the order you visited them.*

Example 1:



```
Input: rows = 1, cols = 4, rStart = 0, cStart = 0
Output: [[0,0],[0,1],[0,2],[0,3]]
```

Example 2:



```
Input: rows = 5, cols = 6, rStart = 1, cStart = 4
Output: [[1,4],[1,5],[2,5],[2,4],[2,3],[1,3],[0,3],[0,4],[0,5],[3,5],[3,4],[3,3],[3,2],[2,2],[1,2],[0,
2],[4,5],[4,4],[4,3],[4,2],[4,1],[3,1],[2,1],[1,1],[0,1],[4,0],[3,0],[2,0],[1,0],[0,0]]
```

Constraints:

- `1 <= rows, cols <= 100`
- `0 <= rStart < rows`
- `0 <= cStart < cols`

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Walk the grid in an east-south-west-north spiral from a given start. Step lengths are 1,1,2,2,3,3,…. The grid is at most 100× 100, so simulation is enough. Advance by the current direction and length, recording in-bound cells. After east and south the length grows by one, and again after west and north. Stop when rows· cols cells are collected.

Python 3

```python
class Solution:
    def spiralMatrixIII(
        self, rows: int, cols: int, rStart: int, cStart: int
    ) -> List[List[int]]:
        ans = [[rStart, cStart]]
        if rows * cols == 1:
            return ans
        k = 1
        while True:
            for dr, dc, dk in [[0, 1, k], [1, 0, k], [0, -1, k + 1], [-1, 0, k + 1]]:
                for _ in range(dk):
                    rStart += dr
                    cStart += dc
                    if 0 <= rStart < rows and 0 <= cStart < cols:
                        ans.append([rStart, cStart])
                        if len(ans) == rows * cols:
                            return ans
            k += 2
```

Complexity. Time: O(max(rows, cols)^2). Space: O(rows * cols) for the answer.

2349. Design a Number Container System

Medium · Design, Hash Table, Ordered Set, Heap (Priority Queue)

leetcode.com/problems/design-a-number-container-system

PROBLEM

Design a number container system that can do the following:

- **Insert** or **Replace** a number at the given index in the system.
- **Return** the smallest index for the given number in the system.

Implement the `NumberContainers` class:

- `NumberContainers()` Initializes the number container system.
- `void change(int index, int number)` Fills the container at `index` with the `number`. If there is already a number at that `index`, replace it.
- `int find(int number)` Returns the smallest index for the given `number`, or `-1` if there is no index that is filled by `number` in the system.

Example 1:

```
Input
["NumberContainers", "find", "change", "change", "change", "change", "find", "change", "find"]
[[], [10], [2, 10], [1, 10], [3, 10], [5, 10], [10], [1, 20], [10]]
Output
[null, -1, null, null, null, null, 1, null, 2]

Explanation
NumberContainers nc = new NumberContainers();
nc.find(10); // There is no index that is filled with number 10. Therefore, we return -1.
nc.change(2, 10); // Your container at index 2 will be filled with number 10.
nc.change(1, 10); // Your container at index 1 will be filled with number 10.
nc.change(3, 10); // Your container at index 3 will be filled with number 10.
nc.change(5, 10); // Your container at index 5 will be filled with number 10.
nc.find(10); // Number 10 is at the indices 1, 2, 3, and 5. Since the smallest index that is filled
with 10 is 1, we return 1.
nc.change(1, 20); // Your container at index 1 will be filled with number 20. Note that index 1 was
filled with 10 and then replaced with 20.
nc.find(10); // Number 10 is at the indices 2, 3, and 5. The smallest index that is filled with 10 is
2. Therefore, we return 2.
```

Constraints:

- $1 \leq index, number \leq 10^9$
- At most 10^5 calls will be made **in total** to `change` and `find`.

SOLUTION (PYTHON 3)

Solution 1: Hash Table + Ordered Set

> **How to think about it**
>
> We change the number at an index and query the smallest index of a number. Up to 10^5 operations rule out linear scans. Map d stores the value at each index; a sorted set g[number] stores its indices. A change removes the old index and inserts the new one; find reads the first element of the set.

We use a hash table d to record the mapping relationship between indices and numbers, and another hash table g to record the set of indices corresponding to each number. Here, we can use an ordered set to store the indices, which allows us to conveniently find the smallest index.

When calling the `change` method, we first check if the index already exists. If it does, we remove the original number from its corresponding index set and then add the new number to the corresponding index set. The time complexity is O(log n).

When calling the `find` method, we simply return the first element of the index set corresponding to the number. The time complexity is O(1).

The space complexity is O(n), where n is the number of numbers.

Python 3

```
class NumberContainers:

    def __init__(self):
        self.d = {}
        self.g = defaultdict(SortedSet)

    def change(self, index: int, number: int) -> None:
        if index in self.d:
            old_number = self.d[index]
            self.g[old_number].remove(index)
        self.d[index] = number
        self.g[number].add(index)

    def find(self, number: int) -> int:
        ids = self.g[number]
        return ids[0] if ids else -1

# Your NumberContainers object will be instantiated and called as such:
# obj = NumberContainers()
# obj.change(index,number)
# param_2 = obj.find(number)
```

529. Minesweeper

Medium · Depth-First Search, Breadth-First Search, Array, Matrix

leetcode.com/problems/minesweeper

★ **TOP 10 PROBLEM** in Simulation / Array Rearrangement: master this one first

PROBLEM

Let's play the minesweeper game (Wikipedia, online game)!

You are given an `m x n` char matrix `board` representing the game board where:

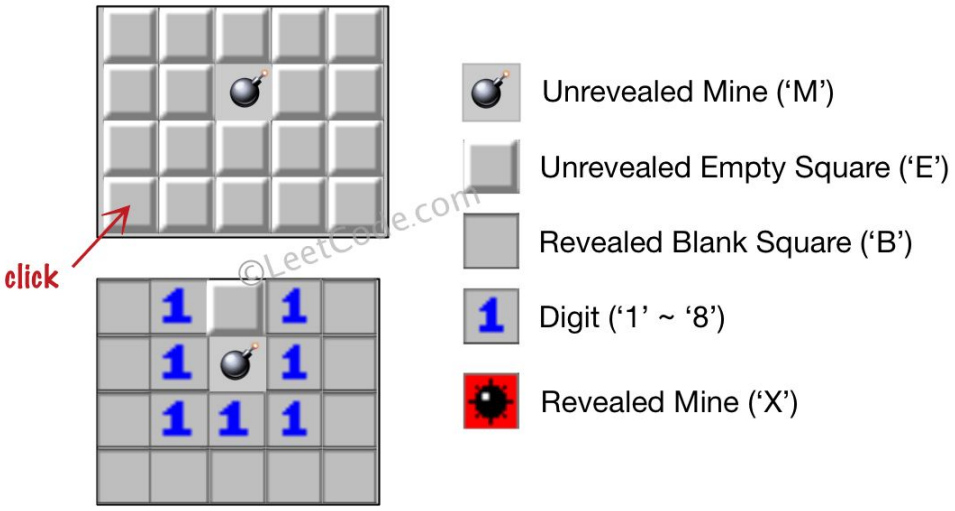
- `'M'` represents an unrevealed mine,
- `'E'` represents an unrevealed empty square,
- `'B'` represents a revealed blank square that has no adjacent mines (i.e., above, below, left, right, and all 4 diagonals),
- digit (`'1'` to `'8'`) represents how many mines are adjacent to this revealed square, and
- `'X'` represents a revealed mine.

You are also given an integer array `click` where `click = [click_r, click_c]` represents the next click position among all the unrevealed squares (`'M'` or `'E'`).

Return *the board after revealing this position according to the following rules*:

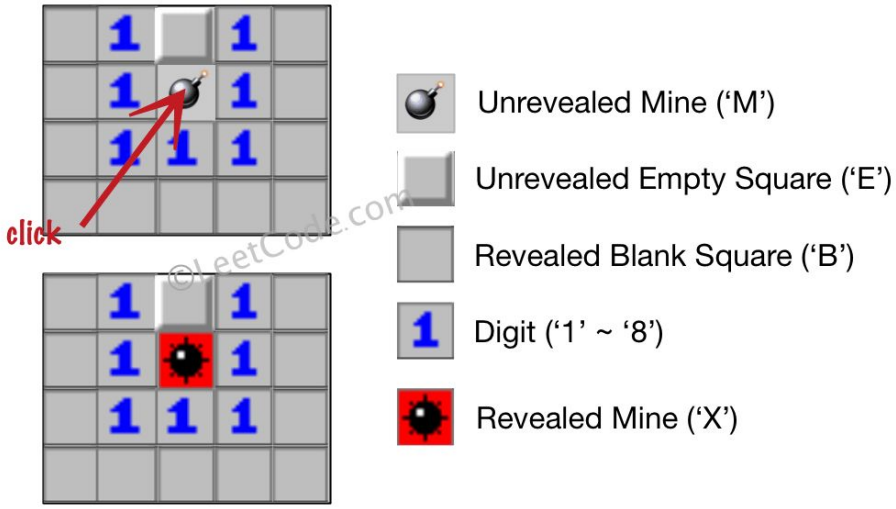
1. If a mine `'M'` is revealed, then the game is over. You should change it to `'X'`.
2. If an empty square `'E'` with no adjacent mines is revealed, then change it to a revealed blank `'B'` and all of its adjacent unrevealed squares should be revealed recursively.
3. If an empty square `'E'` with at least one adjacent mine is revealed, then change it to a digit (`'1'` to `'8'`) representing the number of adjacent mines.
4. Return the board when no more squares will be revealed.

Example 1:



```
Input: board =
[["E","E","E","E","E"],["E","E","M","E","E"],["E","E","E","E","E"],["E","E","E","E","E"]], click =
[3,0]
Output: [["B","1","E","1","B"],["B","1","M","1","B"],["B","1","1","1","B"],["B","B","B","B","B"]]
```

Example 2:



```
Input: board =
[["B","1","E","1","B"],["B","1","M","1","B"],["B","1","1","1","B"],["B","B","B","B","B"]], click =
[1,2]
Output: [["B","1","E","1","B"],["B","1","X","1","B"],["B","1","1","1","B"],["B","B","B","B","B"]]
```

Constraints:

- `m == board.length`
- `n == board[i].length`
- `1 <= m, n <= 50`
- `board[i][j]` is either `'M'`, `'E'`, `'B'`, or a digit from `'1'` to `'8'`.
- `click.length == 2`
- $0 \le click_r < m$
- $0 \le click_c < n$
- $board[click_r][click_c]$ is either `'M'` or `'E'`.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

A click on a mine becomes `X`. Otherwise count adjacent mines: write the count, or write `B` and flood neighboring empties. Only the click region needs to be revealed. If the cell is `M`, mark `X`. Otherwise DFS: count neighbors, write the digit and stop if any mine, else write `B` and recurse on adjacent `E` cells. Each cell expands at most once.

Python 3

```
class Solution:
    def updateBoard(self, board: List[List[str]], click: List[int]) -> List[List[str]]:
        def dfs(i: int, j: int):
            cnt = 0
            for x in range(i - 1, i + 2):
                for y in range(j - 1, j + 2):
                    if 0 <= x < m and 0 <= y < n and board[x][y] == "M":
                        cnt += 1
            if cnt:
                board[i][j] = str(cnt)
            else:
                board[i][j] = "B"
                for x in range(i - 1, i + 2):
                    for y in range(j - 1, j + 2):
                        if 0 <= x < m and 0 <= y < n and board[x][y] == "E":
                            dfs(x, y)

        m, n = len(board), len(board[0])
        i, j = click
        if board[i][j] == "M":
            board[i][j] = "X"
        else:
            dfs(i, j)
        return board
```

Complexity. Time: O(m * n). Space: O(m * n) recursion in the worst case.

1424. Diagonal Traverse II

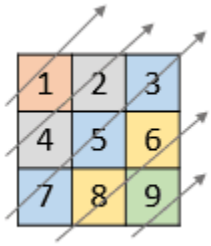
Medium · Array, Sorting, Heap (Priority Queue)

leetcode.com/problems/diagonal-traverse-ii

PROBLEM

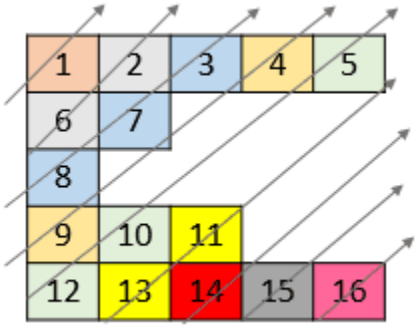
Given a 2D integer array `nums`, return *all elements of* `nums` *in diagonal order as shown in the below images*.

Example 1:



```
Input: nums = [[1,2,3],[4,5,6],[7,8,9]]
Output: [1,4,2,7,5,3,8,6,9]
```

Example 2:



```
Input: nums = [[1,2,3,4,5],[6,7],[8],[9,10,11],[12,13,14,15,16]]
Output: [1,6,2,8,7,3,9,4,12,10,5,13,11,14,15,16]
```

Constraints:

- `1 <= nums.length <= 10^5`
- `1 <= nums[i].length <= 10^5`
- `1 <= sum(nums[i].length) <= 10^5`
- `1 <= nums[i][j] <= 10^5`

SOLUTION (PYTHON 3)

Solution 1: Sorting

How to think about it

Rows have unequal lengths and there are up to 10^5 entries, so walking diagonals with raw indices is awkward. Entries on one diagonal share i+j; diagonals increase by i+j, and within a diagonal j increases. Store triples (i+j,j,v), sort, and emit the values.

We observe that:

- The value of i + j is the same for each diagonal;
- The value of i + j for the next diagonal is greater than that of the previous diagonal;
- Within the same diagonal, the value of i + j is the same, and the value of j increases from small to large.

Therefore, we store all numbers in the form of (i, j, nums[i][j]) into arr, and then sort according to the first two items. Finally, return the array composed of the values at index 2 of all elements in arr.

The time complexity is O(n × log n), where n is the number of elements in the array nums. The space complexity is O(n).

Python 3

```
class Solution:
    def findDiagonalOrder(self, nums: List[List[int]]) -> List[int]:
        arr = []
        for i, row in enumerate(nums):
            for j, v in enumerate(row):
                arr.append((i + j, j, v))
        arr.sort()
        return [v[2] for v in arr]
```

                best[r + c] = nums[r][c]
    return [best[k] for k in sorted(best)]
```

1914. Cyclically Rotating a Grid

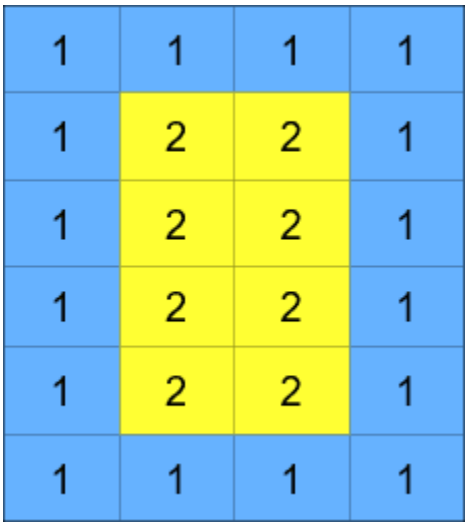
Medium · Array, Matrix, Simulation

leetcode.com/problems/cyclically-rotating-a-grid

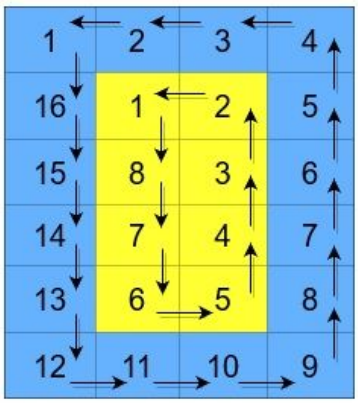
PROBLEM

You are given an `m x n` integer matrix `grid`, where `m` and `n` are both **even** integers, and an integer `k`.

The matrix is composed of several layers, which is shown in the below image, where each color is its own layer:



A cyclic rotation of the matrix is done by cyclically rotating **each layer** in the matrix. To cyclically rotate a layer once, each element in the layer will take the place of the adjacent element in the **counter-clockwise** direction. An example rotation is shown below:

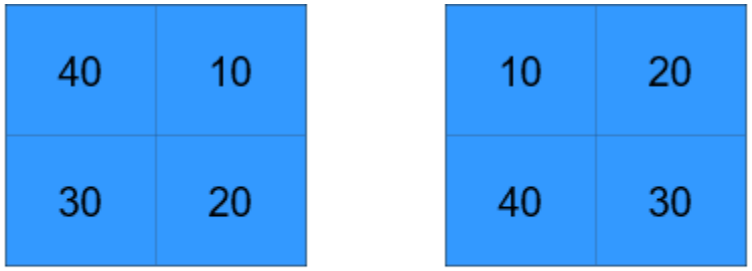


Before rotation

After rotation with k = 1

Return *the matrix after applying* `k` *cyclic rotations to it*.

Example 1:



Before Any Rotations **After One Rotation**

```
Input: grid = [[40,10],[30,20]], k = 1
Output: [[10,20],[40,30]]
Explanation: The figures above represent the grid at every state.
```

Example 2:

```
Input: grid = [[1,2,3,4],[5,6,7,8],[9,10,11,12],[13,14,15,16]], k = 2
Output: [[3,4,8,12],[2,11,10,16],[1,7,6,15],[5,9,13,14]]
Explanation: The figures above represent the grid at every state.
```

Constraints:

- `m == grid.length`
- `n == grid[i].length`
- `2 <= m, n <= 50`
- Both `m` and `n` are **even** integers.
- `1 <= grid[i][j] <= 5000`
- `1 <= k <= 10^9`

SOLUTION (PYTHON 3)

Solution 1: Layer-by-Layer Simulation

How to think about it

Layers are disjoint cycles and k may exceed a cycle length, so stepping cell by cell wastes work. Flatten each layer clockwise, reduce k modulo its length, then write back. Collect top, right, bottom, and left in that order and restore in the same order. Layers are independent, so the total time is linear in the grid size.

First, we compute the number of layers in the matrix, denoted by p, and then simulate the cyclic rotation layer by layer from the outside to the inside.

For each layer, we traverse clockwise and append the elements on the top, right, bottom, and left edges to an array nums in order. Let the length of nums be l. Next, we take k mod l. Then, starting from index k in the array, we write the elements back to the matrix along the top, right, bottom, and left edges in order.

The time complexity is O(m × n), and the space complexity is O(m + n), where m and n are the number of rows and columns of the matrix, respectively.

Python 3

```python
class Solution:
    def rotateGrid(self, grid: List[List[int]], k: int) -> List[List[int]]:
        def rotate(p: int, k: int):
            nums = []
            for j in range(p, n - p - 1):
                nums.append(grid[p][j])
            for i in range(p, m - p - 1):
                nums.append(grid[i][n - p - 1])
            for j in range(n - p - 1, p, -1):
                nums.append(grid[m - p - 1][j])
            for i in range(m - p - 1, p, -1):
                nums.append(grid[i][p])
            k %= len(nums)
            if k == 0:
                return
            nums = nums[k:] + nums[:k]
            k = 0
            for j in range(p, n - p - 1):
                grid[p][j] = nums[k]
                k += 1
            for i in range(p, m - p - 1):
                grid[i][n - p - 1] = nums[k]
                k += 1
            for j in range(n - p - 1, p, -1):
                grid[m - p - 1][j] = nums[k]
                k += 1
            for i in range(m - p - 1, p, -1):
                grid[i][p] = nums[k]
                k += 1

        m, n = len(grid), len(grid[0])
        for p in range(min(m, n) >> 1):
            rotate(p, k)
        return grid
```

            seen.add((r, right))
        sums.append(sum(grid[r][c] for r, c in seen))
    return sums
```

1975. Maximum Matrix Sum

Medium · Greedy, Array, Matrix

leetcode.com/problems/maximum-matrix-sum

PROBLEM

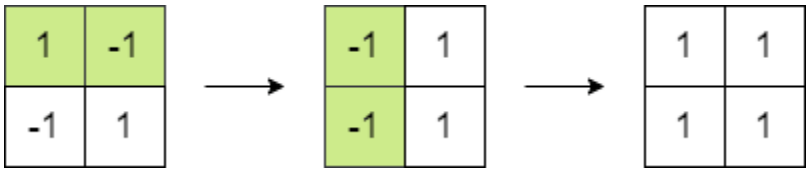
You are given an `n x n` integer `matrix`. You can do the following operation **any** number of times:

- Choose any two **adjacent** elements of `matrix` and **multiply** each of them by `-1`.

Two elements are considered **adjacent** if and only if they share a **border**.

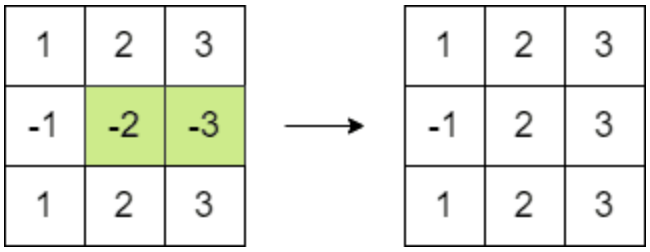
Your goal is to **maximize** the summation of the matrix's elements. Return *the **maximum** sum of the matrix's elements using the operation mentioned above.*

Example 1:



```
Input: matrix = [[1,-1],[-1,1]]
Output: 4
Explanation: We can follow the following steps to reach sum equals 4:
- Multiply the 2 elements in the first row by -1.
- Multiply the 2 elements in the first column by -1.
```

Example 2:



```
Input: matrix = [[1,2,3],[-1,-2,-3],[1,2,3]]
Output: 16
Explanation: We can follow the following step to reach sum equals 16:
- Multiply the 2 last elements in the second row by -1.
```

Constraints:

- `n == matrix.length == matrix[i].length`
- `2 <= n <= 250`
- `-10^5 <= matrix[i][j] <= 10^5`

SOLUTION (PYTHON 3)

Solution 1: Greedy

How to think about it

Flipping two adjacent signs moves a minus around the grid. A zero or an even number of minuses can be cleared; an odd count leaves exactly one. The answer is the sum of absolute values, minus twice the smallest absolute value when the minus count is odd.

If there is a zero in the matrix, or the number of negative numbers in the matrix is even, then the maximum sum is the sum of the absolute values of all elements in the matrix.

Otherwise, if there are an odd number of negative numbers in the matrix, there will be one negative number left in the end. We choose the number with the smallest absolute value and make it negative, so that the final sum is maximized.

The time complexity is O(m × n), where m and n are the number of rows and columns of the matrix, respectively. The space complexity is O(1).

Python 3

```python
class Solution:
    def maxMatrixSum(self, matrix: List[List[int]]) -> int:
        mi = inf
        s = cnt = 0
        for row in matrix:
            for x in row:
                cnt += x < 0
                y = abs(x)
                mi = min(mi, y)
                s += y
        return s if cnt % 2 == 0 else s - mi * 2
```

840. Magic Squares In Grid

Medium · Array, Hash Table, Math, Matrix

leetcode.com/problems/magic-squares-in-grid

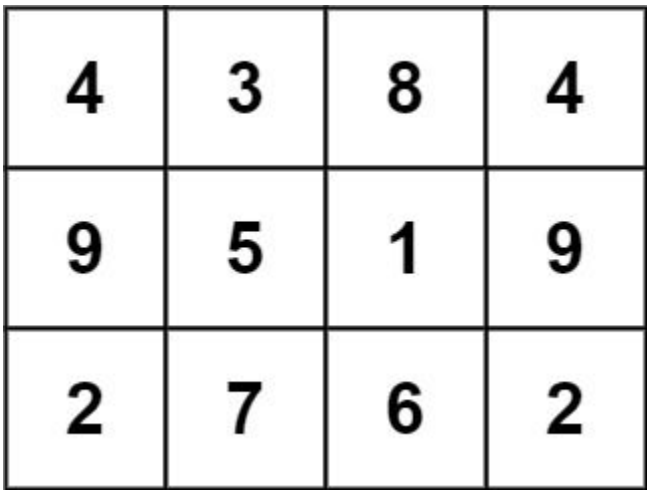
PROBLEM

A `3 x 3` **magic square** is a `3 x 3` grid filled with distinct numbers **from** 1 **to** 9 such that each row, column, and both diagonals all have the same sum.

Given a `row x col grid` of integers, how many `3 x 3` magic square subgrids are there?

Note: while a magic square can only contain numbers from 1 to 9, `grid` may contain numbers up to 15.

Example 1:



```
Input: grid = [[4,3,8,4],[9,5,1,9],[2,7,6,2]]
Output: 1
Explanation:
The following subgrid is a 3 x 3 magic square:

while this one is not:

In total, there is only one magic square inside the given grid.
```

Example 2:

```
Input: grid = [[8]]
Output: 0
```

Constraints:

- `row == grid.length`
- `col == grid[i].length`
- `1 <= row, col <= 10`
- `0 <= grid[i][j] <= 15`

SOLUTION (PYTHON 3)

Solution 1: Enumeration

> **How to think about it**
>
> A magic square uses 1… 9 once each and equal line sums. The grid is at most 10× 10, so every 3× 3 window can be checked. Collect the set and the row, column, and diagonal sums. Duplicates, out-of-range values, or unequal sums reject the window. Count the valid ones.

We directly enumerate the top-left coordinates (i, j) of each 3 × 3 submatrix, then check whether the submatrix satisfies the "magic square" property. If so, we increment the answer by one. After the enumeration, we return the answer.

The time complexity is O(m × n), where m and n are the number of rows and columns of the matrix, respectively. The space complexity is O(1).

Python 3

```python
class Solution:
    def numMagicSquaresInside(self, grid: List[List[int]]) -> int:
        def check(i: int, j: int) -> int:
            if i + 3 > m or j + 3 > n:
                return 0
            s = set()
            row = [0] * 3
            col = [0] * 3
            a = b = 0
            for x in range(i, i + 3):
                for y in range(j, j + 3):
                    v = grid[x][y]
                    if v < 1 or v > 9:
                        return 0
                    s.add(v)
                    row[x - i] += v
                    col[y - j] += v
                    if x - i == y - j:
                        a += v
                    if x - i == 2 - (y - j):
                        b += v
            if len(s) != 9 or a != b:
                return 0
            if any(x != a for x in row) or any(x != a for x in col):
                return 0
            return 1

        m, n = len(grid), len(grid[0])
        return sum(check(i, j) for i in range(m) for j in range(n))
```

1861. Rotating the Box

Medium · Array, Two Pointers, Matrix

leetcode.com/problems/rotating-the-box

★ **TOP 10 PROBLEM** in Simulation / Array Rearrangement: master this one first

PROBLEM

You are given an `m x n` matrix of characters `boxGrid` representing a side-view of a box. Each cell of the box is one of the following:

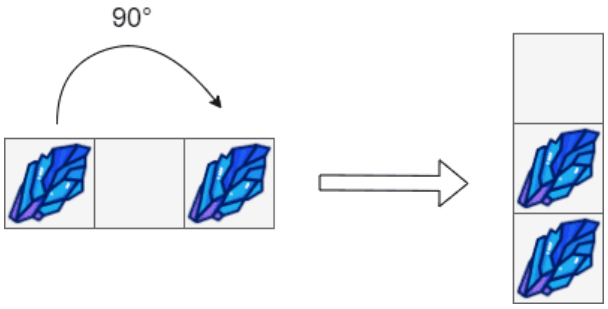
- A stone `'#'`
- A stationary obstacle `'*'`
- Empty `'.'`

The box is rotated **90 degrees clockwise**, causing some of the stones to fall due to gravity. Each stone falls down until it lands on an obstacle, another stone, or the bottom of the box. Gravity **does not** affect the obstacles' positions, and the inertia from the box's rotation **does not** affect the stones' horizontal positions.

It is **guaranteed** that each stone in `boxGrid` rests on an obstacle, another stone, or the bottom of the box.

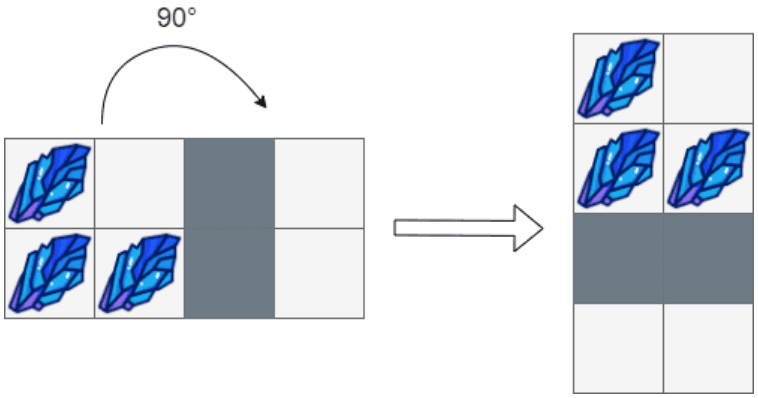
Return *an* `n x m` *matrix representing the box after the rotation described above*.

Example 1:



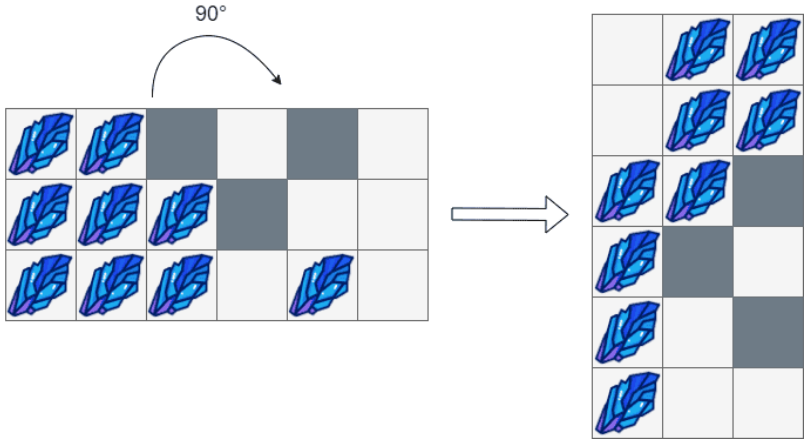
```
Input: boxGrid = [["#",".","#"]]
Output: [["."],
         ["#"],
         ["#"]]
```

Example 2:



```
Input: boxGrid = [["#",".","*","."],
                  ["#","#","*","."]]
Output: [["#","."],
         ["#","#"],
         ["*","*"],
         [".","."]]
```

Example 3:



```
Input: boxGrid = [["#","#","*",".","*","."],
                  ["#","#","#","*",".","."],
                  ["#","#","#",".","#","."]]
Output: [[".","#","#"],
         [".","#","#"],
         ["#","#","*"],
         ["#","*","."],
         ["#",".","*"],
         ["#",".","."]]
```

Constraints:

- `m == boxGrid.length`
- `n == boxGrid[i].length`
- `1 <= m, n <= 500`
- `boxGrid[i][j]` is either `'#'`, `'*'`, or `'.'`.

SOLUTION (PYTHON 3)

Solution 1: Queue Simulation

> **How to think about it**
>
> Rotate 90° clockwise, then let stones fall until they hit an obstacle or the floor. Moving each stone step by step can revisit the same cells. After the rotation, scan each column from the bottom: enqueue empty rows, swap a stone with the first empty slot, and clear the queue at an obstacle. Each cell is handled once and stones settle in the lowest reachable empties.

We first rotate the matrix 90 degrees clockwise, then simulate the falling process of stones in each column.

Specifically, we use a queue q to store the row indices of empty positions in the current column. When traversing each column, we scan from bottom to top. If we encounter a stone, we drop it to the first empty position in q, remove that empty position from q, and add the current position's row index to q since it becomes empty. If we encounter an obstacle, we clear q because stones cannot pass through obstacles. If we encounter an empty position, we add its row index to q.

The time complexity is $O(m \times n)$, and the space complexity is $O(m \times n)$, where m and n are the number of rows and columns of the matrix respectively.

Python 3

```python
class Solution:
    def rotateTheBox(self, boxGrid: List[List[str]]) -> List[List[str]]:
        m, n = len(boxGrid), len(boxGrid[0])
        ans = [[None] * m for _ in range(n)]
        for i in range(m):
            for j in range(n):
                ans[j][m - i - 1] = boxGrid[i][j]
        for j in range(m):
            q = deque()
            for i in range(n - 1, -1, -1):
                if ans[i][j] == "*":
                    q.clear()
                elif ans[i][j] == ".":
                    q.append(i)
                elif q:
                    ans[q.popleft()][j] = "#"
                    ans[i][j] = "."
                    q.append(i)
        return ans
```

            count += 1
    return count
```

2132. Stamping the Grid

Hard · Greedy, Array, Matrix, Prefix Sum

leetcode.com/problems/stamping-the-grid

PROBLEM

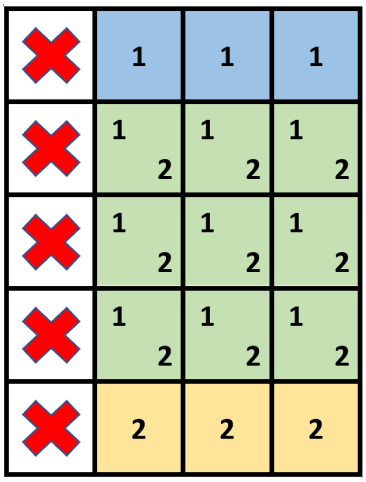
You are given an `m x n` binary matrix `grid` where each cell is either `0` (empty) or `1` (occupied).

You are then given stamps of size `stampHeight x stampWidth`. We want to fit the stamps such that they follow the given **restrictions** and **requirements**:

1. Cover all the **empty** cells.
2. Do not cover any of the **occupied** cells.
3. We can put as **many** stamps as we want.
4. Stamps can **overlap** with each other.
5. Stamps are not allowed to be **rotated**.
6. Stamps must stay completely **inside** the grid.

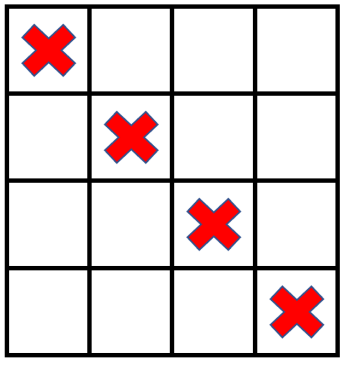
Return `true` *if it is possible to fit the stamps while following the given restrictions and requirements. Otherwise, return* `false`.

Example 1:



```
Input: grid = [[1,0,0,0],[1,0,0,0],[1,0,0,0],[1,0,0,0],[1,0,0,0]], stampHeight = 4, stampWidth = 3
Output: true
Explanation: We have two overlapping stamps (labeled 1 and 2 in the image) that are able to cover all the empty cells.
```

Example 2:



```
Input: grid = [[1,0,0,0],[0,1,0,0],[0,0,1,0],[0,0,0,1]], stampHeight = 2, stampWidth = 2
Output: false
Explanation: There is no way to fit the stamps onto all the empty cells without the stamps going
outside the grid.
```

Constraints:

- `m == grid.length`
- `n == grid[r].length`
- `1 <= m, n <= 10^5`
- `1 <= m * n <= 2 * 10^5`
- `grid[r][c]` is either `0` or `1`.
- `1 <= stampHeight, stampWidth <= 10^5`

SOLUTION (PYTHON 3)

Solution 1: Two-Dimensional Prefix Sum + Two-Dimensional Difference

How to think about it

Every stamp must sit on empty cells only, and every empty cell must be covered at least once. Marking each legal placement cell by cell is O(mn· hw) and too slow. A 2-D prefix sum tests an h× w block in O(1); successful placements are recorded in a 2-D difference array, which is then reconstructed to test coverage of every empty cell. Build the occupied prefix s, increment the difference d for each valid top-left, reconstruct d, and reject an empty cell whose coverage is still 0.

According to the problem description, every empty cell must be covered by a stamp, and no occupied cell can be covered. Therefore, we can traverse the two-dimensional matrix, and for each cell, if all cells in the area of stampHeight × stampWidth with this cell as the upper left corner are empty (i.e., not occupied), then we can place a stamp at this cell.

To quickly determine whether all cells in an area are empty, we can use a two-dimensional prefix sum. We use $s_{i,j}$ to represent the number of occupied cells in the sub-matrix from (1,1) to (i,j) in the two-dimensional matrix. That is, $s_{i, j} = s_{i - 1, j} + s_{i, j - 1} - s_{i - 1, j - 1} + grid_{i-1, j-1}$.

Then, with (i, j) as the upper left corner, and the height and width are stampHeight and stampWidth respectively, the lower right coordinate of the sub-matrix is (x, y) = (i + stampHeight - 1, j + stampWidth - 1). We can calculate the number of occupied cells in this sub-matrix through $s_{x, y} - s_{x, j - 1} - s_{i - 1, y} + s_{i - 1, j - 1}$. If the number of occupied cells in this sub-matrix is 0, then we can place a stamp at (i, j). After placing the stamp, all cells in this stampHeight × stampWidth area will become occupied cells. We can use a two-dimensional difference array d to record this change. That is:

$$\begin{aligned} &d_{i, j} \mathrel{+}= 1 \\ &d_{i, y + 1} \mathrel{-}= 1 \\ &d_{x + 1, j} \mathrel{-}= 1 \\ &d_{x + 1, y + 1} \mathrel{+}= 1 \end{aligned}$$

Finally, we perform a prefix sum operation on the two-dimensional difference array d to find out the number of times each cell is covered by a stamp. If a cell is not occupied and the number of times it is covered by a stamp is 0, then we cannot place a stamp at this cell, so we need to return false. If all "unoccupied cells" are successfully covered by stamps, return true.

The time complexity is O(m × n), and the space complexity is O(m × n). Here, m and n are the height and width of the two-dimensional matrix, respectively.

Python 3

```python
class Solution:
    def possibleToStamp(
        self, grid: List[List[int]], stampHeight: int, stampWidth: int
    ) -> bool:
        m, n = len(grid), len(grid[0])
        s = [[0] * (n + 1) for _ in range(m + 1)]
        for i, row in enumerate(grid, 1):
            for j, v in enumerate(row, 1):
                s[i][j] = s[i - 1][j] + s[i][j - 1] - s[i - 1][j - 1] + v
        d = [[0] * (n + 2) for _ in range(m + 2)]
        for i in range(1, m - stampHeight + 2):
            for j in range(1, n - stampWidth + 2):
                x, y = i + stampHeight - 1, j + stampWidth - 1
                if s[x][y] - s[x][j - 1] - s[i - 1][y] + s[i - 1][j - 1] == 0:
                    d[i][j] += 1
                    d[i][y + 1] -= 1
                    d[x + 1][j] -= 1
                    d[x + 1][y + 1] += 1
        for i, row in enumerate(grid, 1):
            for j, v in enumerate(row, 1):
                d[i][j] += d[i - 1][j] + d[i][j - 1] - d[i - 1][j - 1]
                if v == 0 and d[i][j] == 0:
                    return False
        return True
```

    return count
```

PATTERN 37 OF 41

Two Heaps

20 problems · 3 Easy · 10 Medium · 7 Hard

THE IDEA

A max-heap for the smaller half and a min-heap for the larger half give the median (or any split point) in O(1) with O(log n) updates.

Signals: find median from a data stream, sliding window median, IPO, maximize capital.

A TEMPLATE TO KEEP IN YOUR HANDS (PYTHON)

```
import heapq
small, large = [], []                    # small is a max-heap (store negatives)
def add(x):
    heapq.heappush(small, -x)
    heapq.heappush(large, -heapq.heappop(small))
    if len(large) > len(small):
        heapq.heappush(small, -heapq.heappop(large))
def median():
    if len(small) > len(large):
        return -small[0]
    return (-small[0] + large[0]) / 2
```

1942. The Number of the Smallest Unoccupied Chair

Medium · Array, Hash Table, Heap (Priority Queue)

leetcode.com/problems/the-number-of-the-smallest-unoccupied-chair

PROBLEM

There is a party where `n` friends numbered from `0` to `n - 1` are attending. There is an **infinite** number of chairs in this party that are numbered from `0` to `infinity`. When a friend arrives at the party, they sit on the unoccupied chair with the **smallest number**.

- For example, if chairs `0`, `1`, and `5` are occupied when a friend comes, they will sit on chair number `2`.

When a friend leaves the party, their chair becomes unoccupied at the moment they leave. If another friend arrives at that same moment, they can sit in that chair.

You are given a **0-indexed** 2D integer array `times` where `times[i] = [arrival`$_i$`, leaving`$_i$`]`, indicating the arrival and leaving times of the `i`th friend respectively, and an integer `targetFriend`. All arrival times are **distinct**.

Return *the **chair number** that the friend numbered* `targetFriend` *will sit on*.

Example 1:

```
Input: times = [[1,4],[2,3],[4,6]], targetFriend = 1
Output: 1
Explanation:
- Friend 0 arrives at time 1 and sits on chair 0.
- Friend 1 arrives at time 2 and sits on chair 1.
- Friend 1 leaves at time 3 and chair 1 becomes empty.
- Friend 0 leaves at time 4 and chair 0 becomes empty.
- Friend 2 arrives at time 4 and sits on chair 0.
Since friend 1 sat on chair 1, we return 1.
```

Example 2:

```
Input: times = [[3,10],[1,5],[2,6]], targetFriend = 0
Output: 2
Explanation:
- Friend 1 arrives at time 1 and sits on chair 0.
- Friend 2 arrives at time 2 and sits on chair 1.
- Friend 0 arrives at time 3 and sits on chair 2.
- Friend 1 leaves at time 5 and chair 0 becomes empty.
- Friend 2 leaves at time 6 and chair 1 becomes empty.
- Friend 0 leaves at time 10 and chair 2 becomes empty.
Since friend 0 sat on chair 2, we return 2.
```

Constraints:

- `n == times.length`
- `2 <= n <= 10`^{4}
- `times[i].length == 2`
- `1 <= arrival`$_i$ `< leaving`$_i$ `<= 10`^{5}
- `0 <= targetFriend <= n - 1`
- Each `arrival`$_i$ time is **distinct**.

SOLUTION (PYTHON 3)

Solution 1: Priority Queue (Min-Heap)

How to think about it

Friends take the smallest idle chair on arrival and release it on leaving. Scanning all chairs each time adds a linear factor. A min-heap of idle indices and a min-heap of (leaving,chair) handle reuse. On arrival we free every expired chair, then pop the smallest idle index. We stop when the target friend is seated. Sorting plus heaps is O(nlog n).

First, we create a tuple for each friend consisting of their arrival time, leaving time, and index, then sort these tuples by arrival time.

We use a min-heap idle to store the currently available chair numbers. Initially, we add 0, 1, …, n-1 to idle. We also use a min-heap busy to store tuples (leaving, chair), where leaving represents the leaving time and chair represents the chair number.

We iterate through each friend's arrival time, leaving time, and index. For each friend, we first remove all friends from busy whose leaving time is less than or equal to the current friend's arrival time, and add their chair numbers back to idle. Then we pop a chair number from idle, assign it to the current friend, and add (leaving, chair) to busy. If the current friend's index is equal to targetFriend, we return the assigned chair number.

The time complexity is O(n × log n), and the space complexity is O(n). Here, n is the number of friends.

Python 3

```python
class Solution:
    def smallestChair(self, times: List[List[int]], targetFriend: int) -> int:
        n = len(times)
        for i in range(n):
            times[i].append(i)
        times.sort()
        idle = list(range(n))
        heapify(idle)
        busy = []
        for arrival, leaving, i in times:
            while busy and busy[0][0] <= arrival:
                heappush(idle, heappop(busy)[1])
            j = heappop(idle)
            if i == targetFriend:
                return j
            heappush(busy, (leaving, j))
```

PATTERN 37 · TWO HEAPS · PROBLEM 10 OF 20

1792. Maximum Average Pass Ratio

Medium · Greedy, Array, Heap (Priority Queue)

leetcode.com/problems/maximum-average-pass-ratio

PROBLEM

There is a school that has classes of students and each class will be having a final exam. You are given a 2D integer array `classes`, where `classes[i] = [pass_i, total_i]`. You know beforehand that in the i^{th} class, there are `total_i` total students, but only `pass_i` number of students will pass the exam.

You are also given an integer `extraStudents`. There are another `extraStudents` brilliant students that are **guaranteed** to pass the exam of any class they are assigned to. You want to assign each of the `extraStudents` students to a class in a way that **maximizes** the **average** pass ratio across **all** the classes.

The **pass ratio** of a class is equal to the number of students of the class that will pass the exam divided by the total number of students of the class. The **average pass ratio** is the sum of pass ratios of all the classes divided by the number of the classes.

Return *the **maximum** possible average pass ratio after assigning the* `extraStudents` *students.* Answers within 10^{-5} of the actual answer will be accepted.

Example 1:

```
Input: classes = [[1,2],[3,5],[2,2]], extraStudents = 2
Output: 0.78333
Explanation: You can assign the two extra students to the first class. The average pass ratio will be equal to (3/4 + 3/5 + 2/2) / 3 = 0.78333.
```

Example 2:

```
Input: classes = [[2,4],[3,9],[4,5],[2,10]], extraStudents = 4
Output: 0.53485
```

Constraints:

- `1 <= classes.length <= 10^5`
- `classes[i].length == 2`
- `1 <= pass_i <= total_i <= 10^5`
- `1 <= extraStudents <= 10^5`

SOLUTION (PYTHON 3)

Solution 1: Priority Queue (Max-Heap of Increment)

> **How to think about it**
>
> Each extra passing student joins one class; we maximize the average of pass ratios. The gain (a+1)/(b+1)-a/b decreases as a class grows, so always give the next student to the class with the largest current gain. A heap keyed by that gain (or its negation) pops a class, increments both counts, and pushes it back. Average the final ratios.

Suppose a class currently has a pass rate of a/b. If we arrange a smart student into this class, then the pass rate of the class will become (a+1)/(b+1). We can find that the increment of the pass rate is (a+1)/(b+1) - a/b.

We maintain a max-heap, which stores the increment of the pass rate for each class.

Perform `extraStudents` operations, each time taking a class from the top of the heap, adding 1 to both the number of students and the number of passes in this class, then recalculating the increment of the pass rate of this class and putting it back into the heap. Repeat this process until all students are allocated.

Finally, we sum up the pass rates of all classes, and then divide by the number of classes to get the answer.

The time complexity is O(n × log n), and the space complexity is O(n). Here, n is the number of classes.

Python 3

```python
class Solution:
    def maxAverageRatio(self, classes: List[List[int]], extraStudents: int) -> float:
        h = [(a / b - (a + 1) / (b + 1), a, b) for a, b in classes]
        heapify(h)
        for _ in range(extraStudents):
            _, a, b = heappop(h)
            a, b = a + 1, b + 1
            heappush(h, (a / b - (a + 1) / (b + 1), a, b))
        return sum(v[1] / v[2] for v in h) / len(classes)
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

        heapq.heappush(heap, (-gain(state[i][0], state[i][1]), i))
        averages.append(total_ratio / len(classes))
    return averages
```

PATTERN 37 · TWO HEAPS · PROBLEM 15 OF 20

480. Sliding Window Median

Hard · Array, Hash Table, Treap, Sliding Window, Heap (Priority Queue)

leetcode.com/problems/sliding-window-median

★ **TOP 10 PROBLEM** in Two Heaps: master this one first

PROBLEM

The **median** is the middle value in an ordered integer list. If the size of the list is even, there is no middle value. So the median is the mean of the two middle values.

- For examples, if `arr = [2,3,4]`, the median is `3`.
- For examples, if `arr = [1,2,3,4]`, the median is `(2 + 3) / 2 = 2.5`.

You are given an integer array `nums` and an integer `k`. There is a sliding window of size `k` which is moving from the very left of the array to the very right. You can only see the `k` numbers in the window. Each time the sliding window moves right by one position.

Return *the median array for each window in the original array*. Answers within 10^{-5} of the actual value will be accepted.

Example 1:

```
Input: nums = [1,3,-1,-3,5,3,6,7], k = 3
Output: [1.00000,-1.00000,-1.00000,3.00000,5.00000,6.00000]
Explanation:
Window position Median
--------------- -----
[1 3 -1] -3 5 3 6 7 1
 1 [3 -1 -3] 5 3 6 7 -1
 1 3 [-1 -3 5] 3 6 7 -1
 1 3 -1 [-3 5 3] 6 7 3
 1 3 -1 -3 [5 3 6] 7 5
 1 3 -1 -3 5 [3 6 7] 6
```

Example 2:

```
Input: nums = [1,2,3,4,2,3,1,4,2], k = 3
Output: [2.00000,3.00000,3.00000,3.00000,2.00000,3.00000,2.00000]
```

Constraints:

- `1 <= k <= nums.length <=` 10^5
- -2^{31} `<= nums[i] <=` $2^{31} - 1$

SOLUTIONS (PYTHON 3)

Solution 1: Dual Priority Queues (Min-Heap and Max-Heap) + Lazy Deletion

How to think about it

Median of every window. Sorting each window is O(nklog k). Heaps give the median but cannot delete an arbitrary outgoing value. Two heaps: a max-heap for the lower half, a min-heap for the upper half, plus a lazy-deletion map. After insert or erase, only expired heap tops are popped, then the live sizes are rebalanced. Lazy deletion turns an arbitrary erase into a top pop; live sizes are counted separately so the tops remain the median candidates.

We can use two priority queues (min-heap and max-heap) to maintain the elements in the current window. One priority queue stores the smaller half of the elements, and the other priority queue stores the larger half of the elements. This way, the median of the current window is either the average of the top elements of the two heaps or one of the top elements.

We design a class MedianFinder to maintain the elements in the current window. This class includes the following methods:

- `add_num(num)`: Adds num to the current window.
- `find_median()`: Returns the median of the elements in the current window.
- `remove_num(num)`: Removes num from the current window.
- `prune(pq)`: If the top element of the heap is in the lazy deletion dictionary delayed, it pops the top element from the heap and decrements its lazy deletion count. If the lazy deletion count of the element becomes zero, it removes the element from the lazy deletion dictionary.
- `rebalance()`: If the number of elements in the smaller half exceeds the number of elements in the larger half by 2, it moves the top element of the larger half to the smaller half. If the number of elements in the smaller half is less than the number of elements in the larger half, it moves the top element of the larger half to the smaller half.

In the `add_num(num)` method, we first consider adding num to the smaller half. If num is greater than the top element of the larger half, we add num to the larger half. Then we call the `rebalance()` method to ensure that the size difference between the two priority queues does not exceed 1.

In the `remove_num(num)` method, we increment the lazy deletion count of num. Then we compare num with the top element of the smaller half. If num is less than or equal to the top element of the smaller half, we update the size of the smaller half and call the `prune()` method to ensure that the top element of the smaller half is not in the lazy deletion dictionary. Otherwise, we update the size of the larger half and call the `prune()` method to ensure that the top element of the larger half is not in the lazy deletion dictionary.

In the `find_median()` method, if the current window size is odd, we return the top element of the smaller half; otherwise, we return the average of the top elements of the smaller half and the larger half.

In the `prune(pq)` method, if the top element of the heap is in the lazy deletion dictionary, it pops the top element from the heap and decrements its lazy deletion count. If the lazy deletion count of the element becomes zero, it removes the element from the lazy deletion dictionary.

In the `rebalance()` method, if the number of elements in the smaller half exceeds the number of elements in the larger half by 2, it moves the top element of the larger half to the smaller half. If the number of elements in the smaller half is less than the number of elements in the larger half, it moves the top element of the larger half to the smaller half.

The time complexity is O(n × log n), and the space complexity is O(n). Here, n is the length of the array nums.

Python 3

```
class MedianFinder:
    def __init__(self, k: int):
        self.k = k
        self.small = []
        self.large = []
        self.delayed = defaultdict(int)
        self.small_size = 0
        self.large_size = 0

    def add_num(self, num: int):
        if not self.small or num <= -self.small[0]:
            heappush(self.small, -num)
            self.small_size += 1
        else:
            heappush(self.large, num)
            self.large_size += 1
        self.rebalance()

    def find_median(self) -> float:
        return -self.small[0] if self.k & 1 else (-self.small[0] + self.large[0]) / 2

    def remove_num(self, num: int):
        self.delayed[num] += 1
        if num <= -self.small[0]:
            self.small_size -= 1
            if num == -self.small[0]:
                self.prune(self.small)
        else:
            self.large_size -= 1
            if num == self.large[0]:
                self.prune(self.large)
        self.rebalance()

    def prune(self, pq: List[int]):
        sign = -1 if pq is self.small else 1
        while pq and sign * pq[0] in self.delayed:
            self.delayed[sign * pq[0]] -= 1
            if self.delayed[sign * pq[0]] == 0:
                self.delayed.pop(sign * pq[0])
            heappop(pq)

    def rebalance(self):
        if self.small_size > self.large_size + 1:
            heappush(self.large, -heappop(self.small))
            self.small_size -= 1
            self.large_size += 1
            self.prune(self.small)
        elif self.small_size < self.large_size:
            heappush(self.small, -heappop(self.large))
            self.large_size -= 1
            self.small_size += 1
            self.prune(self.large)

class Solution:
    def medianSlidingWindow(self, nums: List[int], k: int) -> List[float]:
        finder = MedianFinder(k)
        for x in nums[:k]:
            finder.add_num(x)
        ans = [finder.find_median()]
```

```
        for i in range(k, len(nums)):
            finder.add_num(nums[i])
            finder.remove_num(nums[i - k])
            ans.append(finder.find_median())
        return ans
```

Solution 2: Ordered Set

> **How to think about it**
>
> Lazy heaps are long to implement. An ordered set inserts and deletes in O(log k). The left set holds the lower half, the right the upper half: insert into the right, move its minimum left, and rebalance. When the window is full, read the ends and remove the outgoing value. The code is shorter if an ordered-set type is available.

We can use two ordered sets to maintain the elements in the current window. The ordered set l stores the smaller half of the elements in the current window, and the ordered set r stores the larger half of the elements.

We traverse the array nums. For each element x, we add it to the ordered set r, then move the smallest element in the ordered set r to the ordered set l. If the size of the ordered set l is greater than the size of the ordered set r by more than 1, we move the largest element in the ordered set l to the ordered set r.

If the total number of elements in the current window is k and the size is odd, the maximum value in the ordered set l is the median. If the size of the current window is even, the average of the maximum value in the ordered set l and the minimum value in the ordered set r is the median. Then, we remove the leftmost element of the window and continue traversing the array.

The time complexity is O(n log k), and the space complexity is O(k). Here, n is the length of the array nums.

Python 3

```python
class Solution:
    def medianSlidingWindow(self, nums: List[int], k: int) -> List[float]:
        l = SortedList()
        r = SortedList()
        ans = []
        for i, x in enumerate(nums):
            r.add(x)
            l.add(r.pop(0))
            while len(l) - len(r) > 1:
                r.add(l.pop())
            j = i - k + 1
            if j >= 0:
                ans.append(l[-1] if k & 1 else (l[-1] + r[0]) / 2)

PATTERN 37 · TWO HEAPS · PROBLEM 16 OF 20

502. IPO

Hard · Greedy, Array, Sorting, Heap (Priority Queue)

leetcode.com/problems/ipo

★ **TOP 10 PROBLEM** in Two Heaps: master this one first

PROBLEM

Suppose LeetCode will start its **IPO** soon. In order to sell a good price of its shares to Venture Capital, LeetCode would like to work on some projects to increase its capital before the **IPO**. Since it has limited resources, it can only finish at most `k` distinct projects before the **IPO**. Help LeetCode design the best way to maximize its total capital after finishing at most `k` distinct projects.

You are given `n` projects where the i^{th} project has a pure profit `profits[i]` and a minimum capital of `capital[i]` is needed to start it.

Initially, you have `w` capital. When you finish a project, you will obtain its pure profit and the profit will be added to your total capital.

Pick a list of **at most** `k` distinct projects from given projects to **maximize your final capital**, and return *the final maximized capital*.

The answer is guaranteed to fit in a 32-bit signed integer.

Example 1:

```
Input: k = 2, w = 0, profits = [1,2,3], capital = [0,1,1]
Output: 4
Explanation: Since your initial capital is 0, you can only start the project indexed 0.
After finishing it you will obtain profit 1 and your capital becomes 1.
With capital 1, you can either start the project indexed 1 or the project indexed 2.
Since you can choose at most 2 projects, you need to finish the project indexed 2 to get the maximum
capital.
Therefore, output the final maximized capital, which is 0 + 1 + 3 = 4.
```

Example 2:

```
Input: k = 3, w = 0, profits = [1,2,3], capital = [0,1,2]
Output: 6
```

Constraints:

- `1 <= k <=` 10^5
- `0 <= w <=` 10^9
- `n == profits.length`
- `n == capital.length`
- `1 <= n <=` 10^5
- `0 <= profits[i] <=` 10^4
- `0 <= capital[i] <=` 10^9

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Each of the k choices should take the most profitable project we can afford. Scanning all n projects every time is O(kn), which is heavy for n,k ≤ 10^5. Capital never decreases, so keep locked projects in a min-heap by capital and move those we can afford into a max-heap by profit. Each round pops the best profit and updates capital. Both heaps expose the next unlock and the best pick at the top.

Python 3

```
class Solution:
    def findMaximizedCapital(
        self, k: int, w: int, profits: List[int], capital: List[int]
    ) -> int:
        h1 = [(c, p) for c, p in zip(capital, profits)]
        heapify(h1)
        h2 = []
        while k:
            while h1 and h1[0][0] <= w:
                heappush(h2, -heappop(h1)[1])
            if not h2:
                break
            w -= heappop(h2)
            k -= 1
        return w
```

PATTERN 37 · TWO HEAPS · PROBLEM 20 OF 20

1675. Minimize Deviation in Array

Hard · Greedy, Array, Ordered Set, Heap (Priority Queue)

leetcode.com/problems/minimize-deviation-in-array

★ **TOP 10 PROBLEM** in Two Heaps: master this one first

PROBLEM

You are given an array `nums` of `n` positive integers.

You can perform two types of operations on any element of the array any number of times:

- If the element is **even**, **divide** it by `2`.
  - For example, if the array is `[1,2,3,4]`, then you can do this operation on the last element, and the array will be `[1,2,3,2]`.
- If the element is **odd**, **multiply** it by `2`.
  - For example, if the array is `[1,2,3,4]`, then you can do this operation on the first element, and the array will be `[2,2,3,4]`.

The **deviation** of the array is the **maximum difference** between any two elements in the array.

Return *the **minimum deviation** the array can have after performing some number of operations.*

Example 1:

```
Input: nums = [1,2,3,4]
Output: 1
Explanation: You can transform the array to [1,2,3,2], then to [2,2,3,2], then the deviation will be 3 - 2 = 1.
```

Example 2:

```
Input: nums = [4,1,5,20,3]
Output: 3
Explanation: You can transform the array after two operations to [4,2,5,5,3], then the deviation will be 5 - 2 = 3.
```

Example 3:

```
Input: nums = [2,10,8]
Output: 3
```

Constraints:

- `n == nums.length`
- `2 <= n <= 5 * 10^4`
- `1 <= nums[i] <= 10^9`

SOLUTION (PYTHON 3)

Solution 1: Greedy + Priority Queue

How to think about it

An odd value may be doubled once; an even value may be halved repeatedly. We want the smallest max-min. n can be 5× 10^4, so we cannot list every reachable value of every element. Double every odd first so only halving remains. A max-heap holds the current maximum and we track the global minimum; repeatedly halve the top and update the deviation until the top is odd and cannot shrink.

Intuitively, to get the minimum offset of the array, we need to decrease the maximum value of the array and increase the minimum value of the array.

Since there are two operations that can be performed each time: multiply an odd number by 2; divide an even number by 2, the situation is more complex. We can multiply all odd numbers by 2 to convert them into even numbers, which is equivalent to having only one division operation. The division operation can only reduce a certain number, and only by reducing the maximum value can the result be more optimal.

Therefore, we use a priority queue (max heap) to maintain the maximum value of the array. Each time we take out the top element of the heap for division operation, put the new value into the heap, and update the minimum value and the minimum value of the difference between the top element of the heap and the minimum value.

When the top element of the heap is an odd number, the operation stops.

The time complexity is O(nlog n × log m). Where n and m are the length of the array `nums` and the maximum element of the array, respectively. Since the maximum element in the array is divided by 2 at most O(log m) times, all elements are divided by 2 at most O(nlog m) times. Each time the heap is popped and put into operation, the time complexity is O(log n). Therefore, the total time complexity is O(nlog n × log m).

Python 3

```python
class Solution:
    def minimumDeviation(self, nums: List[int]) -> int:
        h = []
        mi = inf
        for v in nums:
            if v & 1:
                v <<= 1
            h.append(-v)
            mi = min(mi, v)
        heapify(h)
        ans = -h[0] - mi
        while h[0] % 2 == 0:
            x = heappop(h) // 2
            heappush(h, x)
            mi = min(mi, -x)
            ans = min(ans, -h[0] - mi)
        return ans
```

PATTERN 38 · K-WAY MERGE · PROBLEM 5 OF 20

373. Find K Pairs with Smallest Sums

Medium · Array, Heap (Priority Queue)

leetcode.com/problems/find-k-pairs-with-smallest-sums

★ **TOP 10 PROBLEM** in K-way Merge: master this one first

PROBLEM

You are given two integer arrays `nums1` and `nums2` sorted in **non-decreasing order** and an integer `k`.

Define a pair `(u, v)` which consists of one element from the first array and one element from the second array.

Return *the* `k` *pairs* $(u_1, v_1), (u_2, v_2), \ldots, (u_k, v_k)$ *with the smallest sums*.

Example 1:

```
Input: nums1 = [1,7,11], nums2 = [2,4,6], k = 3
Output: [[1,2],[1,4],[1,6]]
Explanation: The first 3 pairs are returned from the sequence:
[1,2],[1,4],[1,6],[7,2],[7,4],[11,2],[7,6],[11,4],[11,6]
```

Example 2:

```
Input: nums1 = [1,1,2], nums2 = [1,2,3], k = 2
Output: [[1,1],[1,1]]
Explanation: The first 2 pairs are returned from the sequence:
[1,1],[1,1],[1,2],[2,1],[1,2],[2,2],[1,3],[1,3],[2,3]
```

Constraints:

- `1 <= nums1.length, nums2.length <=` 10^5
- -10^9 `<= nums1[i], nums2[i] <=` 10^9
- `nums1` and `nums2` both are sorted in **non-decreasing order**.
- `1 <= k <=` 10^4
- `k <= nums1.length * nums2.length`

SOLUTION (PYTHON 3)

Solution 1

How to think about it

The k pairs of smallest sums from two sorted arrays. Sorting all pairs is O(mnlog(mn)). For fixed i, increasing j increases the sum, so a heap pops the current minimum and only advances j. Push (nums1[i]+nums2[0], i, 0) for i<k. Each pop, if j+1 exists, pushes the next column of the same i. At most k pops.

Python 3

```
class Solution:
    def kSmallestPairs(
        self, nums1: List[int], nums2: List[int], k: int
    ) -> List[List[int]]:
        q = [[u + nums2[0], i, 0] for i, u in enumerate(nums1[:k])]
        heapify(q)
        ans = []
        while q and k > 0:
            _, i, j = heappop(q)
            ans.append([nums1[i], nums2[j]])
            k -= 1
            if j + 1 < len(nums2):
                heappush(q, [nums1[i] + nums2[j + 1], i, j + 1])
        return ans
```

PATTERN 38 · K-WAY MERGE · PROBLEM 7 OF 20

313. Super Ugly Number

Medium · Array, Math, Dynamic Programming

leetcode.com/problems/super-ugly-number

★ **TOP 10 PROBLEM** in K-way Merge: master this one first

PROBLEM

A **super ugly number** is a positive integer whose prime factors are in the array `primes`.

Given an integer `n` and an array of integers `primes`, return *the* n^{th} ***super ugly number***.

The n^{th} **super ugly number** is **guaranteed** to fit in a **32-bit** signed integer.

Example 1:

```
Input: n = 12, primes = [2,7,13,19]
Output: 32
Explanation: [1,2,4,7,8,13,14,16,19,26,28,32] is the sequence of the first 12 super ugly numbers given
primes = [2,7,13,19].
```

Example 2:

```
Input: n = 1, primes = [2,3,5]
Output: 1
Explanation: 1 has no prime factors, therefore all of its prime factors are in the array primes =
[2,3,5].
```

Constraints:

- `1 <= n <=` 10^5
- `1 <= primes.length <= 100`
- `2 <= primes[i] <= 1000`
- `primes[i]` is **guaranteed** to be a prime number.
- All the values of `primes` are **unique** and sorted in **ascending order**.

SOLUTIONS (PYTHON 3)

Solution 1: Priority Queue (Min Heap)

How to think about it

A super ugly number uses only the given primes. Trial-dividing every integer is too slow for large n. Start from 1, pop the heap minimum x, and push x× p when it does not overflow. If x is divisible by the current prime, skip later primes (Euler-sieve style). The n-th pop is the answer.

We use a priority queue (min heap) to maintain all possible super ugly numbers, initially putting 1 into the queue.

Each time we take the smallest super ugly number x from the queue, multiply x by each number in the array `primes`, and put the product into the queue. Repeat the above operation n times to get the nth super ugly number.

Since the problem guarantees that the nth super ugly number is within the range of a 32-bit signed integer, before we put the product into the queue, we can first check whether the product exceeds 2^{31} - 1. If it does, there is no need to put the product into the queue. In addition, the Euler sieve can be used for optimization.

The time complexity is O(n × m × log (n × m)), and the space complexity is O(n × m). Where m and n are the length of the array `primes` and the given integer n respectively.

Python 3

```
class Solution:
    def nthSuperUglyNumber(self, n: int, primes: List[int]) -> int:
        q = [1]
        x = 0
        mx = (1 << 31) - 1
        for _ in range(n):
            x = heappop(q)
            for k in primes:
                if x <= mx // k:
                    heappush(q, k * x)
                if x % k == 0:
                    break
        return x
```

Solution 2: Dynamic Programming + Multi-pointer Heap

> **How to think about it**
>
> Method 1 fans each ugly number across every prime and the heap grows large. Keep one pointer per prime: the heap top is the next candidate; after writing it, push that prime's next multiple. The heap stays O(m) and the time is O(nlog m).

Store the first n super ugly numbers in ugly[1..n], and keep a min-heap. Each heap entry belongs to one prime p and records the next candidate p × ugly[index].

Initialize ugly[1] = 1 and push (p, p, 2) for every prime. Repeatedly pop the heap minimum into ugly, then advance that prime's pointer and push it back. Each prime keeps a single pointer, so we do not expand every generated ugly number against the whole prime list.

The time complexity is O(n × log m), and the space complexity is O(n + m), where m is the length of primes.

Python 3 (written for this guide: the doocs page has no Python 3 version of this solution)

```
from heapq import heapify, heappop, heappush

class Solution:
    def nthSuperUglyNumber(self, n: int, primes: List[int]) -> int:
        ugly = [0] * (n + 1)
        ugly[1] = 1
        # every prime keeps one entry: (next candidate, prime, index of the ugly number it multiplies next)
        heap = [(p, p, 2) for p in primes]
        heapify(heap)
        count = 2
        while count <= n:
            value, prime, index = heappop(heap)
            if ugly[count - 1] != value:
                ugly[count] = value
                count += 1
            heappush(heap, (ugly[index] * prime, prime, index + 1))
        return ugly[n]
```

1705. Maximum Number of Eaten Apples

Medium · Greedy, Array, Heap (Priority Queue)

leetcode.com/problems/maximum-number-of-eaten-apples

PROBLEM

There is a special kind of apple tree that grows apples every day for `n` days. On the i^{th} day, the tree grows `apples[i]` apples that will rot after `days[i]` days, that is on day `i + days[i]` the apples will be rotten and cannot be eaten. On some days, the apple tree does not grow any apples, which are denoted by `apples[i] == 0` and `days[i] == 0`.

You decided to eat **at most** one apple a day (to keep the doctors away). Note that you can keep eating after the first `n` days.

Given two integer arrays `days` and `apples` of length `n`, return *the maximum number of apples you can eat.*

Example 1:

```
Input: apples = [1,2,3,5,2], days = [3,2,1,4,2]
Output: 7
Explanation: You can eat 7 apples:
- On the first day, you eat an apple that grew on the first day.
- On the second day, you eat an apple that grew on the second day.
- On the third day, you eat an apple that grew on the second day. After this day, the apples that grew
on the third day rot.
- On the fourth to the seventh days, you eat apples that grew on the fourth day.
```

Example 2:

```
Input: apples = [3,0,0,0,0,2], days = [3,0,0,0,0,2]
Output: 5
Explanation: You can eat 5 apples:
- On the first to the third day you eat apples that grew on the first day.
- Do nothing on the fouth and fifth days.
- On the sixth and seventh days you eat apples that grew on the sixth day.
```

Constraints:

- `n == apples.length == days.length`
- `1 <= n <= 2 * 10^4`
- `0 <= apples[i], days[i] <= 2 * 10^4`
- `days[i] = 0` if and only if `apples[i] = 0`.

SOLUTION (PYTHON 3)

Solution 1: Greedy + Priority Queue

> **How to think about it**
>
> At most one apple may be eaten per day, and it must not have rotted. Eating long-lived apples first wastes those about to expire and reduces the total. Among still-edible apples, always eat the soonest to rot. That policy is a min-heap keyed by expiry. On day i, push any new batch as (expiry,count). After dropping expired batches, eat one from the heap top and push the remainder back. Continue until both production and the heap are empty.

We can greedily choose the apples that are closest to rotting among the unrotten apples, so that we can eat as many apples as possible.

Therefore, we can use a priority queue (min-heap) to store the rotting time of the apples and the corresponding number of apples. Each time, we take out the apples with the smallest rotting time from the priority queue, then decrement their quantity by one. If the quantity is not zero after decrementing, we put them back into the priority queue. If the apples have

already rotted, we remove them from the priority queue.

The time complexity is O(n × log n + M), and the space complexity is O(n). Here, n is the length of the array days, and M = max(days).

Python 3

```
class Solution:
    def eatenApples(self, apples: List[int], days: List[int]) -> int:
        n = len(days)
        i = ans = 0
        q = []
        while i < n or q:
            if i < n and apples[i]:
                heappush(q, (i + days[i] - 1, apples[i]))
            while q and q[0][0] < i:
                heappop(q)
            if q:
                t, v = heappop(q)
                v -= 1
                ans += 1
                if v and t > i:
                    heappush(q, (t, v))
            i += 1
        return ans
```

```

632. Smallest Range Covering Elements from K Lists

Hard · Greedy, Array, Hash Table, Sorting, Sliding Window, Heap (Priority Queue)

leetcode.com/problems/smallest-range-covering-elements-from-k-lists

★ **TOP 10 PROBLEM** in K-way Merge: master this one first

PROBLEM

You have `k` lists of sorted integers in **non-decreasing order**. Find the **smallest** range that includes at least one number from each of the `k` lists.

We define the range `[a, b]` is smaller than range `[c, d]` if `b - a < d - c` **or** `a < c` if `b - a == d - c`.

Example 1:

```
Input: nums = [[4,10,15,24,26],[0,9,12,20],[5,18,22,30]]
Output: [20,24]
Explanation:
List 1: [4, 10, 15, 24,26], 24 is in range [20,24].
List 2: [0, 9, 12, 20], 20 is in range [20,24].
List 3: [5, 18, 22, 30], 22 is in range [20,24].
```

Example 2:

```
Input: nums = [[1,2,3],[1,2,3],[1,2,3]]
Output: [1,1]
```

Constraints:

- `nums.length == k`
- `1 <= k <= 3500`
- `1 <= nums[i].length <= 50`
- -10^5 `<= nums[i][j] <=` 10^5
- `nums[i]` is sorted in **non-decreasing** order.

SOLUTIONS (PYTHON 3)

Solution 1: Sorting + Sliding Window

How to think about it

We need one element from each of k sorted lists so the covering range is shortest. Index combinations do not scale. Flatten (value, group) pairs and sort. The task is the shortest window that covers all k groups; expand the right end and shrink the left while a counter still sees k groups.

We construct a data item (x, i) for each number x and its group i, and store these items in a new array t. Then, we sort t by the value of the numbers (similar to merging multiple sorted arrays into a new sorted array).

Next, we traverse each data item in t, focusing on the group to which each number belongs. We use a hash table to record the groups of numbers within the sliding window. If the number of groups is k, it means the current window meets the problem's requirements. At this point, we calculate the start and end positions of the window and update the answer.

The time complexity is O(n × log n), and the space complexity is O(n). Here, n is the total number of numbers in all arrays.

Python 3

```python
class Solution:
    def smallestRange(self, nums: List[List[int]]) -> List[int]:
        t = [(x, i) for i, v in enumerate(nums) for x in v]
        t.sort()
        cnt = Counter()
        ans = [-inf, inf]
        j = 0
        for i, (b, v) in enumerate(t):
            cnt[v] += 1
            while len(cnt) == len(nums):
                a = t[j][0]
                x = b - a - (ans[1] - ans[0])
                if x < 0 or (x == 0 and a < ans[0]):
                    ans = [a, b]
                w = t[j][1]
                cnt[w] -= 1
                if cnt[w] == 0:
                    cnt.pop(w)
                j += 1
        return ans
```

Solution 2: Priority Queue (Heap)

> **How to think about it**
>
> Method 1 materializes every value. Because each list is sorted, a min-heap of the k current pointers plus a running maximum already describes a candidate range; advance the list that produced the minimum. Space is O(k).

Python 3 (written for this guide: the doocs page has no Python 3 version of this solution)

```python
from heapq import heapify, heappop, heappush

class Solution:
    def smallestRange(self, nums: List[List[int]]) -> List[int]:
        k = len(nums)
        heap = [(row[0], j, 0) for j, row in enumerate(nums)]
        heapify(heap)
        biggest = max(row[0] for row in nums)
        left, right = 0, float("inf")
        while len(heap) == k:                    # the heap holds one number of every list
            smallest, j, i = heappop(heap)
            if biggest - smallest < right - left:
                left, right = smallest, biggest
            if i + 1 < len(nums[j]):
                nxt = nums[j][i + 1]
                heappush(heap, (nxt, j, i + 1))
                biggest = max(biggest, nxt)
        return [left, right]
```

            have[pairs[left][1]] -= 1
            if have[pairs[left][1]] == 0:
                del have[pairs[left][1]]
            left += 1
    return best
```

668. Kth Smallest Number in Multiplication Table

Hard · Math, Binary Search

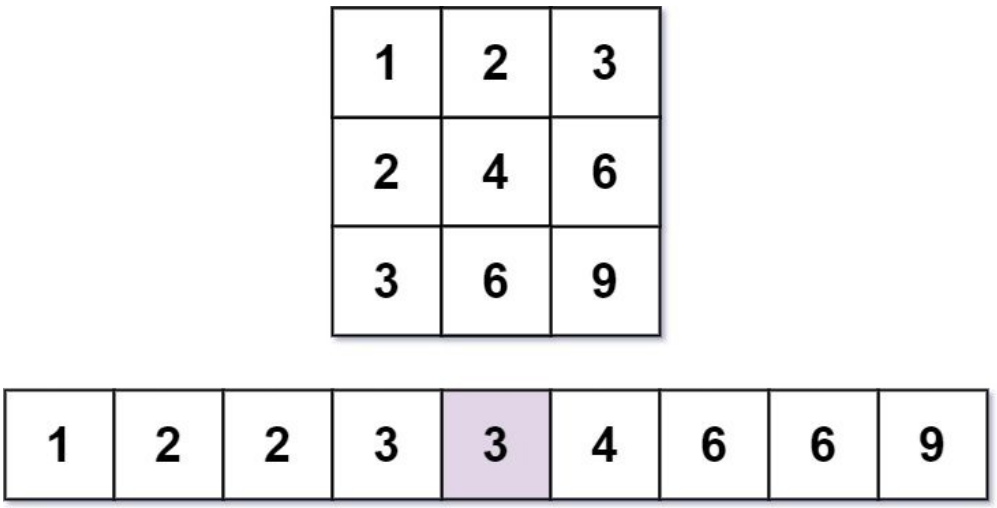
leetcode.com/problems/kth-smallest-number-in-multiplication-table

PROBLEM

Nearly everyone has used the Multiplication Table. The multiplication table of size `m x n` is an integer matrix `mat` where `mat[i][j] == i * j` (**1-indexed**).

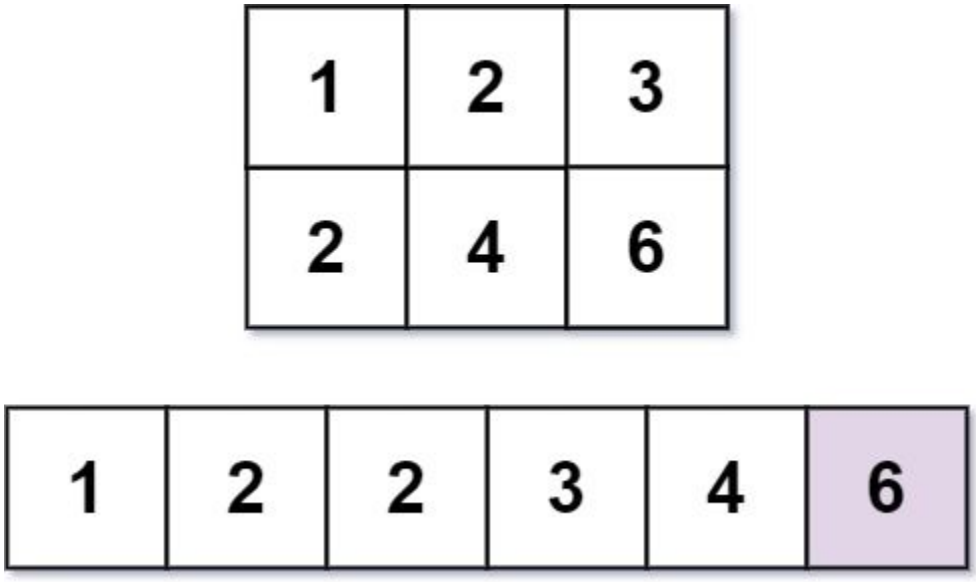
Given three integers `m`, `n`, and `k`, return *the* k^{th} *smallest element in the* `m x n` *multiplication table*.

Example 1:



```
Input: m = 3, n = 3, k = 5
Output: 3
Explanation: The 5th smallest number is 3.
```

Example 2:



```
Input: m = 2, n = 3, k = 6
Output: 6
Explanation: The 6th smallest number is 6.
```

Constraints:

- `1 <= m, n <= 3 * 10^4`
- `1 <= k <= m * n`

SOLUTION (PYTHON 3)

Solution 1

How to think about it

The k-th smallest entry of an m× n multiplication table cannot be materialized when sides reach 3· 10^4. Binary-search the value x. Row i contributes min(floor(x/i), n) entries ≤ x. The answer is the smallest x with count ≥ k.

Python 3

```python
class Solution:
    def findKthNumber(self, m: int, n: int, k: int) -> int:
        left, right = 1, m * n
        while left < right:
            mid = (left + right) >> 1
            cnt = 0
            for i in range(1, m + 1):
                cnt += min(mid // i, n)
            if cnt >= k:
                right = mid
            else:
                left = mid + 1
        return left
```

Complexity. Time: O(m * log(m * n)). Space: O(1).

PATTERN 38 · K-WAY MERGE · PROBLEM 18 OF 20

719. Find K-th Smallest Pair Distance

Hard · Array, Two Pointers, Binary Search, Sorting

leetcode.com/problems/find-k-th-smallest-pair-distance

★ **TOP 10 PROBLEM** in K-way Merge: master this one first

PROBLEM

The **distance of a pair** of integers `a` and `b` is defined as the absolute difference between `a` and `b`.

Given an integer array `nums` and an integer `k`, return *the* k^{th} *smallest* ***distance among all the pairs*** `nums[i]` *and* `nums[j]` *where* `0 <= i < j < nums.length`.

Example 1:

```
Input: nums = [1,3,1], k = 1
Output: 0
Explanation: Here are all the pairs:
(1,3) -> 2
(1,1) -> 0
(3,1) -> 2
Then the 1st smallest distance pair is (1,1), and its distance is 0.
```

Example 2:

```
Input: nums = [1,1,1], k = 2
Output: 0
```

Example 3:

```
Input: nums = [1,6,1], k = 3
Output: 5
```

Constraints:

- `n == nums.length`
- `2 <= n <=` 10^4
- `0 <= nums[i] <=` 10^6
- `1 <= k <= n * (n - 1) / 2`

SOLUTION (PYTHON 3)

Solution 1

How to think about it

We want the k-th smallest pairwise distance. n≤ 10^4 forbids listing all O(n^2) pairs. Distances lie in [0,max-min] and the count of pairs ≤ d is monotone in d. Binary-search d and count pairs with distance ≤ d. After sorting, each right value b has a leftmost partner b-d; a lower-bound search counts them in O(nlog n). The smallest d whose count is at least k is the answer, searched in [0, nums[-1]-nums[0]].

Python 3

```
class Solution:
    def smallestDistancePair(self, nums: List[int], k: int) -> int:
        def count(dist):
            cnt = 0
            for i, b in enumerate(nums):
                a = b - dist
                j = bisect_left(nums, a, 0, i)
                cnt += i - j

PATTERN 38 · K-WAY MERGE · PROBLEM 19 OF 20

786. K-th Smallest Prime Fraction

Medium · Array, Two Pointers, Binary Search, Sorting, Heap (Priority Queue)

leetcode.com/problems/k-th-smallest-prime-fraction

PROBLEM

You are given a sorted integer array `arr` containing `1` and **prime** numbers, where all the integers of `arr` are unique. You are also given an integer `k`.

For every `i` and `j` where `0 <= i < j < arr.length`, we consider the fraction `arr[i] / arr[j]`.

Return *the* k^{th} *smallest fraction considered*. Return your answer as an array of integers of size `2`, where `answer[0] == arr[i]` and `answer[1] == arr[j]`.

Example 1:

```
Input: arr = [1,2,3,5], k = 3
Output: [2,5]
Explanation: The fractions to be considered in sorted order are:
1/5, 1/3, 2/5, 1/2, 3/5, and 2/3.
The third fraction is 2/5.
```

Example 2:

```
Input: arr = [1,7], k = 1
Output: [1,7]
```

Constraints:

- `2 <= arr.length <= 1000`
- `1 <= arr[i] <= 3 * 10^4`
- `arr[0] == 1`
- `arr[i]` is a **prime** number for `i > 0`.
- All the numbers of `arr` are **unique** and sorted in **strictly increasing** order.
- `1 <= k <= arr.length * (arr.length - 1) / 2`

Follow up:

Can you solve the problem with better than

$O(n^2)$

complexity?

SOLUTION (PYTHON 3)

Solution 1

How to think about it

The k-th smallest proper fraction arr[i]/arr[j] over a sorted prime list. n≤ 1000; listing all pairs is $O(n^2 \log n)$. For fixed j the fractions increase with i. A min-heap merges these n-1 chains. Start with 1/arr[j] for each j, pop k-1 times while pushing the next numerator. The heap top is the answer.

Python 3

```
class Solution:
    def kthSmallestPrimeFraction(self, arr: List[int], k: int) -> List[int]:
        h = [(1 / y, 0, j + 1) for j, y in enumerate(arr[1:])]
        heapify(h)
        for _ in range(k - 1):
            _, i, j = heappop(h)
            if i + 1 < j:
                heappush(h, (arr[i + 1] / arr[j], i + 1, j))
        return [arr[h[0][1]], arr[h[0][2]]]
```

PATTERN 38 · K-WAY MERGE · PROBLEM 20 OF 20

1439. Find the Kth Smallest Sum of a Matrix With Sorted Rows

Hard · Array, Binary Search, Matrix, Heap (Priority Queue)

leetcode.com/problems/find-the-kth-smallest-sum-of-a-matrix-with-sorted-rows

PROBLEM

You are given an `m x n` matrix `mat` that has its rows sorted in non-decreasing order and an integer `k`.

You are allowed to choose **exactly one element** from each row to form an array.

Return *the* k^{th} *smallest array sum among all possible arrays*.

Example 1:

```
Input: mat = [[1,3,11],[2,4,6]], k = 5
Output: 7
Explanation: Choosing one element from each row, the first k smallest sum are:
[1,2], [1,4], [3,2], [3,4], [1,6]. Where the 5th sum is 7.
```

Example 2:

```
Input: mat = [[1,3,11],[2,4,6]], k = 9
Output: 17
```

Example 3:

```
Input: mat = [[1,10,10],[1,4,5],[2,3,6]], k = 7
Output: 9
Explanation: Choosing one element from each row, the first k smallest sum are:
[1,1,2], [1,1,3], [1,4,2], [1,4,3], [1,1,6], [1,5,2], [1,5,3]. Where the 7th sum is 9.
```

Constraints:

- `m == mat.length`
- `n == mat.length[i]`
- `1 <= m, n <= 40`
- `1 <= mat[i][j] <= 5000`
- `1 <= k <= min(200, n^m)`
- `mat[i]` is a non-decreasing array.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

One value per row yields n^m sums, but k≤ 200. We only need the k smallest partial sums. Rows are sorted, so combining with the next row uses at most its first k entries. Let pre be the k smallest sums so far. Cartesian-add the current row, sort, and keep k values. After the last row, pre[k-1] is the answer.

Python 3

```python
class Solution:
    def kthSmallest(self, mat: List[List[int]], k: int) -> int:
        pre = [0]
        for cur in mat:
            pre = sorted(a + b for a in pre for b in cur[:k])[:k]
        return pre[-1]
```

Complexity. Time: O(m * k^2 * log k). Space: O(k^2).

PATTERN 39 · GAME THEORY / MINIMAX · PROBLEM 1 OF 20

292. Nim Game

Easy · Brainteaser, Minimax, Math, Game Theory, Nim Game, Impartial Game

leetcode.com/problems/nim-game

★ **TOP 10 PROBLEM** in Game Theory / Minimax: master this one first

PROBLEM

You are playing the following Nim Game with your friend:

- Initially, there is a heap of stones on the table.
- You and your friend will alternate taking turns, and **you go first**.
- On each turn, the person whose turn it is will remove 1 to 3 stones from the heap.
- The one who removes the last stone is the winner.

Given `n`, the number of stones in the heap, return `true` *if you can win the game assuming both you and your friend play optimally, otherwise return* `false`.

Example 1:

```
Input: n = 4
Output: false
Explanation: These are the possible outcomes:
1. You remove 1 stone. Your friend removes 3 stones, including the last stone. Your friend wins.
2. You remove 2 stones. Your friend removes 2 stones, including the last stone. Your friend wins.
3. You remove 3 stones. Your friend removes the last stone. Your friend wins.
In all outcomes, your friend wins.
```

Example 2:

```
Input: n = 1
Output: true
```

Example 3:

```
Input: n = 2
Output: true
```

Constraints:

- $1 <= n <= 2^{31} - 1$

SOLUTION (PYTHON 3)

Solution 1: Finding the Pattern

How to think about it

Each turn takes 1 to 3 stones. A multiple of 4 cannot be cleared in one move, and the opponent can always restore a multiple of 4. The first player wins iff n is not divisible by 4.

The first player who gets a multiple of 4 (i.e., n can be divided by 4) will lose the game.

Proof:

1. When n < 4, the first player can directly take all the stones, so the first player will win the game.
1. When n = 4, no matter whether the first player chooses 1, 2, 3, the second player can always choose the remaining number, so the first player will lose the game.
1. When 4 < n < 8, i.e., n = 5, 6, 7, the first player can correspondingly reduce the number to 4, then the "death number" 4 is given to the second player, and the second player will lose the game.

1. When n = 8, no matter whether the first player chooses 1, 2, 3, it will leave a number between 4 < n < 8 to the second player, so the first player will lose the game.
1. ...
1. By induction, when a player gets the number n, and n can be divided by 4, he will lose the game, otherwise, he will win the game.

The time complexity is O(1), and the space complexity is O(1).

Python 3

```
class Solution:
    def canWinNim(self, n: int) -> bool:
        return n % 4 != 0
```

PATTERN 39 · GAME THEORY / MINIMAX · PROBLEM 2 OF 20

1025. Divisor Game

Easy · Brainteaser, Math, Dynamic Programming, Game Theory, Impartial Game

leetcode.com/problems/divisor-game

★ **TOP 10 PROBLEM** in Game Theory / Minimax: master this one first

PROBLEM

Alice and Bob take turns playing a game, with Alice starting first.

Initially, there is a number `n` on the chalkboard. On each player's turn, that player makes a move consisting of:

- Choosing any integer `x` with `0 < x < n` and `n % x == 0`.
- Replacing the number `n` on the chalkboard with `n - x`.

Also, if a player cannot make a move, they lose the game.

Return `true` *if and only if Alice wins the game, assuming both players play optimally*.

Example 1:

```
Input: n = 2
Output: true
Explanation: Alice chooses 1, and Bob has no more moves.
```

Example 2:

```
Input: n = 3
Output: false
Explanation: Alice chooses 1, Bob chooses 1, and Alice has no more moves.
```

Constraints:

- `1 <= n <= 1000`

SOLUTION (PYTHON 3)

Solution 1: Mathematical Induction

How to think about it

With n≤ 1000 we could DP each remaining value: the starter wins if some x leaves a losing position. Small cases already suggest that odd n loses and even n wins, which induction confirms. A proper divisor of an odd integer is odd, so the opponent receives an even number. From an even integer we can subtract 1 and leave an odd number. The outcome depends only on the parity of n. It is enough to return whether n is even.

- When n=1, the first player loses.
- When n=2, the first player takes 1, leaving 1, the second player loses, the first player wins.
- When n=3, the first player takes 1, leaving 2, the second player wins, the first player loses.
- When n=4, the first player takes 1, leaving 3, the second player loses, the first player wins.
- ...

We conjecture that when n is odd, the first player loses; when n is even, the first player wins.

Proof:

1. If n=1 or n=2, the conclusion holds.
1. If n > 2, assume that the conclusion holds when n ≤ k, then when n=k+1:
   - If k+1 is odd, since x is a divisor of k+1, then x can only be odd, so k+1-x is even, the second player wins, the first player loses.

- If k+1 is even, now x can be either odd 1 or even. If x is odd, then k+1-x is odd, the second player loses, the first player wins.

In conclusion, when n is odd, the first player loses; when n is even, the first player wins. The conclusion is correct.

The time complexity is O(1), and the space complexity is O(1).

Python 3

```
class Solution:
    def divisorGame(self, n: int) -> bool:
        return n % 2 == 0

PATTERN 39 · GAME THEORY / MINIMAX · PROBLEM 3 OF 20

293. Flip Game

Easy · String

leetcode.com/problems/flip-game

★ **TOP 10 PROBLEM** in Game Theory / Minimax: master this one first

PROBLEM

You are playing a Flip Game with your friend.

You are given a string `currentState` that contains only `'+'` and `'-'`. You and your friend take turns to flip **two consecutive** `"++"` into `"--"`. The game ends when a person can no longer make a move, and therefore the other person will be the winner.

Return all possible states of the string `currentState` after **one valid move**. You may return the answer in **any order**. If there is no valid move, return an empty list `[]`.

Example 1:

```
Input: currentState = "++++"
Output: ["--++","+--+","++--"]
```

Example 2:

```
Input: currentState = "+"
Output: []
```

Constraints:

- `1 <= currentState.length <= 500`
- `currentState[i]` is either `'+'` or `'-'`.

SOLUTION (PYTHON 3)

Solution 1: Traversal + Simulation

How to think about it

A move flips one occurrence of ++ to --. Scan adjacent pairs, flip each ++, record the string, and restore.

We traverse the string. If the current character and the next character are both `+`, we change these two characters to `-`, add the result to the result array, and then change these two characters back to `+`.

After the traversal ends, we return the result array.

The time complexity is $O(n^2)$, where n is the length of the string. Ignoring the space complexity of the result array, the space complexity is O(n) or O(1).

Python 3

```python
class Solution:
    def generatePossibleNextMoves(self, currentState: str) -> List[str]:
        s = list(currentState)
        ans = []
        for i, (a, b) in enumerate(pairwise(s)):
            if a == b == "+":
                s[i] = s[i + 1] = "-"
                ans.append("".join(s))
                s[i] = s[i + 1] = "+"
        return ans
```

PATTERN 39 · GAME THEORY / MINIMAX · PROBLEM 4 OF 20

877. Stone Game

Medium · Minimax, Array, Math, Dynamic Programming, Game Theory, Zero-Sum Game

leetcode.com/problems/stone-game

★ **TOP 10 PROBLEM** in Game Theory / Minimax: master this one first

PROBLEM

Alice and Bob play a game with piles of stones. There are an **even** number of piles arranged in a row, and each pile has a **positive** integer number of stones `piles[i]`.

The objective of the game is to end with the most stones. The **total** number of stones across all the piles is **odd**, so there are no ties.

Alice and Bob take turns, with **Alice starting first**. Each turn, a player takes the entire pile of stones either from the **beginning** or from the **end** of the row. This continues until there are no more piles left, at which point the person with the **most stones wins**.

Assuming Alice and Bob play optimally, return `true` *if Alice wins the game, or* `false` *if Bob wins*.

Example 1:

```
Input: piles = [5,3,4,5]
Output: true
Explanation:
Alice starts first, and can only take the first 5 or the last 5.
Say she takes the first 5, so that the row becomes [3, 4, 5].
If Bob takes 3, then the board is [4, 5], and Alice takes 5 to win with 10 points.
If Bob takes the last 5, then the board is [3, 4], and Alice takes 4 to win with 9 points.
This demonstrated that taking the first 5 was a winning move for Alice, so we return true.
```

Example 2:

```
Input: piles = [3,7,2,3]
Output: true
```

Constraints:

- `2 <= piles.length <= 500`
- `piles.length` is **even**.
- `1 <= piles[i] <= 500`
- `sum(piles[i])` is **odd**.

SOLUTIONS (PYTHON 3)

Solution 1: Memoization Search

How to think about it

Players take from either end of a zero-sum pile array; we ask whether Alice scores more. With ≤ 500 piles, the state is the net score on interval [i,j]. dfs(i,j) is the max of piles[i]-dfs(i+1,j) and piles[j]-dfs(i,j-1). A positive net score wins. Alice always wins under the constraints, but the code still computes the interval DP.

We design a function dfs(i, j) that represents the maximum difference in the number of stones between the current player and the other player when considering piles from the i-th to the j-th. The answer is then dfs(0, n - 1) > 0.

The function dfs(i, j) is computed as follows:

- If i > j, there are no stones left, so the current player cannot take any stones and the difference is 0, i.e., dfs(i, j) = 0.

- Otherwise, the current player has two choices: if they take the i-th pile, the difference between the current player and the other player is piles[i] - dfs(i + 1, j); if they take the j-th pile, the difference is piles[j] - dfs(i, j - 1). The current player will choose the option with the larger difference, so dfs(i, j) = max(piles[i] - dfs(i + 1, j), piles[j] - dfs(i, j - 1)).

Finally, we only need to check whether dfs(0, n - 1) > 0.

To avoid redundant computation, we can use memoization: we use an array f to record all values of dfs(i, j), so that when the function is called again, we can directly retrieve the answer from f without recomputing.

The time complexity is $O(n^2)$ and the space complexity is $O(n^2)$, where n is the number of stone piles.

Python 3

```
class Solution:
    def stoneGame(self, piles: List[int]) -> bool:
        @cache
        def dfs(i: int, j: int) -> int:
            if i > j:
                return 0
            return max(piles[i] - dfs(i + 1, j), piles[j] - dfs(i, j - 1))

        return dfs(0, len(piles) - 1) > 0
```

Solution 2: Dynamic Programming

> **How to think about it**
>
> The memoized recurrence tabulates without recursion. f[i][j] is the net score on [i,j], filled from the length-1 diagonal outward. The transition matches Method 1. The answer is whether f[0][n-1] is positive.

We can also use dynamic programming. Define f[i][j] as the maximum difference in the number of stones the current player can obtain over the other player from piles piles[i..j]. The final answer is then f[0][n - 1] > 0.

Initially, f[i][i] = piles[i], because with only one pile, the current player can only take that pile, and the difference is piles[i].

For f[i][j] where i < j, there are two cases:

- If the current player takes pile piles[i], the remaining piles are piles[i + 1..j], and it becomes the other player's turn, so f[i][j] = piles[i] - f[i + 1][j].
- If the current player takes pile piles[j], the remaining piles are piles[i..j - 1], and it becomes the other player's turn, so f[i][j] = piles[j] - f[i][j - 1].

Therefore, the final state transition equation is f[i][j] = max(piles[i] - f[i + 1][j], piles[j] - f[i][j - 1]).

Finally, we only need to check whether f[0][n - 1] > 0.

The time complexity is $O(n^2)$ and the space complexity is $O(n^2)$, where n is the number of stone piles.

1140. Stone Game II

Medium · Minimax, Array, Math, Dynamic Programming, Game Theory, Prefix Sum, Zero-Sum Game

leetcode.com/problems/stone-game-ii

★ **TOP 10 PROBLEM** in Game Theory / Minimax: master this one first

PROBLEM

Alice and Bob continue their games with piles of stones. There are a number of piles **arranged in a row**, and each pile has a positive integer number of stones `piles[i]`. The objective of the game is to end with the most stones.

Alice and Bob take turns, with Alice starting first.

On each player's turn, that player can take **all the stones** in the **first** `X` remaining piles, where `1 <= X <= 2M`. Then, we set `M = max(M, X)`. Initially, M = 1.

The game continues until all the stones have been taken.

Assuming Alice and Bob play optimally, return the maximum number of stones Alice can get.

Example 1:

Input: piles = [2,7,9,4,4]

Output: 10

Explanation:

- If Alice takes one pile at the beginning, Bob takes two piles, then Alice takes 2 piles again. Alice can get `2 + 4 + 4 = 10` stones in total.
- If Alice takes two piles at the beginning, then Bob can take all three piles left. In this case, Alice get `2 + 7 = 9` stones in total.

So we return 10 since it's larger.

Example 2:

Input: piles = [1,2,3,4,5,100]

Output: 104

Constraints:

- `1 <= piles.length <= 100`
- `1 <= piles[i] <= 10^4`

SOLUTIONS (PYTHON 3)

Solution 1: Prefix Sum + Memoization Search

How to think about it

Players take 1..2M piles from the remaining prefix; the state is the start index and M. Naive search repeats subproblems. A prefix sum is the suffix total from i; the current player gets that total minus the opponent's optimum. If 2M covers the rest, take it all; otherwise try each X with memoization. Alice starts at (0,1).

Since the player can take all the stones from the first X piles each time, that is, they can take the stones from an interval, we can first preprocess a prefix sum array s of length n+1, where s[i] represents the sum of the first i elements of the array `piles`.

Then we design a function dfs(i, m), which represents the maximum number of stones that the current player can take when they can start from index i of the array `piles`, and the current M is m. Initially, Alice starts from index 0, and M=1, so the answer we need to find is dfs(0, 1).

The calculation process of the function dfs(i, m) is as follows:

- If the current player can take all the remaining stones, the maximum number of stones they can take is s[n] - s[i];
- Otherwise, the current player can take all the stones from the first x piles of the remaining ones, where $1 \le x \le 2m$, and the maximum number of stones they can take is s[n] - s[i] - dfs(i + x, max(m, x)). That is to say, the number of stones that the current player can take is the number of all the remaining stones minus the number of stones that the opponent can take in the next round. We need to enumerate all x, and take the maximum value as the return value of the function dfs(i, m).

To avoid repeated calculations, we can use memoization search.

Finally, we return dfs(0, 1) as the answer.

The time complexity is $O(n^3)$, and the space complexity is $O(n^2)$. Here, n is the length of the array `piles`.

Python 3

```
class Solution:
    def stoneGameII(self, piles: List[int]) -> int:
        @cache
        def dfs(i, m):
            if m * 2 >= n - i:
                return s[n] - s[i]
            return max(
                s[n] - s[i] - dfs(i + x, max(m, x)) for x in range(1, m << 1 | 1)
            )

        n = len(piles)
        s = list(accumulate(piles, initial=0))
        return dfs(0, 1)
```

Solution 2

> **How to think about it**
>
> Method 1 returns the suffix sum when everything can be taken. Method 2 always enumerates X and writes the same optimum as suffix minus the opponent's minimum, with an out-of-range base case of 0. The state is unchanged; the code is more uniform.

Python 3

```
class Solution:
    def stoneGameII(self, piles: List[int]) -> int:
        @cache
        def dfs(i: int, m: int = 1) -> int:
            if i >= len(piles):
                return 0
            t = inf
            for x in range(1, m << 1 | 1):
                t = min(t, dfs(i + x, max(m, x)))
            return s[-1] - s[i] - t

        s = list(accumulate(piles, initial=0))
        return dfs(0)
```

Complexity. Time: O(n^3). Space: O(n^2).

PATTERN 39 · GAME THEORY / MINIMAX · PROBLEM 6 OF 20

1686. Stone Game VI

Medium · Greedy, Minimax, Array, Math, Game Theory, Sorting, Heap (Priority Queue), Zero-Sum Game

leetcode.com/problems/stone-game-vi

PROBLEM

Alice and Bob take turns playing a game, with Alice starting first.

There are `n` stones in a pile. On each player's turn, they can **remove** a stone from the pile and receive points based on the stone's value. Alice and Bob may **value the stones differently**.

You are given two integer arrays of length `n`, `aliceValues` and `bobValues`. Each `aliceValues[i]` and `bobValues[i]` represents how Alice and Bob, respectively, value the i^{th} stone.

The winner is the person with the most points after all the stones are chosen. If both players have the same amount of points, the game results in a draw. Both players will play **optimally**. Both players know the other's values.

Determine the result of the game, and:

- If Alice wins, return `1`.
- If Bob wins, return `-1`.
- If the game results in a draw, return `0`.

Example 1:

```
Input: aliceValues = [1,3], bobValues = [2,1]
Output: 1
Explanation:
If Alice takes stone 1 (0-indexed) first, Alice will receive 3 points.
Bob can only choose stone 0, and will only receive 2 points.
Alice wins.
```

Example 2:

```
Input: aliceValues = [1,2], bobValues = [3,1]
Output: 0
Explanation:
If Alice takes stone 0, and Bob takes stone 1, they will both have 1 point.
Draw.
```

Example 3:

```
Input: aliceValues = [2,4,3], bobValues = [1,6,7]
Output: -1
Explanation:
Regardless of how Alice plays, Bob will be able to have more points than Alice.
For example, if Alice takes stone 1, Bob can take stone 2, and Alice takes stone 0, Alice will have 6
points to Bob's 7.
Bob wins.
```

Constraints:

- `n == aliceValues.length == bobValues.length`
- `1 <= n <= 10^5`
- `1 <= aliceValues[i], bobValues[i] <= 100`

SOLUTION (PYTHON 3)

Solution 1: Greedy + Sorting

> **How to think about it**
>
> Players alternate taking a stone, scoring their own value and denying the opponent's. The comparison should count both “I gain a_i” and “they lose b_i”, so take stones in decreasing a_i+b_i. After that sort Alice takes even indices and Bob odd ones; compare the two scores for 1, 0, or -1.

The optimal strategy for picking stones is to maximize one's own score while making the opponent lose as much as possible. Therefore, we create an array vals, where vals[i] = (aliceValues[i] + bobValues[i], i) represents the total value and index of the i-th stone. Then we sort vals in descending order by total value.

Next, we let Alice and Bob pick stones alternately according to the order of vals. Alice picks the stones at even positions in vals, and Bob picks the stones at odd positions in vals. Finally, we compare the scores of Alice and Bob and return the corresponding result.

The time complexity is O(n × log n), and the space complexity is O(n), where n is the length of the arrays `aliceValues` and `bobValues`.

Python 3

```python
class Solution:
    def stoneGameVI(self, aliceValues: List[int], bobValues: List[int]) -> int:
        vals = [(a + b, i) for i, (a, b) in enumerate(zip(aliceValues, bobValues))]
        vals.sort(reverse=True)
        a = sum(aliceValues[i] for _, i in vals[::2])
        b = sum(bobValues[i] for _, i in vals[1::2])
        if a > b:
            return 1
        if a < b:
            return -1
        return 0
```

```

PATTERN 39 · GAME THEORY / MINIMAX · PROBLEM 7 OF 20

1690. Stone Game VII

Medium · Minimax, Array, Math, Dynamic Programming, Game Theory, Zero-Sum Game

leetcode.com/problems/stone-game-vii

PROBLEM

Alice and Bob take turns playing a game, with **Alice starting first**.

There are `n` stones arranged in a row. On each player's turn, they can **remove** either the leftmost stone or the rightmost stone from the row and receive points equal to the **sum** of the remaining stones' values in the row. The winner is the one with the higher score when there are no stones left to remove.

Bob found that he will always lose this game (poor Bob, he always loses), so he decided to **minimize the score's difference**. Alice's goal is to **maximize the difference** in the score.

Given an array of integers `stones` where `stones[i]` represents the value of the i^{th} stone **from the left**, return *the **difference** in Alice and Bob's score if they both play **optimally**.*

Example 1:

```
Input: stones = [5,3,1,4,2]
Output: 6
Explanation:
- Alice removes 2 and gets 5 + 3 + 1 + 4 = 13 points. Alice = 13, Bob = 0, stones = [5,3,1,4].
- Bob removes 5 and gets 3 + 1 + 4 = 8 points. Alice = 13, Bob = 8, stones = [3,1,4].
- Alice removes 3 and gets 1 + 4 = 5 points. Alice = 18, Bob = 8, stones = [1,4].
- Bob removes 1 and gets 4 points. Alice = 18, Bob = 12, stones = [4].
- Alice removes 4 and gets 0 points. Alice = 18, Bob = 12, stones = [].
The score difference is 18 - 12 = 6.
```

Example 2:

```
Input: stones = [7,90,5,1,100,10,10,2]
Output: 122
```

Constraints:

- `n == stones.length`
- `2 <= n <= 1000`
- `1 <= stones[i] <= 1000`

SOLUTIONS (PYTHON 3)

Solution 1: Memorization Search

> **How to think about it**
>
> Each turn removes one end and scores the sum of what remains. The first-player minus second-player gap on an interval is a memoized game: dfs(i,j) is the current player's advantage. Prefix sums s give the score after dropping the left or right end; take the larger of s[j+1]-s[i+1]-dfs(i+1,j) and s[j]-s[i]-dfs(i,j-1).

First, we preprocess to get the prefix sum array s, where s[i] represents the total sum of the first i stones.

Next, we design a function dfs(i, j), which represents the score difference between the first and second players when the remaining stones are stones[i], stones[i + 1], …, stones[j]. The answer is dfs(0, n - 1).

The calculation process of the function dfs(i, j) is as follows:

- If i > j, it means there are no stones currently, so return 0;
- Otherwise, the first player has two choices, which are to remove stones[i] or stones[j], and then calculate the score difference, i.e., a = s[j + 1] - s[i + 1] - dfs(i + 1, j) and b = s[j] - s[i] - dfs(i, j - 1). We take the larger of the two as the return

value of dfs(i, j).

During the process, we use memorization search, i.e., use an array f to record the return value of the function dfs(i, j), to avoid repeated calculations.

The time complexity is $O(n^2)$, and the space complexity is $O(n^2)$. Here, n is the number of stones.

Python 3

```
class Solution:
    def stoneGameVII(self, stones: List[int]) -> int:
        @cache
        def dfs(i: int, j: int) -> int:
            if i > j:
                return 0
            a = s[j + 1] - s[i + 1] - dfs(i + 1, j)
            b = s[j] - s[i] - dfs(i, j - 1)
            return max(a, b)

        s = list(accumulate(stones, initial=0))
        ans = dfs(0, len(stones) - 1)
        dfs.cache_clear()
        return ans
```

Solution 2: Dynamic Programming

> **How to think about it**
>
> Solution 1 already fills this interval with decreasing i and increasing j. The f[i][j] below is that same table.

Solution 1 already fills this transition with decreasing i and increasing j. Define f[i][j] as the score difference between the first and second players when the remaining stones are stones[i], stones[i + 1], …, stones[j]. Therefore, the answer is f[0][n - 1].

The state transition equation is as follows:

$$f[i][j] = \max(s[j + 1] - s[i + 1] - f[i + 1][j], s[j] - s[i] - f[i][j - 1])$$

When calculating f[i][j], we need to ensure that f[i + 1][j] and f[i][j - 1] have been calculated. Therefore, we need to enumerate i in descending order and j in ascending order.

Finally, the answer is f[0][n - 1].

The time complexity is $O(n^2)$, and the space complexity is $O(n^2)$. Here, n is the number of stones.

Python 3

```
class Solution:
    def stoneGameVII(self, stones: List[int]) -> int:
        s = list(accumulate(stones, initial=0))
        n = len(stones)
        f = [[0] * n for _ in range(n)]
        for i in range(n - 2, -1, -1):
            for j in range(i + 1, n):
                a = s[j + 1] - s[i + 1] - f[i + 1][j]
                b = s[j] - s[i] - f[i][j - 1]
                f[i][j] = max(a, b)
        return f[0][-1]
```

Solution 3: Dynamic Programming

> **How to think about it**
>
> Enumerating both players' choices is exponential. There can be 1000 stones, and the branch that removes the left stone first always advances the left endpoint, so the search has depth n. The current player's advantage on [i,j] depends only on shorter intervals. Let f[i][j] store that difference, with a single stone worth 0, and fill decreasing i and increasing j: removing the left end scores s[j+1]-s[i+1]-f[i+1][j], removing the right end scores s[j]-s[i]-f[i][j-1], and the state keeps the larger one.

Precompute the prefix sums s, where s[i] is the sum of the first i stones. Let f[i][j] be the score difference between the current player and the opponent on stones[i], stones[i + 1], …, stones[j]. A single stone has difference 0. For i from n-2 down to 0, and for each i with j from i+1 to n-1, the shorter states f[i+1][j] and f[i][j-1] are already known. Removing the left stone scores s[j+1]-s[i+1]-f[i+1][j], and removing the right stone scores s[j]-s[i]-f[i][j-1]. f[i][j] is the larger of the two. The answer is f[0][n-1].

The time complexity is $O(n^2)$, and the space complexity is $O(n^2)$. Here, n is the number of stones.

Python 3

```
class Solution:
    def stoneGameVII(self, stones: List[int]) -> int:
        s = list(accumulate(stones, initial=0))
        n = len(stones)
        f = [[0] * n for _ in range(n)]
        for i in range(n - 2, -1, -1):
            for j in range(i + 1, n):
                a = s[j + 1] - s[i + 1] - f[i + 1][j]
                b = s[j] - s[i] - f[i][j - 1]
                f[i][j] = max(a, b)
        return f[0][-1]
```

486. Predict the Winner

Medium · Recursion, Minimax, Array, Math, Dynamic Programming, Game Theory, Zero-Sum Game

leetcode.com/problems/predict-the-winner

★ **TOP 10 PROBLEM** in Game Theory / Minimax: master this one first

PROBLEM

You are given an integer array `nums`.

Two players are playing a game with this array: Player 1 and Player 2.

Player 1 and Player 2 take turns, with Player 1 starting first. Both players start the game with a score of 0.

At each turn, the current player takes the number at **either end** of the array (i.e., `nums[0]` or `nums[nums.length - 1]`), **removing** it from the array and adding it to their own score. The game ends when there are no more elements in the array.

Return `true` if Player 1's final score is **greater than or equal** to Player 2's final score, and `false` otherwise.

Note that a tie counts as a win for Player 1. You may assume that both players play optimally.

Example 1:

Input: nums = [1,5,2]

Output: false

Explanation:

- Player 1 must open by taking either 1 or 2, and both choices lead to the same result.
- If Player 1 takes 1, the array becomes `[5,2]`. Player 2 takes 5, leaving 2 for Player 1.
- If Player 1 takes 2, the array becomes `[1,5]`. Player 2 takes 5, leaving 1 for Player 1.
- Either way, Player 1 finishes with `1 + 2 = 3` and Player 2 finishes with `5`. Player 1 can never win, so return `false`.

Example 2:

Input: nums = [1,5,233,7]

Output: true

Explanation:

- Player 1 first takes 1, leaving `[5,233,7]`. Player 2 must then choose between 5 and 7, and no matter which number Player 2 chooses, Player 1 can take 233 on the next turn.
- Player 1 finishes with a higher score (234) than Player 2 (12), so return `true`.

Constraints:

- `1 <= nums.length <= 20`
- `0 <= nums[i] <= 10^7`

SOLUTIONS (PYTHON 3)

Solution 1: Memoization Search

How to think about it

Players take from the two ends; the first player wins if her score is at least the second's. The game tree repeats the same interval. dfs(i,j) is the best score gap on [i,j]: take the left end for nums[i]-dfs(i+1,j), or the right end symmetrically. The first player wins iff dfs(0,n-1)≥ 0. There are $O(n^2)$ intervals; memoization makes every leftover interval optimal for the player to move.

We design a function dfs(i, j), which represents the maximum difference in scores between the current player and the other player from the i-th number to the j-th number. The answer is dfs(0, n - 1) ≥ 0.

The function dfs(i, j) is calculated as follows:

- If i > j, it means there are no numbers left, so the current player cannot take any points, and the difference is 0, i.e., dfs(i, j) = 0.
- Otherwise, the current player has two choices. If they choose the i-th number, the difference in scores between the current player and the other player is nums[i] - dfs(i + 1, j). If they choose the j-th number, the difference in scores between the current player and the other player is nums[j] - dfs(i, j - 1). The current player will choose the option with the larger difference, so dfs(i, j) = max(nums[i] - dfs(i + 1, j), nums[j] - dfs(i, j - 1)).

Finally, we only need to check if dfs(0, n - 1) ≥ 0.

To avoid repeated calculations, we can use memoization. We use an array f to record all the values of dfs(i, j). When the function is called again, we can directly retrieve the answer from f without recalculating it.

The time complexity is $O(n^2)$, and the space complexity is $O(n^2)$. Here, n is the length of the array nums.

Python 3

```python
class Solution:
    def predictTheWinner(self, nums: List[int]) -> bool:
        @cache
        def dfs(i: int, j: int) -> int:
            if i > j:
                return 0
            return max(nums[i] - dfs(i + 1, j), nums[j] - dfs(i, j - 1))

        return dfs(0, len(nums) - 1) >= 0
```

Solution 2: Dynamic Programming

> **How to think about it**
>
> The same recurrence fills a table: f[i][j] starts from the length-1 diagonal, then grows by decreasing i and increasing j. No call stack, same asymptotics.

We can also use dynamic programming. Define f[i][j] to represent the maximum score difference the current player can achieve in the range nums[i..j]. The final answer is f[0][n - 1] ≥ 0.

Initially, f[i][i] = nums[i], because with only one number, the current player can only take that number, and the score difference is nums[i].

Consider f[i][j] where i < j, there are two cases:

- If the current player takes nums[i], the remaining numbers are nums[i + 1..j], and it is the other player's turn. So, f[i][j] = nums[i] - f[i + 1][j].
- If the current player takes nums[j], the remaining numbers are nums[i..j - 1], and it is the other player's turn. So, f[i][j] = nums[j] - f[i][j - 1].

Therefore, the state transition equation is f[i][j] = max(nums[i] - f[i + 1][j], nums[j] - f[i][j - 1]).

Finally, we only need to check if f[0][n - 1] ≥ 0.

The time complexity is $O(n^2)$, and the space complexity is $O(n^2)$. Here, n is the length of the array nums.

PATTERN 39 · GAME THEORY / MINIMAX · PROBLEM 9 OF 20

464. Can I Win

Medium · Bit Manipulation, Memoization, Math, Dynamic Programming, Bitmask, Game Theory

leetcode.com/problems/can-i-win

★ **TOP 10 PROBLEM** in Game Theory / Minimax: master this one first

PROBLEM

In the "100 game" two players take turns adding, to a running total, any integer from `1` to `10`. The player who first causes the running total to **reach or exceed** 100 wins.

What if we change the game so that players **cannot** re-use integers?

For example, two players might take turns drawing from a common pool of numbers from 1 to 15 without replacement until they reach a total >= 100.

Given two integers `maxChoosableInteger` and `desiredTotal`, return `true` if the first player to move can force a win, otherwise, return `false`. Assume both players play **optimally**.

Example 1:

```
Input: maxChoosableInteger = 10, desiredTotal = 11
Output: false
Explanation:
No matter which integer the first player choose, the first player will lose.
The first player can choose an integer from 1 up to 10.
If the first player choose 1, the second player can only choose integers from 2 up to 10.
The second player will win by choosing 10 and get a total = 11, which is >= desiredTotal.
Same with other integers chosen by the first player, the second player will always win.
```

Example 2:

```
Input: maxChoosableInteger = 10, desiredTotal = 0
Output: true
```

Example 3:

```
Input: maxChoosableInteger = 10, desiredTotal = 1
Output: true
```

Constraints:

- `1 <= maxChoosableInteger <= 20`
- `0 <= desiredTotal <= 300`

SOLUTION (PYTHON 3)

Solution 1: State Compression + Memoization

How to think about it

Players draw without replacement from 1..n and the first to reach the target wins. n≤ 20, so the state is the used set; a raw game tree repeats positions. If the total is too small, nobody can win. Otherwise dfs(mask,s) tries each unused i: a win if s+i already meets the target or the opponent loses afterwards. Memoize on mask. A bit mask packs the set; at most 2^n subproblems. The total check skips a hopeless search.

First, we check if the sum of all selectable integers is less than the target value. If so, it means that we cannot win no matter what, so we directly return `false`.

Then, we design a function `dfs(mask, s)`, where `mask` represents the current state of the selected integers, and `s` represents the current cumulative sum. The return value of the function is whether the current player can win.

The execution process of the function `dfs(mask, s)` is as follows:

We iterate through each integer `i` from `1` to `maxChoosableInteger`. If `i` has not been selected, we can choose `i`. If the cumulative sum `s + i` after choosing `i` is greater than or equal to the target value `desiredTotal`, or if the result of the opponent choosing `i` is losing, then the current player is winning, return `true`.

If no choice can make the current player win, then the current player is losing, return `false`.

To avoid repeated calculations, we use a hash table `f` to record the calculated states, where the key is `mask`, and the value is whether the current player can win.

The time complexity is $O(2^n)$, and the space complexity is $O(2^n)$. Where n is `maxChoosableInteger`.

Python 3

```python
class Solution:
    def canIWin(self, maxChoosableInteger: int, desiredTotal: int) -> bool:
        @cache
        def dfs(mask: int, s: int) -> bool:
            for i in range(1, maxChoosableInteger + 1):
                if mask >> i & 1 ^ 1:
                    if s + i >= desiredTotal or not dfs(mask | 1 << i, s + i):
                        return True
            return False

        if (1 + maxChoosableInteger) * maxChoosableInteger // 2 < desiredTotal:
            return False
        return dfs(0, 0)
```

PATTERN 39 · GAME THEORY / MINIMAX · PROBLEM 10 OF 20

375. Guess Number Higher or Lower II

Medium · Minimax, Math, Dynamic Programming, Game Theory

leetcode.com/problems/guess-number-higher-or-lower-ii

★ **TOP 10 PROBLEM** in Game Theory / Minimax: master this one first

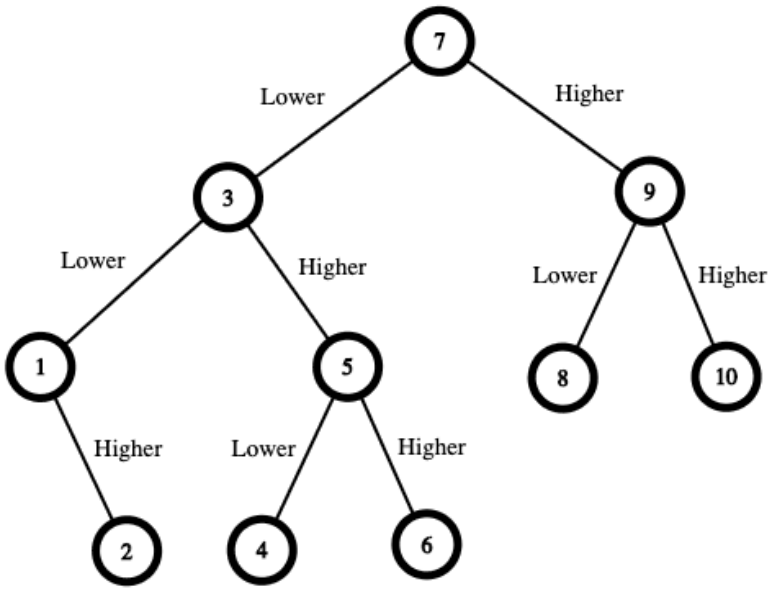
PROBLEM

We are playing the Guessing Game. The game will work as follows:

1. I pick a number between `1` and `n`.
2. You guess a number.
3. If you guess the right number, **you win the game**.
4. If you guess the wrong number, then I will tell you whether the number I picked is **higher or lower**, and you will continue guessing.
5. Every time you guess a wrong number `x`, you will pay `x` dollars. If you run out of money, **you lose the game**.

Given a particular `n`, return *the minimum amount of money you need to **guarantee a win regardless of what number I pick***.

Example 1:



```
Input: n = 10
Output: 16
Explanation: The winning strategy is as follows:
- The range is [1,10]. Guess 7.
    - If this is my number, your total is $0. Otherwise, you pay $7.
    - If my number is higher, the range is [8,10]. Guess 9.
        - If this is my number, your total is $7. Otherwise, you pay $9.
        - If my number is higher, it must be 10. Guess 10. Your total is $7 + $9 = $16.
        - If my number is lower, it must be 8. Guess 8. Your total is $7 + $9 = $16.
    - If my number is lower, the range is [1,6]. Guess 3.
        - If this is my number, your total is $7. Otherwise, you pay $3.
        - If my number is higher, the range is [4,6]. Guess 5.
            - If this is my number, your total is $7 + $3 = $10. Otherwise, you pay $5.
            - If my number is higher, it must be 6. Guess 6. Your total is $7 + $3 + $5 = $15.
            - If my number is lower, it must be 4. Guess 4. Your total is $7 + $3 + $5 = $15.
        - If my number is lower, the range is [1,2]. Guess 1.
            - If this is my number, your total is $7 + $3 = $10. Otherwise, you pay $1.
            - If my number is higher, it must be 2. Guess 2. Your total is $7 + $3 + $1 = $11.
The worst case in all these scenarios is that you pay $16. Hence, you only need $16 to guarantee a win.
```

Example 2:

```
Input: n = 1
Output: 0
Explanation: There is only one possible number, so you can guess 1 and not have to pay anything.
```

Example 3:

```
Input: n = 2
Output: 1
Explanation: There are two possible numbers, 1 and 2.
- Guess 1.
    - If this is my number, your total is $0. Otherwise, you pay $1.
    - If my number is higher, it must be 2. Guess 2. Your total is $1.
The worst case is that you pay $1.
```

Constraints:

- `1 <= n <= 200`

SOLUTION (PYTHON 3)

Solution 1: Dynamic Programming

> **How to think about it**
>
> A wrong guess costs that number; we want the min-max cost to guarantee a win. Searching guess orders is a game tree. The optimum on [i,j] depends only on shorter intervals. f[i][j] is that min-max cost. Guessing k costs k+max(left,right); minimize over k. Fill by interval length; the answer is f[1][n].

We define f[i][j] as the minimum cost required to guess any number in the interval [i, j]. Initially, f[i][i] = 0 because there is no cost to guess the only number, and for i > j, we also have f[i][j] = 0. The answer is f[1][n].

For f[i][j], we can enumerate any number k in [i, j], divide the interval [i, j] into two parts, [i, k - 1] and [k + 1, j], choose the larger value of the two parts plus the cost of k,

Python 3

```python
class Solution:
    def getMoneyAmount(self, n: int) -> int:
        f = [[0] * (n + 1) for _ in range(n + 1)]
        for i in range(n - 1, 0, -1):
            for j in range(i + 1, n + 1):
                f[i][j] = j + f[i][j - 1]
                for k in range(i, j):
                    f[i][j] = min(f[i][j], max(f[i][k - 1], f[k + 1][j]) + k)
        return f[1][n]
```

Complexity. Time: O(n^3). Space: O(n^2).

    return go(low, high)
```

1561. Maximum Number of Coins You Can Get

Medium · Greedy, Array, Math, Game Theory, Sorting

leetcode.com/problems/maximum-number-of-coins-you-can-get

PROBLEM

There are `3n` piles of coins of varying size, you and your friends will take piles of coins as follows:

- In each step, you will choose **any** `3` piles of coins (not necessarily consecutive).
- Of your choice, Alice will pick the pile with the maximum number of coins.
- You will pick the next pile with the maximum number of coins.
- Your friend Bob will pick the last pile.
- Repeat until there are no more piles of coins.

Given an array of integers `piles` where `piles[i]` is the number of coins in the i^{th} pile.

Return the maximum number of coins that you can have.

Example 1:

```
Input: piles = [2,4,1,2,7,8]
Output: 9
Explanation: Choose the triplet (2, 7, 8), Alice Pick the pile with 8 coins, you the pile with 7 coins and Bob the last one.
Choose the triplet (1, 2, 4), Alice Pick the pile with 4 coins, you the pile with 2 coins and Bob the last one.
The maximum number of coins which you can have are: 7 + 2 = 9.
On the other hand if we choose this arrangement (1, 2, 8), (2, 4, 7) you only get 2 + 4 = 6 coins which is not optimal.
```

Example 2:

```
Input: piles = [2,4,5]
Output: 4
```

Example 3:

```
Input: piles = [9,8,7,6,5,1,2,3,4]
Output: 18
```

Constraints:

- `3 <= piles.length <= 10^5`
- `piles.length % 3 == 0`
- `1 <= piles[i] <= 10^4`

SOLUTION (PYTHON 3)

Solution 1: Greedy + Sorting

> **How to think about it**
>
> Three players each take one pile per round: Alice the current largest, we the next, Bob the smallest. n reaches 10^5, so we should not simulate comparisons. After sorting, Bob always receives the smallest third. The remaining piles alternate between Alice and us; ours are every other value starting at index n/3. Sum them.

To maximize the number of coins we get, we can greedily let Bob take the smallest n piles of coins. Each time, we let Alice take the largest pile of coins, then we take the second largest pile of coins, and so on, until there are no more coins to take.

The time complexity is O(n × log n), and the space complexity is O(log n). Here, n is the number of piles of coins.

Python 3

```python
class Solution:
    def maxCoins(self, piles: List[int]) -> int:
        piles.sort()
        return sum(piles[len(piles) // 3 :][::2])
```

```

2029. Stone Game IX

Medium · Greedy, Minimax, Array, Math, Counting, Game Theory, Nim Game, Zero-Sum Game

leetcode.com/problems/stone-game-ix

PROBLEM

Alice and Bob continue their games with stones. There is a row of n stones, and each stone has an associated value. You are given an integer array `stones`, where `stones[i]` is the **value** of the i^{th} stone.

Alice and Bob take turns, with **Alice** starting first. On each turn, the player may remove any stone from `stones`. The player who removes a stone **loses** if the **sum** of the values of **all removed stones** is divisible by `3`. Bob will win automatically if there are no remaining stones (even if it is Alice's turn).

Assuming both players play **optimally**, return `true` *if Alice wins and* `false` *if Bob wins*.

Example 1:

```
Input: stones = [2,1]
Output: true
Explanation: The game will be played as follows:
- Turn 1: Alice can remove either stone.
- Turn 2: Bob removes the remaining stone.
The sum of the removed stones is 1 + 2 = 3 and is divisible by 3. Therefore, Bob loses and Alice wins the game.
```

Example 2:

```
Input: stones = [2]
Output: false
Explanation: Alice will remove the only stone, and the sum of the values on the removed stones is 2.
Since all the stones are removed and the sum of values is not divisible by 3, Bob wins the game.
```

Example 3:

```
Input: stones = [5,1,2,4,3]
Output: false
Explanation: Bob will always win. One possible way for Bob to win is shown below:
- Turn 1: Alice can remove the second stone with value 1. Sum of removed stones = 1.
- Turn 2: Bob removes the fifth stone with value 3. Sum of removed stones = 1 + 3 = 4.
- Turn 3: Alices removes the fourth stone with value 4. Sum of removed stones = 1 + 3 + 4 = 8.
- Turn 4: Bob removes the third stone with value 2. Sum of removed stones = 1 + 3 + 4 + 2 = 10.
- Turn 5: Alice removes the first stone with value 5. Sum of removed stones = 1 + 3 + 4 + 2 + 5 = 15.
Alice loses the game because the sum of the removed stones (15) is divisible by 3. Bob wins the game.
```

Constraints:

- `1 <= stones.length <= 10^5`
- `1 <= stones[i] <= 10^4`

SOLUTIONS (PYTHON 3)

Solution 1: Greedy + Case Discussion

How to think about it

Only residues modulo 3 matter; n ≤ 10^5 forbids full play. Residue 0 does not change the running sum and can be inserted; Alice cannot open with 0. Opening with 1 yields the optimal stream 1,1,2,1,2,… (symmetric for 2). After folding in the zeros, Alice wins if the length is odd and the two nonzero piles are not tied empty. Test cnt and the swapped (cnt[0],cnt[2],cnt[1]); either opening suffices.

Since the player's goal is to ensure the total value of the removed stones is not divisible by 3, we only need to consider the remainder of each stone's value when divided by 3.

We use an array cnt of length 3 to maintain the count of the current remaining stones' values modulo 3, where cnt[0] represents the count of stones with a remainder of 0, and cnt[1] and cnt[2] respectively represent the counts of stones with remainders of 1 and 2.

In the first round, Alice cannot remove stones with a remainder of 0, as this would make the total value of the removed stones divisible by 3. Therefore, Alice can only remove stones with a remainder of 1 or 2.

First, let's consider the case where Alice removes a stone with a remainder of 1. If Alice removes a stone with a remainder of 1, the remainder of the total value of stones 0 against 3 will not change, so stones with a value remainder of 0 can be removed in any round, which we will not consider for now. Thus, Bob can only remove stones with a remainder of 1, followed by Alice removing stones with a remainder of 2, and so on, in the sequence 1, 1, 2, 1, 2, …. In this scenario, if the final round is odd and there are still remaining stones, then Alice wins; otherwise, Bob wins.

For the case where Alice removes a stone with a remainder of 2 in the first round, we can draw a similar conclusion.

The time complexity is O(n), where n is the length of the array stones. The space complexity is O(1).

Python 3

```python
class Solution:
    def stoneGameIX(self, stones: List[int]) -> bool:
        def check(cnt: List[int]) -> bool:
            if cnt[1] == 0:
                return False
            cnt[1] -= 1
            r = 1 + min(cnt[1], cnt[2]) * 2 + cnt[0]
            if cnt[1] > cnt[2]:
                cnt[1] -= 1
                r += 1
            return r % 2 == 1 and cnt[1] != cnt[2]

        c1 = [0] * 3
        for x in stones:
            c1[x % 3] += 1
        c2 = [c1[0], c1[2], c1[1]]
        return check(c1) or check(c2)
```

Solution 2: Simulation

> **How to think about it**
>
> Solution 1 uses a closed-form parity test. The same counts can instead decrement along the residue sequence and, when the needed residue runs out, ask whether zeros make the turn index odd. It remains an O(n) count plus a constant simulation, easier to check at the boundaries.

As in Solution 1, count the residues of stone values modulo 3. Alice's first move can only take a residue-1 or residue-2 stone.

For each opening, both players follow the optimal residue sequence: starting with 1 gives 1, 1, 2, 1, 2, …; starting with 2 is symmetric. When the required residue runs out, Alice wins if the remaining residue-0 stones make the current turn count odd.

Return true if either opening lets Alice win.

The time complexity is O(n) and the space complexity is O(1), where n is the length of stones.

Python 3 (written for this guide: the doocs page has no Python 3 version of this solution)

```python
class Solution:
    def stoneGameIX(self, stones: List[int]) -> bool:
        if len(stones) == 1:
            return False
        count = [0] * 3
        for x in stones:
            count[x % 3] += 1

        def check(first: int, count: List[int]) -> bool:
            turn = 1
            count[first] -= 1
            if count[first] < 0:
                return False
            x = first
            while count[1] or count[2]:
                if count[x]:
                    count[x] -= 1
                    x = 2 if x == 1 else 1
                else:
                    return (turn + count[0]) % 2 == 1
                turn += 1
            return False

        return check(1, count[:]) or check(2, count[:])
```

```

1770. Maximum Score from Performing Multiplication Operations

Hard · Array, Dynamic Programming

leetcode.com/problems/maximum-score-from-performing-multiplication-operations

PROBLEM

You are given two **0-indexed** integer arrays `nums` and `multipliers` of size `n` and `m` respectively, where `n >= m`.

You begin with a score of `0`. You want to perform **exactly** `m` operations. On the `i`th operation (**0-indexed**) you will:

- Choose one integer `x` from **either the start or the end** of the array `nums`.
- Add `multipliers[i] * x` to your score.
  - Note that `multipliers[0]` corresponds to the first operation, `multipliers[1]` to the second operation, and so on.
- Remove `x` from `nums`.

Return *the **maximum** score after performing* `m` *operations.*

Example 1:

```
Input: nums = [1,2,3], multipliers = [3,2,1]
Output: 14
Explanation: An optimal solution is as follows:
- Choose from the end, [1,2,3], adding 3 * 3 = 9 to the score.
- Choose from the end, [1,2], adding 2 * 2 = 4 to the score.
- Choose from the end, [1], adding 1 * 1 = 1 to the score.
The total score is 9 + 4 + 1 = 14.
```

Example 2:

```
Input: nums = [-5,-3,-3,-2,7,1], multipliers = [-10,-5,3,4,6]
Output: 102
Explanation: An optimal solution is as follows:
- Choose from the start, [-5,-3,-3,-2,7,1], adding -5 * -10 = 50 to the score.
- Choose from the start, [-3,-3,-2,7,1], adding -3 * -5 = 15 to the score.
- Choose from the start, [-3,-2,7,1], adding -3 * 3 = -9 to the score.
- Choose from the end, [-2,7,1], adding 1 * 4 = 4 to the score.
- Choose from the end, [-2,7], adding 7 * 6 = 42 to the score.
The total score is 50 + 15 - 9 + 4 + 42 = 102.
```

Constraints:

- `n == nums.length`
- `m == multipliers.length`
- `1 <= m <= 300`
- `m <= n <= 10`^{5}
- `-1000 <= nums[i], multipliers[i] <= 1000`

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

Each step multiplies one end of nums by multipliers[k]. After m moves only the two ends change, so a state is how many were taken from the left and from the right. Memoize f(i,j,k) with left index i, right index j, and multiplier k. Recur on taking left or right; stop at k=m. There are $O(m^2)$ states.

Python 3

```python
class Solution:
    def maximumScore(self, nums: List[int], multipliers: List[int]) -> int:
        @cache
        def f(i, j, k):
            if k >= m or i >= n or j < 0:
                return 0
            a = f(i + 1, j, k + 1) + nums[i] * multipliers[k]
            b = f(i, j - 1, k + 1) + nums[j] * multipliers[k]
            return max(a, b)

        n = len(nums)
        m = len(multipliers)
        return f(0, n - 1, 0)
```

Solution 2

How to think about it

Tabulate the same idea: f[i][j] is the best after taking i from the front and j from the back. Fill by increasing i+j and record answers at i+j=m. Same $O(m^2)$ without recursion.

Python 3

```python
class Solution:
    def maximumScore(self, nums: List[int], multipliers: List[int]) -> int:
        n, m = len(nums), len(multipliers)
        f = [[-inf] * (m + 1) for _ in range(m + 1)]
        f[0][0] = 0
        ans = -inf
        for i in range(m + 1):
            for j in range(m - i + 1):
                k = i + j - 1
                if i > 0:
                    f[i][j] = max(f[i][j], f[i - 1][j] + multipliers[k] * nums[i - 1])
                if j > 0:
                    f[i][j] = max(f[i][j], f[i][j - 1] + multipliers[k] * nums[n - j])
                if i + j == m:
                    ans = max(ans, f[i][j])
        return ans
```

PATTERN 39 · GAME THEORY / MINIMAX · PROBLEM 16 OF 20

1406. Stone Game III

Hard · Minimax, Array, Math, Dynamic Programming, Game Theory, Zero-Sum Game

leetcode.com/problems/stone-game-iii

★ **TOP 10 PROBLEM** in Game Theory / Minimax: master this one first

PROBLEM

Alice and Bob continue their games with piles of stones. There are several stones **arranged in a row**, and each stone has an associated value which is an integer given in the array `stoneValue`.

Alice and Bob take turns, with Alice starting first. On each player's turn, that player can take `1`, `2`, or `3` stones from the **first** remaining stones in the row.

The score of each player is the sum of the values of the stones taken. The score of each player is `0` initially.

The objective of the game is to end with the highest score, and the winner is the player with the highest score and there could be a tie. The game continues until all the stones have been taken.

Assume Alice and Bob **play optimally**.

Return `"Alice"` *if Alice will win,* `"Bob"` *if Bob will win, or* `"Tie"` *if they will end the game with the same score*.

Example 1:

```
Input: stoneValue = [1,2,3,7]
Output: "Bob"
Explanation: Alice will always lose. Her best move will be to take three piles and the score become 6.
Now the score of Bob is 7 and Bob wins.
```

Example 2:

```
Input: stoneValue = [1,2,3,-9]
Output: "Alice"
Explanation: Alice must choose all the three piles at the first move to win and leave Bob with negative
score.
If Alice chooses one pile her score will be 1 and the next move Bob's score becomes 5. In the next
move, Alice will take the pile with value = -9 and lose.
If Alice chooses two piles her score will be 3 and the next move Bob's score becomes 3. In the next
move, Alice will take the pile with value = -9 and also lose.
Remember that both play optimally so here Alice will choose the scenario that makes her win.
```

Example 3:

```
Input: stoneValue = [1,2,3,6]
Output: "Tie"
Explanation: Alice cannot win this game. She can end the game in a draw if she decided to choose all
the first three piles, otherwise she will lose.
```

Constraints:

- `1 <= stoneValue.length <= 5 * 10^4`
- `-1000 <= stoneValue[i] <= 1000`

SOLUTIONS (PYTHON 3)

Solution 1: Memoization Search

> **How to think about it**
>
> Each player takes 1– 3 piles. Plain recursion on n≤ 5× 10^4 recomputes the same suffixes many times. The current player maximizes “stones taken this turn minus the opponent's best difference on the rest”. Let dfs(i) be that value from index i, trying the three prefixes. Memoizing dfs(i) evaluates each start once. The sign of dfs(0) decides Alice, Bob, or a tie.

We design a function dfs(i), which represents the maximum score difference that the current player can obtain when playing the game in the range [i, n). If dfs(0) > 0, it means that the first player Alice can win; if dfs(0) < 0, it means that the second player Bob can win; otherwise, it means that the two players tie.

The execution logic of the function dfs(i) is as follows:

- If i ≥ n, it means that there are no stones to take now, so we can directly return 0;
- Otherwise, we enumerate the index j of the last pile taken by the current player, where i ≤ j < min(i + 3, n), i.e., the current player takes all the piles in the index range [i, j] and gets a score of $\sum_{k=i}^{j}$ stoneValue[k]. Then the score difference that the other player can get in the next round is dfs(j + 1), so the score difference that the current player can get is $\sum_{k=i}^{j}$ stoneValue[k] - dfs(j + 1). We want to maximize the score difference of the current player, so we can use the max function to get the maximum score difference, that is:

$$dfs(i) = \max_{i \le j < \min(i+3,\, n)} \{\sum_{k=i}^{j} stoneValue[k] - dfs(j + 1)\}$$

To prevent repeated calculations, we can use memoization search.

The time complexity is O(n), and the space complexity is O(n). Where n is the number of piles of stones.

Python 3

```python
class Solution:
    def stoneGameIII(self, stoneValue: List[int]) -> str:
        @cache
        def dfs(i: int) -> int:
            if i >= len(stoneValue):
                return 0
            ans = -inf
            s = 0
            for j in range(i, i + 3):
                if j >= len(stoneValue):
                    break
                s += stoneValue[j]
                ans = max(ans, s - dfs(j + 1))
            return ans

        res = dfs(0)
        if res == 0:
            return 'Tie'
        return 'Alice' if res > 0 else 'Bob'
```

Solution 2: Dynamic Programming

> **How to think about it**
>
> Each player takes 1–3 piles. Trying every line of play is exponential, and n≤ 5× 10^4. The current player maximizes the stones taken this turn minus the opponent's best difference on the rest. That difference from index i depends only on the three later starts i+1, i+2, and i+3. Searching the recurrence still calls the next index before it returns, so the chain has depth n and overflows the stack. Those later values are known if we walk from the end. Let f[i] be the best difference from i, fill i from n-1 down to 0, and read the sign of f[0].

We define f[i] as the maximum score difference that the current player can obtain when playing the game in the range [i, n). If f[0] > 0, Alice wins; if f[0] < 0, Bob wins; otherwise the two players tie.

f[i] is calculated as follows:

- If i ≥ n, there are no stones left, so the value is 0;
- Otherwise, we enumerate the index j of the last pile taken by the current player, where i ≤ j < min(i + 3, n). The current player takes every pile in [i, j] and scores $\sum_{k=i}^{j}$ stoneValue[k]. The opponent's best difference on the rest is f[j + 1], so the current difference is that sum minus f[j + 1]. The current player takes the maximum:

$$f[i] = \max_{i \le j < \min(i+3,\, n)} \{\sum_{k=i}^{j} \text{stoneValue}[k] - f[j + 1]\}$$

We calculate f from i = n - 1 down to 0.

The time complexity is O(n), and the space complexity is O(n). Where n is the number of piles of stones.

Python 3

```python
class Solution:
    def stoneGameIII(self, stoneValue: List[int]) -> str:
        n = len(stoneValue)
        f = [0] * (n + 1)
        for i in range(n - 1, -1, -1):
            ans = -inf
            s = 0
            for j in range(i, min(i + 3, n)):
                s += stoneValue[j]
                ans = max(ans, s - f[j + 1])
            f[i] = ans
        res = f[0]
        if res == 0:
            return 'Tie'
        return 'Alice' if res > 0 else 'Bob'
```

1510. Stone Game IV

Hard · Minimax, Math, Dynamic Programming, Game Theory, Nim Game, Sprague–Grundy, Zero-Sum Game

leetcode.com/problems/stone-game-iv

PROBLEM

Alice and Bob take turns playing a game, with Alice starting first.

Initially, there are `n` stones in a pile. On each player's turn, that player makes a *move* consisting of removing **any** non-zero **square number** of stones in the pile.

Also, if a player cannot make a move, he/she loses the game.

Given a positive integer `n`, return `true` if and only if Alice wins the game otherwise return `false`, assuming both players play optimally.

Example 1:

```
Input: n = 1
Output: true
Explanation: Alice can remove 1 stone winning the game because Bob doesn't have any moves.
```

Example 2:

```
Input: n = 2
Output: false
Explanation: Alice can only remove 1 stone, after that Bob removes the last one winning the game (2 -> 1 -> 0).
```

Example 3:

```
Input: n = 4
Output: true
Explanation: n is already a perfect square, Alice can win with one move, removing 4 stones (4 -> 0).
```

Constraints:

- $1 <= n <= 10^5$

SOLUTIONS (PYTHON 3)

Solution 1: Memoization

How to think about it

Players alternately remove a square number of stones from a pile of n; the one who takes the last stone wins. $n \le 10^5$, so expanding the full game tree would recompute the same remainder many times. A position depends only on the remaining count: it is winning if some move leaves the opponent in a losing position. Memoized dfs(i) answers whether the player to move wins with i stones, trying every $j^2 \le i$. Each state has $O(\sqrt{i})$ transitions.

We design a function dfs(i), which represents whether the current player can win the game when there are i stones in the pile. If the current player can win, it returns true; otherwise, it returns false. The answer is dfs(n).

The calculation process of the function dfs(i) is as follows:

- If $i \le 0$, it means the current player cannot make any move, so the current player loses the game, return false;
- Otherwise, enumerate the number of stones j that the current player can take away, where j is a square number. If the other player cannot win the game after the current player takes away j stones, then the current player wins the game, return true. If all j enumerated cannot satisfy the above condition, then the current player loses the game, return false.

To avoid repeated calculations, we can use memoization, i.e., use an array f to record the calculation results of the function dfs(i).

The time complexity is O(n × √n), and the space complexity is O(n). Where n is the number of stones in the pile.

Python 3

```python
@cache
def dfs(i: int) -> bool:
    if i <= 0:
        return False
    k = isqrt(i)
    return any(not dfs(i - j * j) for j in range(1, k + 1))

class Solution:
    def winnerSquareGame(self, n: int) -> bool:
        return dfs(n)
```

Solution 2: Dynamic Programming

> **How to think about it**
>
> Solution 1 already fills this win/loss table from fewer stones to more. The f[i] below is that same table.

Solution 1 already fills this table from fewer stones to more. Define an array f, where f[i] represents whether the current player can win the game when there are i stones in the pile. If the current player can win, then f[i] is true, otherwise it is false. The answer is f[n].

We enumerate i in the range [1,..n], and enumerate j in the range [1,..i], where j is a square number. If the other player cannot win the game after the current player takes away j stones, then the current player wins the game, i.e., f[i] = true. If all j enumerated cannot satisfy the above condition, then the current player loses the game, i.e., f[i] = false. Therefore, we can get the state transition equation:

$$f[i] = \begin{cases} \text{true}, & \text{if } \exists\, j \in [1,..i],\ j^2 \le i \text{ and } f[i-j^2] = \text{false} \\ \text{false}, & \text{otherwise} \end{cases}$$

Finally, we return f[n].

The time complexity is O(n × √n), and the space complexity is O(n). Where n is the number of stones in the pile.

Python 3

```python
class Solution:
    def winnerSquareGame(self, n: int) -> bool:
        f = [False] * (n + 1)
        for i in range(1, n + 1):
            j = 1
            while j <= i // j:
                if not f[i - j * j]:
                    f[i] = True
                    break
                j += 1
        return f[n]
```

Solution 3: Dynamic Programming

> **How to think about it**
>
> Expanding the whole game tree is exponential. There can be 10^5 stones, and the first move always removes one stone, so the search has depth n. Whether a position is winning depends only on the remaining count, and only on smaller counts. Let f[i] record a win with i stones, with f[0] losing, and scan i upward. A square j^2 that leaves a losing position makes f[i] winning.

Let f[i] be whether the player to move wins with i stones. f[0] is false, since no move remains. For i from 1 to n, enumerate squares $j^2 \le i$. If $f[i-j^2]$ is false, the opponent loses from there, so f[i] is true and the remaining squares can be skipped. If every square leaves a winning position for the opponent, f[i] stays false. The answer is f[n].

The time complexity is O(n × √n), and the space complexity is O(n). Where n is the number of stones in the pile.

Python 3

```python
class Solution:
    def winnerSquareGame(self, n: int) -> bool:
        f = [False] * (n + 1)
        for i in range(1, n + 1):
            j = 1
            while j <= i // j:
                if not f[i - j * j]:
                    f[i] = True
                    break
                j += 1
        return f[n]
```

913. Cat and Mouse

Hard · Graph, Topological Sort, Memoization, Minimax, Math, Dynamic Programming, Game Theory, Zero-Sum Game

leetcode.com/problems/cat-and-mouse

★ **TOP 10 PROBLEM** in Game Theory / Minimax: master this one first

PROBLEM

A game on an **undirected** graph is played by two players, Mouse and Cat, who alternate turns.

The graph is given as follows: `graph[a]` is a list of all nodes `b` such that `ab` is an edge of the graph.

The mouse starts at node `1` and goes first, the cat starts at node `2` and goes second, and there is a hole at node `0`.

During each player's turn, they **must** travel along one edge of the graph that meets where they are. For example, if the Mouse is at node 1, it **must** travel to any node in `graph[1]`.

Additionally, it is not allowed for the Cat to travel to the Hole (node `0`).

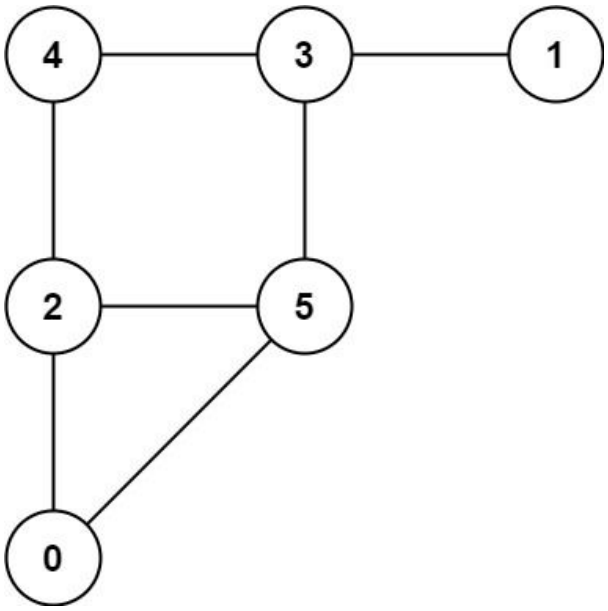
Then, the game can end in three ways:

- If ever the Cat occupies the same node as the Mouse, the Cat wins.
- If ever the Mouse reaches the Hole, the Mouse wins.
- If ever a position is repeated (i.e., the players are in the same position as a previous turn, and it is the same player's turn to move), the game is a draw.

Given a `graph`, and assuming both players play optimally, return

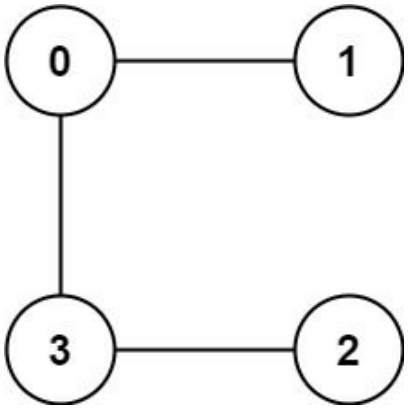
- `1` if the mouse wins the game,
- `2` if the cat wins the game, or
- `0` if the game is a draw.

Example 1:



```
Input: graph = [[2,5],[3],[0,4,5],[1,4,5],[2,3],[0,2,3]]
Output: 0
```

Example 2:



```
Input: graph = [[1,3],[0],[3],[0,2]]
Output: 1
```

Constraints:

- `3 <= graph.length <= 50`
- `1 <= graph[i].length < graph.length`
- `0 <= graph[i][j] < graph.length`
- `graph[i][j] != i`
- `graph[i]` is unique.
- The mouse and the cat can always move.

SOLUTION (PYTHON 3)

Solution 1: Topological Sorting

How to think about it

A state is (mouse, cat, whose turn). n≤ 50, and searching forward struggles to classify draws. Work backward from terminals: the mouse wins in the hole, the cat wins on a coincidence. If the player to move in a previous state can step into their own winning state, mark it a win; otherwise decrease the out-degree and, when it hits zero, mark a loss. After this topological sweep, read the start state (1,2,mouse turn).

According to the problem description, the state of the game is determined by the position of the mouse, the position of the cat, and the player who is moving. The outcome can be directly determined in the following situations:

- When the positions of the cat and the mouse are the same, the cat wins. This is a winning state for the cat and a losing state for the mouse.
- When the mouse is at the hole, the mouse wins. This is a winning state for the mouse and a losing state for the cat.

To determine the result of the initial state, we need to traverse all states starting from the boundary states. Each state includes the position of the mouse, the position of the cat, and the player who is moving. Based on the current state, we can determine all possible states from the previous round. The player who moved in the previous round is the opposite of the player who is moving in the current state, and the positions of the players in the previous round are different from their positions in the current state.

We use the tuple (m, c, t) to represent the current state and (pm, pc, pt) to represent a possible state from the previous round. The possible states from the previous round are:

- If the player moving in the current round is the mouse, then the player moving in the previous round is the cat. The position of the mouse in the previous round is the same as the current position of the mouse, and the position of the cat in the previous round is any adjacent node of the current position of the cat.
- If the player moving in the current round is the cat, then the player moving in the previous round is the mouse. The position of the cat in the previous round is the same as the current position of the cat, and the position of the mouse in the previous round is any adjacent node of the current position of the mouse.

Initially, all states except the boundary states are unknown. Starting from the boundary states, for each state, we determine all possible states from the previous round and update the results. The update logic is as follows:

1. If the player moving in the previous round is the same as the winner in the current round, then the player moving in the previous round can reach the current state and win. We directly update the state of the previous round to the winner of the current round.
2. If the player moving in the previous round is different from the winner in the current round, and all states that the player moving in the previous round can reach are losing states for that player, then we update the state of the previous round to the winner of the current round.

For the second update logic, we need to record the degree of each state. Initially, the degree of each state represents the number of nodes the player moving in that state can move to, which is the number of adjacent nodes of the node where the player is located. If the player is the cat and the node is adjacent to the hole, the degree of that state is reduced by 1.

When all states have been updated, the result of the initial state is the final result.

The time complexity is $O(n^3)$, and the space complexity is $O(n^2)$. Here, n is the number of nodes in the graph.

Python 3

```
HOLE, MOUSE_START, CAT_START = 0, 1, 2
MOUSE_TURN, CAT_TURN = 0, 1
MOUSE_WIN, CAT_WIN, TIE = 1, 2, 0

2193. Minimum Number of Moves to Make Palindrome

Hard · Greedy, Binary Indexed Tree, Two Pointers, String

leetcode.com/problems/minimum-number-of-moves-to-make-palindrome

PROBLEM

You are given a string `s` consisting only of lowercase English letters.

In one **move**, you can select any two **adjacent** characters of `s` and swap them.

Return *the **minimum number of moves** needed to make `s` a palindrome*.

Note that the input will be generated such that `s` can always be converted to a palindrome.

Example 1:

```
Input: s = "aabb"
Output: 2
Explanation:
We can obtain two palindromes from s, "abba" and "baab".
- We can obtain "abba" from s in 2 moves: "aabb" -> "abab" -> "abba".
- We can obtain "baab" from s in 2 moves: "aabb" -> "abab" -> "baab".
Thus, the minimum number of moves needed to make s a palindrome is 2.
```

Example 2:

```
Input: s = "letelt"
Output: 2
Explanation:
One of the palindromes we can obtain from s in 2 moves is "lettel".
One of the ways we can obtain it is "letelt" -> "letetl" -> "lettel".
Other palindromes such as "tleelt" can also be obtained in 2 moves.
It can be shown that it is not possible to obtain a palindrome in less than 2 moves.
```

Constraints:

- `1 <= s.length <= 2000`
- `s` consists only of lowercase English letters.
- `s` can be converted to a palindrome using a finite number of moves.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Adjacent swaps must turn the string into a palindrome; a solution is guaranteed. The cost is the total distance that paired letters travel to symmetric positions. Searching all swap sequences is too large; n≤ 2000 allows an $O(n^2)$ greedy. Fix the leftmost letter a, find the nearest a from the right, swap it to the right end, and recurse on the inner substring. If a has no right match (the unique odd letter), move it to the center at cost equal to the distance to the midpoint. Pairing the outermost letter is never worse than pairing an inner one first, so the greedy is optimal.

Python 3

```python
class Solution:
    def minMovesToMakePalindrome(self, s: str) -> int:
        cs = list(s)
        ans, n = 0, len(s)
        i, j = 0, n - 1
        while i < j:
            even = False
            for k in range(j, i, -1):
                if cs[i] == cs[k]:
                    even = True
                    while k < j:
                        cs[k], cs[k + 1] = cs[k + 1], cs[k]
                        k += 1
                        ans += 1
                    j -= 1
                    break
            if not even:
                ans += n // 2 - i
            i += 1
        return ans
```

```

1872. Stone Game VIII

Hard · Minimax, Array, Math, Dynamic Programming, Game Theory, Prefix Sum, Zero-Sum Game

leetcode.com/problems/stone-game-viii

PROBLEM

Alice and Bob take turns playing a game, with **Alice starting first**.

There are `n` stones arranged in a row. On each player's turn, while the number of stones is **more than one**, they will do the following:

1. Choose an integer `x > 1`, and **remove** the leftmost `x` stones from the row.
2. Add the **sum** of the **removed** stones' values to the player's score.
3. Place a **new stone**, whose value is equal to that sum, on the left side of the row.

The game stops when **only one** stone is left in the row.

The **score difference** between Alice and Bob is `(Alice's score - Bob's score)`. Alice's goal is to **maximize** the score difference, and Bob's goal is the **minimize** the score difference.

Given an integer array `stones` of length `n` where `stones[i]` represents the value of the i^{th} stone **from the left**, return *the **score difference** between Alice and Bob if they both play **optimally**.*

Example 1:

```
Input: stones = [-1,2,-3,4,-5]
Output: 5
Explanation:
- Alice removes the first 4 stones, adds (-1) + 2 + (-3) + 4 = 2 to her score, and places a stone of
  value 2 on the left. stones = [2,-5].
- Bob removes the first 2 stones, adds 2 + (-5) = -3 to his score, and places a stone of value -3 on
  the left. stones = [-3].
The difference between their scores is 2 - (-3) = 5.
```

Example 2:

```
Input: stones = [7,-6,5,10,5,-2,-6]
Output: 13
Explanation:
- Alice removes all stones, adds 7 + (-6) + 5 + 10 + 5 + (-2) + (-6) = 13 to her score, and places a
  stone of value 13 on the left. stones = [13].
The difference between their scores is 13 - 0 = 13.
```

Example 3:

```
Input: stones = [-10,-12]
Output: -22
Explanation:
- Alice can only make one move, which is to remove both stones. She adds (-10) + (-12) = -22 to her
  score and places a stone of value -22 on the left. stones = [-22].
The difference between their scores is (-22) - 0 = -22.
```

Constraints:

- `n == stones.length`
- `2 <= n <= 10^5`
- `-10^4 <= stones[i] <= 10^4`

SOLUTIONS (PYTHON 3)

Solution 1: Prefix Sum + Memoization Search

How to think about it

Each move merges a prefix of at least two piles and scores the new prefix sum; both players maximize the score difference. n≤ 10^5 forbids searching every cut. Merging leaves the prefix-sum array s unchanged. From index i the current player may take s[i] and leave i+1 to the opponent, or postpone the cut. dfs(i)=max(dfs(i+1),s[i]-dfs(i+1)), starting at i=1. Memoization yields linearly many states.

According to the problem description, each time we take the leftmost x stones, add their sum to our score, and then put a stone with this sum value on the leftmost side, it is equivalent to merging these x stones into a stone with this sum value, and the prefix sum remains unchanged.

We can use a prefix sum array s of length n to represent the prefix sum of the array stones, where s[i] represents the sum of the elements stones[0..i].

Next, we design a function dfs(i), which means that we currently take stones from stones[i:], and return the maximum score difference that the current player can get.

The execution process of the function dfs(i) is as follows:

- If i ≥ n - 1, it means that we can only take all the stones at present, so we return s[n - 1].
- Otherwise, we can choose to take all the stones from stones[i + 1:], and the score difference obtained is dfs(i + 1); we can also choose to take the stones stones[:i], and the score difference obtained is s[i] - dfs(i + 1). We take the maximum of the two situations, which is the maximum score difference that the current player can get.

Finally, we can get the score difference between Alice and Bob as dfs(1), that is, Alice must start the game by taking stones from stones[1:].

To avoid repeated calculations, we can use memoization search.

The time complexity is O(n), and the space complexity is O(n). Here, n is the length of the array stones.

Python 3

```
class Solution:
    def stoneGameVIII(self, stones: List[int]) -> int:
        @cache
        def dfs(i: int) -> int:
            if i >= len(stones) - 1:
                return s[-1]
            return max(dfs(i + 1), s[i] - dfs(i + 1))

        s = list(accumulate(stones))
        return dfs(1)
```

Solution 2: Prefix Sum + Dynamic Programming

How to think about it

Solution 1 fills a linear table from the end, and each cell only reads the next one. That table rolls into one scalar. f starts as s[n-1], then f=max(f,s[i]-f) for i=n-2,…,1. Extra space becomes constant.

We can also use dynamic programming to solve this problem.

Similar to Solution 1, we first use a prefix sum array s of length n to represent the prefix sum of the array stones, where s[i] represents the sum of the elements stones[0..i].

We define f[i] to represent the maximum score difference that the current player can get when taking stones from stones[i:].

If the player chooses to take the stones stones[:i], then the score obtained is s[i]. At this time, the other player will take stones from stones[i+1:], and the maximum score difference that the other player can get is f[i+1]. Therefore, the maximum score difference that the current player can get is s[i] - f[i+1].

If the player chooses to take stones from stones[i+1:], then the maximum score difference obtained is f[i+1].

Therefore, we can get the state transition equation:

$$f[i] = \max\{s[i] - f[i+1], f[i+1]\}$$

Finally, we can get the score difference between Alice and Bob as f[1], that is, Alice must start the game by taking stones from stones[1:].

We notice that f[i] is only related to f[i+1], so we only need to use a variable f to represent f[i].

The time complexity is O(n), and the space complexity is O(1). Here, n is the length of the array stones.

Python 3

```
class Solution:
    def stoneGameVIII(self, stones: List[int]) -> int:
        s = list(accumulate(stones))
        f = s[-1]
        for i in range(len(s) - 2, 0, -1):
            f = max(f, s[i] - f)
        return f
```

Solution 3: Prefix Sum + Dynamic Programming

> **How to think about it**
>
> Each move merges a prefix of at least two piles and scores the new prefix sum; both players maximize the score difference. $n \le 10^5$ forbids searching every cut. From index i the current player takes s[i] and leaves i+1, or postpones the cut. That recurrence always calls i+1 first, so the chain has length n and overflows the stack. The next index is known if we walk from the end. Let f[i] be the best difference on stones[i:], with f[n-1]=s[n-1], and fill i from n-2 down to 1.

According to the problem description, each time we take the leftmost x stones, add their sum to our score, and then put a stone with this sum value on the leftmost side, it is equivalent to merging these x stones into a stone with this sum value, and the prefix sum remains unchanged.

We can use a prefix sum array s of length n to represent the prefix sum of the array stones, where s[i] represents the sum of the elements stones[0..i].

Let f[i] be the maximum score difference the current player can get on stones[i:]. The answer is f[1], because Alice must start by taking at least the first two stones. Set f[n - 1] = s[n - 1]: only one pile remains, so the player takes it.

Fill i from n - 2 down to 1. Postponing the cut keeps f[i + 1]. Taking stones[0..i] scores s[i] and leaves the opponent with f[i + 1], so the difference is s[i] - f[i + 1]. Take the larger one:

$$f[i] = \max(f[i + 1], s[i] - f[i + 1])$$

The time complexity is O(n), and the space complexity is O(n). Here, n is the length of the array stones.

Python 3

```
class Solution:
    def stoneGameVIII(self, stones: List[int]) -> int:
        s = list(accumulate(stones))
        n = len(s)
        f = [0] * n
        f[-1] = s[-1]
        for i in range(n - 2, 0, -1):
            f[i] = max(f[i + 1], s[i] - f[i + 1])
        return f[1]
```

1649. Create Sorted Array through Instructions

Hard · Binary Indexed Tree, Segment Tree, Array, Binary Search, Divide and Conquer, Ordered Set, Merge Sort

leetcode.com/problems/create-sorted-array-through-instructions

★ **TOP 10 PROBLEM** in Binary Indexed Tree (Fenwick Tree): master this one first

Also appears in pattern 41 Binary Indexed Tree (Fenwick Tree)

PROBLEM

Given an integer array `instructions`, you are asked to create a sorted array from the elements in `instructions`. You start with an empty container `nums`. For each element from **left to right** in `instructions`, insert it into `nums`. The **cost** of each insertion is the **minimum** of the following:

- The number of elements currently in `nums` that are **strictly less than** `instructions[i]`.
- The number of elements currently in `nums` that are **strictly greater than** `instructions[i]`.

For example, if inserting element `3` into `nums = [1,2,3,5]`, the **cost** of insertion is `min(2, 1)` (elements `1` and `2` are less than `3`, element `5` is greater than `3`) and `nums` will become `[1,2,3,3,5]`.

Return *the **total cost** to insert all elements from* `instructions` *into* `nums`. Since the answer may be large, return it **modulo** $10^9 + 7$

Example 1:

```
Input: instructions = [1,5,6,2]
Output: 1
Explanation: Begin with nums = [].
Insert 1 with cost min(0, 0) = 0, now nums = [1].
Insert 5 with cost min(1, 0) = 0, now nums = [1,5].
Insert 6 with cost min(2, 0) = 0, now nums = [1,5,6].
Insert 2 with cost min(1, 2) = 1, now nums = [1,2,5,6].
The total cost is 0 + 0 + 0 + 1 = 1.
```

Example 2:

```
Input: instructions = [1,2,3,6,5,4]
Output: 3
Explanation: Begin with nums = [].
Insert 1 with cost min(0, 0) = 0, now nums = [1].
Insert 2 with cost min(1, 0) = 0, now nums = [1,2].
Insert 3 with cost min(2, 0) = 0, now nums = [1,2,3].
Insert 6 with cost min(3, 0) = 0, now nums = [1,2,3,6].
Insert 5 with cost min(3, 1) = 1, now nums = [1,2,3,5,6].
Insert 4 with cost min(3, 2) = 2, now nums = [1,2,3,4,5,6].
The total cost is 0 + 0 + 0 + 0 + 1 + 2 = 3.
```

Example 3:

```
Input: instructions = [1,3,3,3,2,4,2,1,2]
Output: 4
Explanation: Begin with nums = [].
Insert 1 with cost min(0, 0) = 0, now nums = [1].
Insert 3 with cost min(1, 0) = 0, now nums = [1,3].
Insert 3 with cost min(1, 0) = 0, now nums = [1,3,3].
Insert 3 with cost min(1, 0) = 0, now nums = [1,3,3,3].
Insert 2 with cost min(1, 3) = 1, now nums = [1,2,3,3,3].
Insert 4 with cost min(5, 0) = 0, now nums = [1,2,3,3,3,4].
Insert 2 with cost min(1, 4) = 1, now nums = [1,2,2,3,3,3,4].
Insert 1 with cost min(0, 6) = 0, now nums = [1,1,2,2,3,3,3,4].
Insert 2 with cost min(2, 4) = 2, now nums = [1,1,2,2,2,3,3,3,4].
The total cost is 0 + 0 + 0 + 0 + 1 + 0 + 1 + 0 + 2 = 4.
```

Constraints:

- `1 <= instructions.length <= 10^5`
- `1 <= instructions[i] <= 10^5`

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

The cost of inserting x is the min of how many existing values are strictly smaller and strictly larger. 10^5 insertions make a linear scan per step too slow. The value domain is also 10^5, so a Fenwick tree queries a prefix count and adds one in O(log M). Before inserting x, add min(query(x-1), i-query(x)), then update(x,1), and reduce modulo.

Python 3

```python
class BinaryIndexedTree:
    def __init__(self, n):
        self.n = n
        self.c = [0] * (n + 1)

    def update(self, x: int, v: int):
        while x <= self.n:
            self.c[x] += v
            x += x & -x

    def query(self, x: int) -> int:
        s = 0
        while x:
            s += self.c[x]
            x -= x & -x
        return s

class Solution:
    def createSortedArray(self, instructions: List[int]) -> int:
        m = max(instructions)
        tree = BinaryIndexedTree(m)
        ans = 0
        mod = 10**9 + 7
        for i, x in enumerate(instructions):
            cost = min(tree.query(x - 1), i - tree.query(x))
            ans += cost
            tree.update(x, 1)
        return ans % mod
```

Solution 2

How to think about it

Solution 1 stores frequencies in a Fenwick tree. A segment tree with range sums answers the same prefix counts. Point add plus queries on [1,x) and (x,M] match the Fenwick version. The Python port is marked TLE here; Java and C++ pass.

Python 3

```
class Node:
    def __init__(self):
        self.l = 0
        self.r = 0
        self.v = 0

class SegmentTree:
    def __init__(self, n):
        self.tr = [Node() for _ in range(4 * n)]
        self.build(1, 1, n)

    def build(self, u, l, r):
        self.tr[u].l = l
        self.tr[u].r = r
        if l == r:
            return
        mid = (l + r) >> 1
        self.build(u << 1, l, mid)
        self.build(u << 1 | 1, mid + 1, r)

    def modify(self, u, x, v):
        if self.tr[u].l == x and self.tr[u].r == x:
            self.tr[u].v += v
            return
        mid = (self.tr[u].l + self.tr[u].r) >> 1
        if x <= mid:
            self.modify(u << 1, x, v)
        else:
            self.modify(u << 1 | 1, x, v)
        self.pushup(u)

    def pushup(self, u):
        self.tr[u].v = self.tr[u << 1].v + self.tr[u << 1 | 1].v

    def query(self, u, l, r):
        if self.tr[u].l >= l and self.tr[u].r <= r:
            return self.tr[u].v
        mid = (self.tr[u].l + self.tr[u].r) >> 1
        v = 0
        if l <= mid:
            v = self.query(u << 1, l, r)
        if r > mid:
            v += self.query(u << 1 | 1, l, r)
        return v

class Solution:
    def createSortedArray(self, instructions: List[int]) -> int:
        n = max(instructions)
        tree = SegmentTree(n)
        ans = 0
        for num in instructions:
            a = tree.query(1, 1, num - 1)
            b = tree.query(1, 1, n) - tree.query(1, 1, num)
            ans += min(a, b)
            tree.modify(1, num, 1)
        return ans % int((1e9 + 7))
```

Complexity. Time: O(m * log M), m = len(instructions), M = largest value. Space: O(M).

2080. Range Frequency Queries

Medium · Design, Segment Tree, Array, Hash Table, Binary Search

leetcode.com/problems/range-frequency-queries

Also appears in pattern 41 Binary Indexed Tree (Fenwick Tree)

PROBLEM

Design a data structure to find the **frequency** of a given value in a given subarray.

The **frequency** of a value in a subarray is the number of occurrences of that value in the subarray.

Implement the `RangeFreqQuery` class:

- `RangeFreqQuery(int[] arr)` Constructs an instance of the class with the given **0-indexed** integer array `arr`.
- `int query(int left, int right, int value)` Returns the **frequency** of `value` in the subarray `arr[left...right]`.

A **subarray** is a contiguous sequence of elements within an array. `arr[left...right]` denotes the subarray that contains the elements of `nums` between indices `left` and `right` (**inclusive**).

Example 1:

```
Input
["RangeFreqQuery", "query", "query"]
[[[12, 33, 4, 56, 22, 2, 34, 33, 22, 12, 34, 56]], [1, 2, 4], [0, 11, 33]]
Output
[null, 1, 2]

Explanation
RangeFreqQuery rangeFreqQuery = new RangeFreqQuery([12, 33, 4, 56, 22, 2, 34, 33, 22, 12, 34, 56]);
rangeFreqQuery.query(1, 2, 4); // return 1. The value 4 occurs 1 time in the subarray [33, 4]
rangeFreqQuery.query(0, 11, 33); // return 2. The value 33 occurs 2 times in the whole array.
```

Constraints:

- $1 <= arr.length <= 10^5$
- $1 <= arr[i], value <= 10^4$
- $0 <= left <= right < arr.length$
- At most 10^5 calls will be made to `query`

SOLUTION (PYTHON 3)

Solution 1: Hash Table + Binary Search

> **How to think about it**
>
> Many range frequency queries on a static array. n and the query count are 10^5; a segment tree works, but one value only needs its index list. A hash map stores increasing indices; two binary searches on [left,right] yield the count.

We use a hash table g to store the array of indices corresponding to each value. In the constructor, we traverse the array arr, adding the index corresponding to each value to the hash table.

In the query function, we first check whether the given value exists in the hash table. If it does not exist, it means that the value does not exist in the array, so we directly return 0. Otherwise, we get the index array idx corresponding to the value. Then we use binary search to find the first index l that is greater than or equal to left, and the first index r that is greater than right. Finally, we return r - l.

In terms of time complexity, the time complexity of the constructor is O(n), and the time complexity of the query function is O(log n). The space complexity is O(n). Where n is the length of the array.

Python 3

```
class RangeFreqQuery:

    def __init__(self, arr: List[int]):
        self.g = defaultdict(list)
        for i, x in enumerate(arr):
            self.g[x].append(i)

    def query(self, left: int, right: int, value: int) -> int:
        idx = self.g[value]
        l = bisect_left(idx, left)
        r = bisect_left(idx, right + 1)
        return r - l

# Your RangeFreqQuery object will be instantiated and called as such:
# obj = RangeFreqQuery(arr)
# param_1 = obj.query(left,right,value)
```

    return total
```

2424. Longest Uploaded Prefix

Medium · Union Find, Design, Binary Indexed Tree, Segment Tree, Hash Table, Binary Search, Ordered Set, Heap (Priority Queue)

leetcode.com/problems/longest-uploaded-prefix

PROBLEM

You are given a stream of `n` videos, each represented by a **distinct** number from `1` to `n` that you need to "upload" to a server. You need to implement a data structure that calculates the length of the **longest uploaded prefix** at various points in the upload process.

We consider `i` to be an uploaded prefix if all videos in the range `1` to `i` (**inclusive**) have been uploaded to the server. The longest uploaded prefix is the **maximum** value of `i` that satisfies this definition.

Implement the `LUPrefix` class:

- `LUPrefix(int n)` Initializes the object for a stream of `n` videos.
- `void upload(int video)` Uploads `video` to the server.
- `int longest()` Returns the length of the **longest uploaded prefix** defined above.

Example 1:

```
Input
["LUPrefix", "upload", "longest", "upload", "longest", "upload", "longest"]
[[4], [3], [], [1], [], [2], []]
Output
[null, null, 0, null, 1, null, 3]

Explanation
LUPrefix server = new LUPrefix(4); // Initialize a stream of 4 videos.
server.upload(3); // Upload video 3.
server.longest(); // Since video 1 has not been uploaded yet, there is no prefix.
                                    // So, we return 0.
server.upload(1); // Upload video 1.
server.longest(); // The prefix [1] is the longest uploaded prefix, so we return 1.
server.upload(2); // Upload video 2.
server.longest(); // The prefix [1,2,3] is the longest uploaded prefix, so we return 3.
```

Constraints:

- `1 <= n <= 10^5`
- `1 <= video <= n`
- All values of `video` are **distinct**.
- At most `2 * 10^5` calls **in total** will be made to `upload` and `longest`.
- At least one call will be made to `longest`.

SOLUTION (PYTHON 3)

Solution 1: Simulation

How to think about it

Up to 2× 10^5 uploads and queries forbid scanning [1,n] each time. The longest prefix is the largest r such that 1..r are all uploaded; only uploading r+1 can extend it. Store uploaded ids in a set and keep r. After an upload, increment r while r+1 is present. Each id advances r at most once, so the extra work is linear overall.

We use a variable r to record the current longest prefix of uploaded videos, and an array or hash table s to record the videos that have been uploaded.

Each time a video is uploaded, we set `s[video]` to `true`, then loop to check whether `s[r + 1]` is `true`. If it is, we update r.

The time complexity is O(n), and the space complexity is O(n). Here, n is the total number of videos.

Python 3

```
class LUPrefix:
    def __init__(self, n: int):
        self.r = 0
        self.s = set()

    def upload(self, video: int) -> None:
        self.s.add(video)
        while self.r + 1 in self.s:
            self.r += 1

    def longest(self) -> int:
        return self.r

# Your LUPrefix object will be instantiated and called as such:
# obj = LUPrefix(n)
# obj.upload(video)
# param_2 = obj.longest()
```

        first_missing = node - self.size
        return min(first_missing, self.n)
```

850. Rectangle Area II

Hard · Segment Tree, Array, Ordered Set, Sweep Line

leetcode.com/problems/rectangle-area-ii

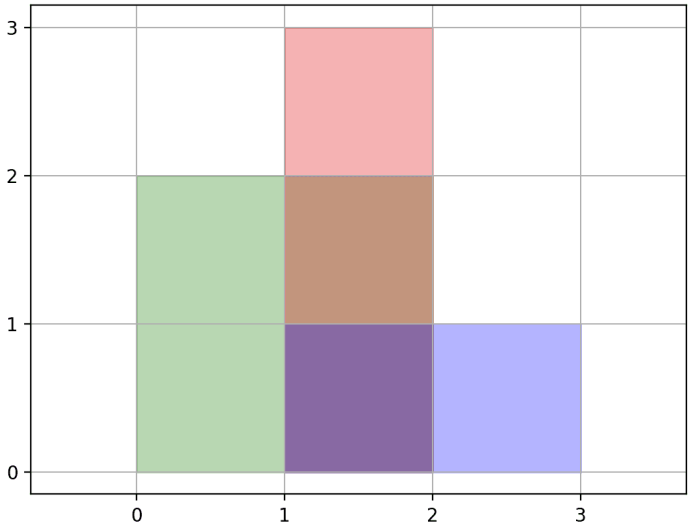
PROBLEM

You are given a 2D array of axis-aligned `rectangles`. Each `rectangle[i] = [$x_{i1}$, $y_{i1}$, $x_{i2}$, $y_{i2}$]` denotes the i^{th} rectangle where (x_{i1}, y_{i1}) are the coordinates of the **bottom-left corner**, and (x_{i2}, y_{i2}) are the coordinates of the **top-right corner**.

Calculate the **total area** covered by all `rectangles` in the plane. Any area covered by two or more rectangles should only be counted **once**.

Return *the **total area***. Since the answer may be too large, return it **modulo** $10^9 + 7$.

Example 1:



```
Input: rectangles = [[0,0,2,2],[1,0,2,3],[1,0,3,1]]
Output: 6
Explanation: A total area of 6 is covered by all three rectangles, as illustrated in the picture.
From (1,1) to (2,2), the green and red rectangles overlap.
From (1,0) to (2,3), all three rectangles overlap.
```

Example 2:

```
Input: rectangles = [[0,0,1000000000,1000000000]]
Output: 49
Explanation: The answer is 1018 modulo (109 + 7), which is 49.
```

Constraints:

- `1 <= rectangles.length <= 200`
- `rectanges[i].length == 4`
- `0 <=` $x_{i1}, y_{i1}, x_{i2}, y_{i2} \le 10^9$
- $x_{i1} <= x_{i2}$
- $y_{i1} <= y_{i2}$
- All rectangles have non zero area.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

We need the area of a union of rectangles with coordinates up to 10^9 and at most 200 rectangles. Inclusion-exclusion explodes with intersections. A vertical sweep is stabler: left and right edges are events, and the measure between them is the covered y-length. Discretize y-coordinates and let a segment tree store the length where the cover count is positive. Sorting events by x, each gap Δ x times the tree length is the area of that slab.

Python 3

```python
class Node:
    def __init__(self):
        self.l = self.r = 0
        self.cnt = self.length = 0

class SegmentTree:
    def __init__(self, nums):
        n = len(nums) - 1
        self.nums = nums
        self.tr = [Node() for _ in range(n << 2)]
        self.build(1, 0, n - 1)

    def build(self, u, l, r):
        self.tr[u].l, self.tr[u].r = l, r
        if l != r:
            mid = (l + r) >> 1
            self.build(u << 1, l, mid)
            self.build(u << 1 | 1, mid + 1, r)

    def modify(self, u, l, r, k):
        if self.tr[u].l >= l and self.tr[u].r <= r:
            self.tr[u].cnt += k

2407. Longest Increasing Subsequence II

Hard · Binary Indexed Tree, Segment Tree, Queue, Array, Divide and Conquer, Dynamic Programming, Monotonic Queue

leetcode.com/problems/longest-increasing-subsequence-ii

★ **TOP 10 PROBLEM** in Segment Tree: master this one first

PROBLEM

You are given an integer array `nums` and an integer `k`.

Find the longest subsequence of `nums` that meets the following requirements:

- The subsequence is **strictly increasing** and
- The difference between adjacent elements in the subsequence is **at most** `k`.

Return *the length of the **longest subsequence** that meets the requirements.*

A **subsequence** is an array that can be derived from another array by deleting some or no elements without changing the order of the remaining elements.

Example 1:

```
Input: nums = [4,2,1,4,3,4,5,8,15], k = 3
Output: 5
Explanation:
The longest subsequence that meets the requirements is [1,3,4,5,8].
The subsequence has a length of 5, so we return 5.
Note that the subsequence [1,3,4,5,8,15] does not meet the requirements because 15 - 8 = 7 is larger than 3.
```

Example 2:

```
Input: nums = [7,4,5,1,8,12,4,7], k = 5
Output: 4
Explanation:
The longest subsequence that meets the requirements is [4,5,8,12].
The subsequence has a length of 4, so we return 4.
```

Example 3:

```
Input: nums = [1,5], k = 1
Output: 1
Explanation:
The longest subsequence that meets the requirements is [1].
The subsequence has a length of 1, so we return 1.
```

Constraints:

- `1 <= nums.length <= 10^5`
- `1 <= nums[i], k <= 10^5`

SOLUTION (PYTHON 3)

Solution 1: Segment Tree

How to think about it

Classic LIS is $O(n^2)$, which fails at $n \le 10^5$, and adjacent values may differ by at most k. The best length ending at v is one plus the maximum f on [v-k,v-1], so we need range-max queries and point updates on the value domain. Values lie in $[1,10^5]$. A segment tree stores f[v]; for each v query then update, in O(nlog V).

We assume that f[v] represents the length of the longest increasing subsequence ending with the number v.

We traverse each element v in the array nums, with the state transition equation: f[v] = max(f[v], f[x]), where the range of x is [v-k, v-1].

Therefore, we need a data structure to maintain the maximum value of the interval. It is not difficult to think of using a segment tree.

The segment tree divides the entire interval into multiple discontinuous subintervals, and the number of subintervals does not exceed log(width). To update the value of an element, only log(width) intervals need to be updated, and these intervals are all contained in a large interval that contains the element.

- Each node of the segment tree represents an interval;
- The segment tree has a unique root node, which represents the entire statistical range, such as [1,N];
- Each leaf node of the segment tree represents an elementary interval of length 1, [x, x];
- For each internal node [l,r], its left child is [l,mid], and the right child is [mid+1,r], where mid = floor((l+r)/2).

For this problem, the information maintained by the segment tree node is the maximum value within the interval range.

The time complexity is O(n × log n), where n is the length of the array nums.

Python 3

```python
class Node:
    def __init__(self):
        self.l = 0
        self.r = 0
        self.v = 0

class SegmentTree:
    def __init__(self, n):
        self.tr = [Node() for _ in range(4 * n)]
        self.build(1, 1, n)

    def build(self, u, l, r):
        self.tr[u].l = l
        self.tr[u].r = r
        if l == r:
            return
        mid = (l + r) >> 1
        self.build(u << 1, l, mid)
        self.build(u << 1 | 1, mid + 1, r)

    def modify(self, u, x, v):
        if self.tr[u].l == x and self.tr[u].r == x:
            self.tr[u].v = v
            return
        mid = (self.tr[u].l + self.tr[u].r) >> 1
        if x <= mid:
            self.modify(u << 1, x, v)
        else:
            self.modify(u << 1 | 1, x, v)
        self.pushup(u)

    def pushup(self, u):
        self.tr[u].v = max(self.tr[u << 1].v, self.tr[u << 1 | 1].v)

    def query(self, u, l, r):
        if self.tr[u].l >= l and self.tr[u].r <= r:
            return self.tr[u].v
        mid = (self.tr[u].l + self.tr[u].r) >> 1
        v = 0
        if l <= mid:
            v = self.query(u << 1, l, r)
        if r > mid:
            v = max(v, self.query(u << 1 | 1, l, r))
        return v

class Solution:
    def lengthOfLIS(self, nums: List[int], k: int) -> int:
        tree = SegmentTree(max(nums))
        ans = 1
        for v in nums:
            t = tree.query(1, v - k, v - 1) + 1
            ans = max(ans, t)
            tree.modify(1, v, t)
        return ans
```

2569. Handling Sum Queries After Update

Hard · Segment Tree, Array

leetcode.com/problems/handling-sum-queries-after-update

PROBLEM

You are given two **0-indexed** arrays `nums1` and `nums2` and a 2D array `queries` of queries. There are three types of queries:

1. For a query of type 1, `queries[i] = [1, l, r]`. Flip the values from `0` to `1` and from `1` to `0` in `nums1` from index `l` to index `r`. Both `l` and `r` are **0-indexed**.
2. For a query of type 2, `queries[i] = [2, p, 0]`. For every index `0 <= i < n`, set `nums2[i] = nums2[i] + nums1[i] * p`.
3. For a query of type 3, `queries[i] = [3, 0, 0]`. Find the sum of the elements in `nums2`.

Return *an array containing all the answers to the third type queries.*

Example 1:

```
Input: nums1 = [1,0,1], nums2 = [0,0,0], queries = [[1,1,1],[2,1,0],[3,0,0]]
Output: [3]
Explanation: After the first query nums1 becomes [1,1,1]. After the second query, nums2 becomes [1,1,1], so the answer to the third query is 3. Thus, [3] is returned.
```

Example 2:

```
Input: nums1 = [1], nums2 = [5], queries = [[2,0,0],[3,0,0]]
Output: [5]
Explanation: After the first query, nums2 remains [5], so the answer to the second query is 5. Thus, [5] is returned.
```

Constraints:

- `1 <= nums1.length,nums2.length <= 10^5`
- `nums1.length = nums2.length`
- `1 <= queries.length <= 10^5`
- `queries[i].length = 3`
- `0 <= l <= r <= nums1.length - 1`
- `0 <= p <= 10^6`
- `0 <= nums1[i] <= 1`
- `0 <= nums2[i] <= 10^9`

SOLUTION (PYTHON 3)

Solution 1: Segment Tree

How to think about it

Three operations: flip a range of nums1; add p×∑ nums1 to every element of nums2; report ∑ nums2. n,q≤ 10^5 forbids walking a range on every flip. ∑ nums2 is a single running total; only the range sum of nums1 matters for the second operation. A segment tree stores how many ones sit in each interval, with a lazy flip that replaces a sum s by length-s. The third operation just records the current total.

According to the problem description:

- Operation 1 is to reverse all numbers in the index range [l,..r] of array `nums1`, that is, change 0 to 1 and 1 to 0.
- Operation 3 is to sum all numbers in array `nums2`.

- Operation 2 is to add the sum of all numbers in array `nums2` with p times the sum of all numbers in array `nums1`, that is, sum(nums2) = sum(nums2) + p * sum(nums1).

Therefore, we actually only need to maintain the segment sum of array `nums1`, which can be implemented through a segment tree.

We define each node of the segment tree as `Node`, each node contains the following attributes:

- `l`: The left endpoint of the node, the index starts from 1.
- `r`: The right endpoint of the node, the index starts from 1.
- `s`: The segment sum of the node.
- `lazy`: The lazy tag of the node.

The segment tree mainly has the following operations:

- `build(u, l, r)`: Build the segment tree.
- `pushdown(u)`: Propagate the lazy tag.
- `pushup(u)`: Update the information of the parent node with the information of the child nodes.
- `modify(u, l, r)`: Modify the segment sum. In this problem, it is to reverse each number in the segment, so the segment sum s = r - l + 1 - s.
- `query(u, l, r)`: Query the segment sum.

First, calculate the sum of all numbers in array `nums2`, denoted as s.

When executing operation 1, we only need to call `modify(1, l + 1, r + 1)`.

When executing operation 2, we update s = s + p × query(1, 1, n).

When executing operation 3, we just need to add s to the answer array.

The time complexity is O(n + m × log n), and the space complexity is O(n). Where n and m are the lengths of arrays `nums1` and `queries` respectively.

Python 3

```python
class Node:
    def __init__(self):
        self.l = self.r = 0
        self.s = self.lazy = 0

class SegmentTree:
    def __init__(self, nums):
        self.nums = nums
        n = len(nums)
        self.tr = [Node() for _ in range(n << 2)]
        self.build(1, 1, n)

    def build(self, u, l, r):
        self.tr[u].l, self.tr[u].r = l, r
        if l == r:
            self.tr[u].s = self.nums[l - 1]
            return
        mid = (l + r) >> 1
        self.build(u << 1, l, mid)
        self.build(u << 1 | 1, mid + 1, r)
        self.pushup(u)

    def modify(self, u, l, r):
        if self.tr[u].l >= l and self.tr[u].r <= r:
            self.tr[u].lazy ^= 1
            self.tr[u].s = self.tr[u].r - self.tr[u].l + 1 - self.tr[u].s

2286. Booking Concert Tickets in Groups

Hard · Design, Binary Indexed Tree, Segment Tree, Binary Search

leetcode.com/problems/booking-concert-tickets-in-groups

PROBLEM

A concert hall has `n` rows numbered from `0` to `n - 1`, each with `m` seats, numbered from `0` to `m - 1`. You need to design a ticketing system that can allocate seats in the following cases:

- If a group of `k` spectators can sit **together** in a row.
- If **every** member of a group of `k` spectators can get a seat. They may or **may not** sit together.

Note that the spectators are very picky. Hence:

- They will book seats only if each member of their group can get a seat with row number **less than or equal** to `maxRow`. `maxRow` can **vary** from group to group.
- In case there are multiple rows to choose from, the row with the **smallest** number is chosen. If there are multiple seats to choose in the same row, the seat with the **smallest** number is chosen.

Implement the `BookMyShow` class:

- `BookMyShow(int n, int m)` Initializes the object with `n` as number of rows and `m` as number of seats per row.
- `int[] gather(int k, int maxRow)` Returns an array of length `2` denoting the row and seat number (respectively) of the **first seat** being allocated to the `k` members of the group, who must sit **together**. In other words, it returns the smallest possible `r` and `c` such that all `[c, c + k - 1]` seats are valid and empty in row `r`, and `r <= maxRow`. Returns `[]` in case it is **not possible** to allocate seats to the group.
- `boolean scatter(int k, int maxRow)` Returns `true` if all `k` members of the group can be allocated seats in rows `0` to `maxRow`, who may or **may not** sit together. If the seats can be allocated, it allocates `k` seats to the group with the **smallest** row numbers, and the smallest possible seat numbers in each row. Otherwise, returns `false`.

Example 1:

```
Input
["BookMyShow", "gather", "gather", "scatter", "scatter"]
[[2, 5], [4, 0], [2, 0], [5, 1], [5, 1]]
Output
[null, [0, 0], [], true, false]

Explanation
BookMyShow bms = new BookMyShow(2, 5); // There are 2 rows with 5 seats each
bms.gather(4, 0); // return [0, 0]
                  // The group books seats [0, 3] of row 0.
bms.gather(2, 0); // return []
                  // There is only 1 seat left in row 0,
                  // so it is not possible to book 2 consecutive seats.
bms.scatter(5, 1); // return True
                   // The group books seat 4 of row 0 and seats [0, 3] of row 1.
bms.scatter(5, 1); // return False
                   // There is only one seat left in the hall.
```

Constraints:

- $1 <= n <= 5 * 10^4$
- $1 <= m, k <= 10^9$
- `0 <= maxRow <= n - 1`
- At most $5 * 10^4$ calls **in total** will be made to `gather` and `scatter`.

SOLUTION (PYTHON 3)

Solution 1: Segment Tree

> **How to think about it**
>
> gather needs k consecutive seats in the lowest possible row; scatter only needs any k seats in the lowest rows. There are 5× 10^4 rows of size 10^9, so a seat array or a linear scan per call is too slow. A segment tree on rows stores remaining-seat sums s and per-row maxima mx. gather finds the leftmost row with mx≥ k and subtracts k. scatter checks the range sum, then walks rows from the left deducting seats.

From the problem description, we can deduce the following:

- For the `gather(k, maxRow)` operation, the goal is to seat k people on the same row with consecutive seats. In other words, we need to find the smallest row where the remaining seats are greater than or equal to k.
- For the `scatter(k, maxRow)` operation, we just need to find k seats in total, but we want to minimize the row number. Therefore, we need to find the first row that has more than 0 seats remaining, allocate seats there, and continue searching for the rest.

We can implement this using a segment tree. Each segment tree node contains the following information:

- `l`: The left endpoint of the node's interval
- `r`: The right endpoint of the node's interval
- `s`: The total remaining seats in the interval corresponding to the node
- `mx`: The maximum remaining seats in the interval corresponding to the node

Note that the index range for the segment tree starts from 1.

The operations of the segment tree are as follows:

- `build(u, l, r)`: Builds node u, corresponding to the interval [l, r], and recursively builds its left and right children.
- `modify(u, x, v)`: Starting from node u, finds the first node corresponding to the interval [l, r] where l = r = x, and modifies the `s` and `mx` values of this node to v, then updates the tree upwards.
- `query_sum(u, l, r)`: Starting from node u, calculates the sum of `s` values in the interval [l, r].
- `query_idx(u, l, r, k)`: Starting from node u, finds the first node in the interval [l, r] where `mx` is greater than or equal to k, and returns the left endpoint `l` of this node. When searching, we start from the largest interval [1, maxRow]. Since we need to find the leftmost node with `mx` greater than or equal to k, we check whether the `mx` of the first half of the interval meets the condition. If so, the answer is in the first half, and we recursively search that half. Otherwise, the answer is in the second half, and we search that half recursively.
- `pushup(u)`: Updates the information of node u using the information from its children.

For the `gather(k, maxRow)` operation, we first use `query_idx(1, 1, n, k)` to find the first row where the remaining seats are greater than or equal to k, denoted as i. Then, we use `query_sum(1, i, i)` to get the remaining seats in this row, denoted as s. Next, we use `modify(1, i, s - k)` to modify the remaining seats of this row to s - k, and update the tree upwards. Finally, we return the result [i - 1, m - s].

For the `scatter(k, maxRow)` operation, we first use `query_sum(1, 1, maxRow)` to calculate the total remaining seats in the first maxRow rows, denoted as s. If s < k, there are not enough seats, so we return `false`. Otherwise, we use `query_idx(1, 1, maxRow, 1)` to find the first row where the remaining seats are greater than or equal to 1, denoted as i. Starting from this row, we use `query_sum(1, i, i)` to get the remaining seats in row i, denoted as s_i. If $s_i \geq k$, we directly use `modify(1, i, s_i - k)` to modify the remaining seats of this row to s_i - k, update the tree upwards, and return `true`. Otherwise, we update k = k - s_i, modify the remaining seats of this row to 0, and update the tree upwards. Finally, we return `true`.

Time complexity:

- The initialization time complexity is O(n).
- The time complexity of `gather(k, maxRow)` is O(log n).
- The time complexity of `scatter(k, maxRow)` is O((n + q) × log n).

The overall time complexity is O(n + q × log n), and the space complexity is O(n). Here, n is the number of rows, and q is the number of operations.

2940. Find Building Where Alice and Bob Can Meet

Hard · Stack, Binary Indexed Tree, Segment Tree, Array, Binary Search, Monotonic Stack, Heap (Priority Queue)

leetcode.com/problems/find-building-where-alice-and-bob-can-meet

PROBLEM

You are given a **0-indexed** array `heights` of positive integers, where `heights[i]` represents the height of the i^{th} building.

If a person is in building `i`, they can move to any other building `j` if and only if `i < j` and `heights[i] < heights[j]`.

You are also given another array `queries` where `queries[i] = [a_i, b_i]`. On the i^{th} query, Alice is in building a_i while Bob is in building b_i.

Return *an array* `ans` *where* `ans[i]` *is* ***the index of the leftmost building*** *where Alice and Bob can meet on the* i^{th} *query. If Alice and Bob cannot move to a common building on query* `i`, *set* `ans[i]` *to* `-1`.

Example 1:

```
Input: heights = [6,4,8,5,2,7], queries = [[0,1],[0,3],[2,4],[3,4],[2,2]]
Output: [2,5,-1,5,2]
Explanation: In the first query, Alice and Bob can move to building 2 since heights[0] < heights[2]
and heights[1] < heights[2].
In the second query, Alice and Bob can move to building 5 since heights[0] < heights[5] and heights[3]
< heights[5].
In the third query, Alice cannot meet Bob since Alice cannot move to any other building.
In the fourth query, Alice and Bob can move to building 5 since heights[3] < heights[5] and heights[4]
< heights[5].
In the fifth query, Alice and Bob are already in the same building.
For ans[i] != -1, It can be shown that ans[i] is the leftmost building where Alice and Bob can meet.
For ans[i] == -1, It can be shown that there is no building where Alice and Bob can meet.
```

Example 2:

```
Input: heights = [5,3,8,2,6,1,4,6], queries = [[0,7],[3,5],[5,2],[3,0],[1,6]]
Output: [7,6,-1,4,6]
Explanation: In the first query, Alice can directly move to Bob's building since heights[0] <
heights[7].
In the second query, Alice and Bob can move to building 6 since heights[3] < heights[6] and heights[5]
< heights[6].
In the third query, Alice cannot meet Bob since Bob cannot move to any other building.
In the fourth query, Alice and Bob can move to building 4 since heights[3] < heights[4] and heights[0]
< heights[4].
In the fifth query, Alice can directly move to Bob's building since heights[1] < heights[6].
For ans[i] != -1, It can be shown that ans[i] is the leftmost building where Alice and Bob can meet.
For ans[i] == -1, It can be shown that there is no building where Alice and Bob can meet.
```

Constraints:

- `1 <= heights.length <= 5 * 10^4`
- `1 <= heights[i] <= 10^9`
- `1 <= queries.length <= 5 * 10^4`
- `queries[i] = [a_i, b_i]`
- `0 <= a_i, b_i <= heights.length - 1`

SOLUTION (PYTHON 3)

Solution 1: Binary Indexed Tree

How to think about it

They meet at some j ≥ max(a,b) strictly taller than the shorter one (or simply at the right building when it is already taller). Scanning the suffix per query is too slow for n,q ≤ 5×10^4. Process queries by decreasing right endpoint and insert buildings to the right of r into a Fenwick tree keyed by compressed height and storing the smallest index. A query for the smallest index taller than heights[l] is the meeting building.

Let's denote queries[i] = [l_i, r_i], where $l_i \le r_i$. If $l_i = r_i$ or heights[l_i] < heights[r_i], then the answer is r_i. Otherwise, we need to find the smallest j among all j > r_i and heights[j] > heights[l_i].

We can sort queries in descending order of r_i, and use a pointer j to point to the current index of heights being traversed.

Next, we traverse each query queries[i] = (l, r). For the current query, if j > r, then we loop to insert heights[j] into the binary indexed tree. The binary indexed tree maintains the minimum index of the suffix height (after discretization). Then, we judge whether l = r or heights[l] < heights[r]. If it is, then the answer to the current query is r. Otherwise, we query the minimum index of heights[l] in the binary indexed tree, which is the answer to the current query.

The time complexity is O((n + m) × log n + m × log m), and the space complexity is O(n + m). Where n and m are the lengths of heights and queries respectively.

    for j in range(len(heights) - 1, start - 1, -1):
        if heights[j] > limit:
            return j
    if a < b and heights[a] < heights[b]:
        return b
    if b < a and heights[b] < heights[a]:
        return a
    return -1
```

PATTERN 40 · SEGMENT TREE · PROBLEM 20 OF 20

2426. Number of Pairs Satisfying Inequality

Hard · Binary Indexed Tree, Segment Tree, Array, Binary Search, Divide and Conquer, Ordered Set, Merge Sort

leetcode.com/problems/number-of-pairs-satisfying-inequality

Also appears in pattern 41 Binary Indexed Tree (Fenwick Tree)

PROBLEM

You are given two **0-indexed** integer arrays `nums1` and `nums2`, each of size `n`, and an integer `diff`. Find the number of **pairs** `(i, j)` such that:

- `0 <= i < j <= n - 1` **and**
- `nums1[i] - nums1[j] <= nums2[i] - nums2[j] + diff`.

Return *the **number of pairs** that satisfy the conditions.*

Example 1:

```
Input: nums1 = [3,2,5], nums2 = [2,2,1], diff = 1
Output: 3
Explanation:
There are 3 pairs that satisfy the conditions:
1. i = 0, j = 1: 3 - 2 <= 2 - 2 + 1. Since i < j and 1 <= 1, this pair satisfies the conditions.
2. i = 0, j = 2: 3 - 5 <= 2 - 1 + 1. Since i < j and -2 <= 2, this pair satisfies the conditions.
3. i = 1, j = 2: 2 - 5 <= 2 - 1 + 1. Since i < j and -3 <= 2, this pair satisfies the conditions.
Therefore, we return 3.
```

Example 2:

```
Input: nums1 = [3,-1], nums2 = [-2,2], diff = -1
Output: 0
Explanation:
Since there does not exist any pair that satisfies the conditions, we return 0.
```

Constraints:

- `n == nums1.length == nums2.length`
- `2 <= n <= 10^5`
- `-10^4 <= nums1[i], nums2[i] <= 10^4`
- `-10^4 <= diff <= 10^4`

SOLUTION (PYTHON 3)

Solution 1: Binary Indexed Tree

> **How to think about it**
>
> The inequality nums1[i]-nums2[i]≤ nums1[j]-nums2[j]+diff for i<j cannot be double-looped at n≤ 10^5. With v=a-b we count prior v_i≤ v_j+diff. After a shift, a Fenwick tree stores seen v. For each j from left to right, query the prefix up to v_j+diff, then insert v_j.

We can transform the inequality in the problem to nums1[i] - nums2[i] ≤ nums1[j] - nums2[j] + diff. Therefore, if we calculate the difference between the corresponding elements of the two arrays and get another array nums, the problem is transformed into finding the number of pairs in nums that satisfy nums[i] ≤ nums[j] + diff.

We can enumerate j from small to large, find out how many numbers before it satisfy nums[i] ≤ nums[j] + diff, and thus calculate the number of pairs. We can use a binary indexed tree to maintain the prefix sum, so we can find out how many numbers before it satisfy nums[i] ≤ nums[j] + diff in O(log n) time.

The time complexity is O(n × log n).

Python 3

```python
class BinaryIndexedTree:
    def __init__(self, n):
        self.n = n
        self.c = [0] * (n + 1)

    @staticmethod
    def lowbit(x):
        return x & -x

    def update(self, x, delta):
        while x <= self.n:
            self.c[x] += delta
            x += BinaryIndexedTree.lowbit(x)

    def query(self, x):
        s = 0
        while x:
            s += self.c[x]
            x -= BinaryIndexedTree.lowbit(x)
        return s

class Solution:
    def numberOfPairs(self, nums1: List[int], nums2: List[int], diff: int) -> int:
        tree = BinaryIndexedTree(10**5)
        ans = 0
        for a, b in zip(nums1, nums2):
            v = a - b
            ans += tree.query(v + diff + 40000)
            tree.update(v + 40000, 1)
        return ans
```

PATTERN 41 OF 41

Binary Indexed Tree (Fenwick Tree)

20 problems · 0 Easy · 10 Medium · 10 Hard

THE IDEA

A compact array that supports prefix sums and point updates in O(log n); the lowest set bit of an index says how many items it covers.

Signals: range sum query with updates, count of smaller numbers after self, reverse pairs, inversion counts.

A TEMPLATE TO KEEP IN YOUR HANDS (PYTHON)

```
tree = [0] * (n + 1)
def update(i, delta):                # 1-based index
    while i <= n:
        tree[i] += delta
        i += i & -i                  # jump to the next range that covers i
def prefix_sum(i):
    total = 0
    while i > 0:
        total += tree[i]
        i -= i & -i                  # strip the lowest set bit
    return total
```

1395. Count Number of Teams

Medium · Binary Indexed Tree, Segment Tree, Array, Dynamic Programming

leetcode.com/problems/count-number-of-teams

PROBLEM

There are `n` soldiers standing in a line. Each soldier is assigned a **unique** `rating` value.

You have to form a team of 3 soldiers amongst them under the following rules:

- Choose 3 soldiers with index (`i`, `j`, `k`) with rating (`rating[i]`, `rating[j]`, `rating[k]`).
- A team is valid if: (`rating[i] < rating[j] < rating[k]`) or (`rating[i] > rating[j] > rating[k]`) where (`0 <= i < j < k < n`).

Return the number of teams you can form given the conditions. (soldiers can be part of multiple teams).

Example 1:

```
Input: rating = [2,5,3,4,1]
Output: 3
Explanation: We can form three teams given the conditions. (2,3,4), (5,4,1), (5,3,1).
```

Example 2:

```
Input: rating = [2,1,3]
Output: 0
Explanation: We can't form any team given the conditions.
```

Example 3:

```
Input: rating = [1,2,3,4]
Output: 4
```

Constraints:

- `n == rating.length`
- `3 <= n <= 1000`
- `1 <= rating[i] <= 10^5`
- All the integers in `rating` are **unique**.

SOLUTIONS (PYTHON 3)

Solution 1: Enumerate Middle Element

How to think about it

Count strictly increasing or decreasing triples. n ≤ 1000 makes a triple loop cubic. Fix the middle rating b: l smaller values on the left times r larger on the right are the increasing teams; the complementary counts are the decreasing ones. Two linear scans per midpoint suffice.

We can enumerate each element rating[i] in the array rating as the middle element, then count the number of elements l that are smaller than it on the left, and the number of elements r that are larger than it on the right. The number of combat units with this element as the middle element is l × r + (i - l) × (n - i - 1 - r). We can add this to the answer.

The time complexity is $O(n^2)$, and the space complexity is O(1). Where n is the length of the array rating.

Python 3

```python
class Solution:
    def numTeams(self, rating: List[int]) -> int:
        ans, n = 0, len(rating)
        for i, b in enumerate(rating):
            l = sum(a < b for a in rating[:i])
            r = sum(c > b for c in rating[i + 1 :])
            ans += l * r
            ans += (i - l) * (n - i - 1 - r)
        return ans
```

Solution 2: Binary Indexed Tree

> **How to think about it**
>
> Scanning both sides per midpoint is $O(n^2)$. After discretizing, two Fenwick trees query "how many smaller on the left / larger on the right" in O(log n): every value starts in the right tree and moves left as i advances.

We can use two binary indexed trees to maintain the number of elements l that are smaller than each element on the left in the array rating, and the number of elements r that are larger than it on the right. Then count the number of combat units with this element as the middle element as l × r + (i - l) × (n - i - 1 - r), and add this to the answer.

The time complexity is O(n × log n), and the space complexity is O(n). Where n is the length of the array rating.

Python 3

```python
class BinaryIndexedTree:
    def __init__(self, n: int):
        self.n = n
        self.c = [0] * (n + 1)

    def update(self, x: int, v: int):
        while x <= self.n:
            self.c[x] += v
            x += x & -x

    def query(self, x: int) -> int:
        s = 0
        while x:
            s += self.c[x]
            x -= x & -x
        return s

class Solution:
    def numTeams(self, rating: List[int]) -> int:
        nums = sorted(set(rating))
        m = len(nums)
        tree1 = BinaryIndexedTree(m)
        tree2 = BinaryIndexedTree(m)
        for v in rating:
            x = bisect_left(nums, v) + 1
            tree2.update(x, 1)
        n = len(rating)
        ans = 0
        for i, v in enumerate(rating):
            x = bisect_left(nums, v) + 1
            tree1.update(x, 1)
            tree2.update(x, -1)
            l = tree1.query(x - 1)
            r = n - i - 1 - tree2.query(x)
            ans += l * r
            ans += (i - l) * (n - i - 1 - r)
        return ans
```

Solution 3: Recursion + Memoization

How to think about it

Fenwick trees need discretization. Memoizing by index, remaining picks, and direction counts increasing or decreasing completions: from i we try every later j that respects the order. O(n) states and O(n) transitions match the first method's bound, expressed as recursion.

Python 3 (written for this guide: the doocs page has no Python 3 version of this solution)

```python
from functools import cache

class Solution:
    def numTeams(self, rating: List[int]) -> int:
        n = len(rating)

        @cache
        def go(i: int, left: int, ascending: bool) -> int:
            # chains of `left` more soldiers after soldier i, all going up (or all going down)
            if left == 0:
                return 1
            total = 0
            for j in range(i + 1, n):
                if (rating[j] > rating[i]) == ascending:
                    total += go(j, left - 1, ascending)
            return total

        return sum(go(i, 2, True) + go(i, 2, False) for i in range(n))
```

```

1996. The Number of Weak Characters in the Game

Medium · Stack, Greedy, Array, Sorting, Monotonic Stack

leetcode.com/problems/the-number-of-weak-characters-in-the-game

★ **TOP 10 PROBLEM** in Binary Indexed Tree (Fenwick Tree): master this one first

PROBLEM

You are playing a game that contains multiple characters, and each of the characters has **two** main properties: **attack** and **defense**. You are given a 2D integer array `properties` where `properties[i] = [attack_i, defense_i]` represents the properties of the i^{th} character in the game.

A character is said to be **weak** if any other character has **both** attack and defense levels **strictly greater** than this character's attack and defense levels. More formally, a character `i` is said to be **weak** if there exists another character `j` where $attack_j > attack_i$ and $defense_j > defense_i$.

Return *the number of **weak** characters*.

Example 1:

```
Input: properties = [[5,5],[6,3],[3,6]]
Output: 0
Explanation: No character has strictly greater attack and defense than the other.
```

Example 2:

```
Input: properties = [[2,2],[3,3]]
Output: 1
Explanation: The first character is weak because the second character has a strictly greater attack and defense.
```

Example 3:

```
Input: properties = [[1,5],[10,4],[4,3]]
Output: 1
Explanation: The third character is weak because the second character has a strictly greater attack and defense.
```

Constraints:

- $2 <= properties.length <= 10^5$
- `properties[i].length == 2`
- $1 <= attack_i, defense_i <= 10^5$

SOLUTION (PYTHON 3)

Solution 1: Sorting + Traversal

How to think about it

A character is weak if another beats it in both attack and defense. Pairwise checks are quadratic. Sort by attack descending and defense ascending so earlier characters have strictly larger attack, or equal attack that cannot be a strict win. Track the maximum defense seen; a smaller current defense is weak.

We can sort all characters in descending order of attack power and ascending order of defense power.

Then, traverse all characters. For the current character, if its defense power is less than the previous maximum defense power, it is a weak character, and we increment the answer by one. Otherwise, update the maximum defense power.

After the traversal, we get the answer.

The time complexity is O(n × log n), and the space complexity is O(log n). Here, n is the number of characters.

Python 3

```python
class Solution:
    def numberOfWeakCharacters(self, properties: List[List[int]]) -> int:
        properties.sort(key=lambda x: (-x[0], x[1]))
        ans = mx = 0
        for _, x in properties:
            ans += x < mx
            mx = max(mx, x)
        return ans
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

Built on the solutions above: helper functions, then the function for each follow-up. No tests and no restating of the question.

```python
# FOLLOW-UPS (answered below, in this order):
# 1. Return which characters are weak
# 2. Count the strong characters (no character is stronger
# in both ways, but one is weaker in both)

# ============================================================
# FOLLOW-UP 1: Return which characters are weak
# ============================================================

# ---- follow-up 1: function ----
# Answer: Sort by attack descending (defence ascending for
# ties) and keep the biggest defence seen; a character
# with a smaller defence is weak.
# Time: O(n log n).  Space: O(n).
def weak_character_indices(properties):

        if properties[i][1] > smallest_defence:
            count += 1
        smallest_defence = min(smallest_defence, properties[i][1])
    return count
```

PATTERN 41 · BINARY INDEXED TREE (FENWICK TREE) · PROBLEM 9 OF 20

1626. Best Team With No Conflicts

Medium · Array, Dynamic Programming, Sorting, Longest Increasing Subsequence

leetcode.com/problems/best-team-with-no-conflicts

PROBLEM

You are the manager of a basketball team. For the upcoming tournament, you want to choose the team with the highest overall score. The score of the team is the **sum** of scores of all the players in the team.

However, the basketball team is not allowed to have **conflicts**. A **conflict** exists if a younger player has a **strictly higher** score than an older player. A conflict does **not** occur between players of the same age.

Given two lists, `scores` and `ages`, where each `scores[i]` and `ages[i]` represents the score and age of the i^{th} player, respectively, return *the highest overall score of all possible basketball teams*.

Example 1:

```
Input: scores = [1,3,5,10,15], ages = [1,2,3,4,5]
Output: 34
Explanation: You can choose all the players.
```

Example 2:

```
Input: scores = [4,5,6,5], ages = [2,1,2,1]
Output: 16
Explanation: It is best to choose the last 3 players. Notice that you are allowed to choose multiple people of the same age.
```

Example 3:

```
Input: scores = [1,2,3,5], ages = [8,9,10,1]
Output: 6
Explanation: It is best to choose the first 3 players.
```

Constraints:

- `1 <= scores.length, ages.length <= 1000`
- `scores.length == ages.length`
- `1 <= scores[i] <= 10^6`
- `1 <= ages[i] <= 1000`

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

A conflict is an older player with a strictly lower score. Sorting by score, then age, reduces the constraint to a nondecreasing age subsequence. With n ≤ 1000, the best score ending at a player is an $O(n^2)$ LIS-style DP: take the best f[j] among earlier players who are no older, then add the current score. The answer is the maximum f[i].

Python 3

```python
class Solution:
    def bestTeamScore(self, scores: List[int], ages: List[int]) -> int:
        arr = sorted(zip(scores, ages))
        n = len(arr)
        f = [0] * n
        for i, (score, age) in enumerate(arr):
            for j in range(i):
                if age >= arr[j][1]:
                    f[i] = max(f[i], f[j])
            f[i] += score
        return max(f)
```

Solution 2

How to think about it

Solution 1 scans every predecessor in $O(n^2)$. After the same sort we only need the best score among ages up to the current one — a prefix maximum. A Fenwick tree stores those maxima: query [1,age], add score, and update that age, for O(nlog m) time.

Python 3

```python
class BinaryIndexedTree:
    def __init__(self, n):
        self.n = n
        self.c = [0] * (n + 1)

    def update(self, x, val):
        while x <= self.n:
            self.c[x] = max(self.c[x], val)
            x += x & -x

    def query(self, x):
        s = 0
        while x:
            s = max(s, self.c[x])
            x -= x & -x
        return s

class Solution:
    def bestTeamScore(self, scores: List[int], ages: List[int]) -> int:
        m = max(ages)
        tree = BinaryIndexedTree(m)
        for score, age in sorted(zip(scores, ages)):
            tree.update(age, score + tree.query(age))
        return tree.query(m)
```

PATTERN 41 · BINARY INDEXED TREE (FENWICK TREE) · PROBLEM 14 OF 20

354. Russian Doll Envelopes

Hard · Array, Binary Search, Dynamic Programming, Sorting, Longest Increasing Subsequence

leetcode.com/problems/russian-doll-envelopes

★ **TOP 10 PROBLEM** in Binary Indexed Tree (Fenwick Tree): master this one first

PROBLEM

You are given a 2D array of integers `envelopes` where `envelopes[i] = [w_i, h_i]` represents the width and the height of an envelope.

One envelope can fit into another if and only if both the width and height of one envelope are greater than the other envelope's width and height.

Return *the maximum number of envelopes you can Russian doll (i.e., put one inside the other)*.

Note: You cannot rotate an envelope.

Example 1:

```
Input: envelopes = [[5,4],[6,4],[6,7],[2,3]]
Output: 3
Explanation: The maximum number of envelopes you can Russian doll is 3 ([2,3] => [5,4] => [6,7]).
```

Example 2:

```
Input: envelopes = [[1,1],[1,1],[1,1]]
Output: 1
```

Constraints:

- `1 <= envelopes.length <= 10^5`
- `envelopes[i].length == 2`
- `1 <= w_i, h_i <= 10^5`

SOLUTION (PYTHON 3)

Solution 1

How to think about it

An envelope nests only if both width and height increase; we want the longest chain. A 2D $O(n^2)$ LIS fails for $n \le 10^5$. After sorting by width, LIS on height is the answer; equal widths must not nest. Sort by width ascending and height descending, then greedy LIS on heights: append if larger than the tail, else binary-replace. Descending heights keep at most one envelope per width.

Python 3

```python
class Solution:
    def maxEnvelopes(self, envelopes: List[List[int]]) -> int:
        envelopes.sort(key=lambda x: (x[0], -x[1]))
        d = [envelopes[0][1]]
        for _, h in envelopes[1:]:
            if h > d[-1]:
                d.append(h)
            else:
                idx = bisect_left(d, h)
                d[idx] = h
        return len(d)
```

2659. Make Array Empty

Hard · Greedy, Binary Indexed Tree, Segment Tree, Array, Binary Search, Ordered Set, Sorting

leetcode.com/problems/make-array-empty

PROBLEM

You are given an integer array `nums` containing **distinct** numbers, and you can perform the following operations **until the array is empty**:

- If the first element has the **smallest** value, remove it
- Otherwise, put the first element at the **end** of the array.

Return *an integer denoting the number of operations it takes to make* `nums` *empty.*

Example 1:

```
Input: nums = [3,4,-1]
Output: 5
```

Operation	Array
1	[4, -1, 3]
2	[-1, 3, 4]
3	[3, 4]
4	[4]
5	[]

Example 2:

```
Input: nums = [1,2,4,3]
Output: 5
```

Operation	Array
1	[2, 4, 3]
2	[4, 3]
3	[3, 4]
4	[4]
5	[]

Example 3:

```
Input: nums = [1,2,3]
Output: 3
```

Operation	Array
1	[2, 3]
2	[3]
3	[]

Constraints:

- $1 <= nums.length <= 10^5$
- $-10^9 <= nums[i] <= 10^9$
- All values in `nums` are **distinct**.

SOLUTIONS (PYTHON 3)

Solution 1: Hash Table + Sorting + Fenwick Tree

> **How to think about it**
>
> Each step rotates left or deletes the current minimum. Simulating rotations fails for $n \le 10^5$. Deletions follow sorted order; the cost is the circular gap between consecutive minima minus already-deleted indices in between. Store original positions, sort the values, and keep deleted indices in an ordered list. The gap j-i drops the deleted count between them; if j wraps before i, add the remaining length of this round.

First, we use a hash table pos to record the position of each element in array nums. Then, we sort array nums. The initial answer is the position of the minimum element in array nums plus 1, which is ans = pos[nums[0]] + 1.

Next, we traverse the sorted array nums, the indexes of the two adjacent elements a and b are i = pos[a], j = pos[b]. The number of operations needed to move the second element b to the first position of the array and delete it is equal to the interval between the two indexes, minus the number of indexes deleted between the two indexes, and add the number of operations to the answer. We can use a Fenwick tree or an ordered list to maintain the deleted indexes between two indexes, so that we can find the number of deleted indexes between two indexes in O(log n) time. Note that if i > j, then we need to increase n - k operations, where k is the current position.

After the traversal is over, return the number of operations ans.

The time complexity is O(n × log n), and the space complexity is O(n). Where n is the length of array nums.

Python 3

```python
class Solution:
    def countOperationsToEmptyArray(self, nums: List[int]) -> int:
        pos = {x: i for i, x in enumerate(nums)}
        nums.sort()
        sl = SortedList()
        ans = pos[nums[0]] + 1
        n = len(nums)
        for k, (a, b) in enumerate(pairwise(nums)):
            i, j = pos[a], pos[b]
            d = j - i - sl.bisect(j) + sl.bisect(i)
            ans += d + (n - k) * int(i > j)
            sl.add(i)
        return ans
```

Solution 2

> **How to think about it**
>
> Solution 1 queries deleted counts in an ordered set. A Fenwick tree offers the same prefix counts: after shifting indices by one, `query(j+1)-query(i+1)` is the deleted amount, and an update is a point add. The wrap-around logic is unchanged.

Python 3

```
class BinaryIndexedTree:
    def __init__(self, n):
        self.n = n
        self.c = [0] * (n + 1)

    def update(self, x, delta):
        while x <= self.n:
            self.c[x] += delta
            x += x & -x

    def query(self, x):
        s = 0
        while x:
            s += self.c[x]
            x -= x & -x
        return s

class Solution:
    def countOperationsToEmptyArray(self, nums: List[int]) -> int:
        pos = {x: i for i, x in enumerate(nums)}
        nums.sort()
        ans = pos[nums[0]] + 1
        n = len(nums)
        tree = BinaryIndexedTree(n)
        for k, (a, b) in enumerate(pairwise(nums)):
            i, j = pos[a], pos[b]
            d = j - i - tree.query(j + 1) + tree.query(i + 1)
            ans += d + (n - k) * int(i > j)
            tree.update(i + 1, 1)
        return ans
```

Complexity. Time: O(n log n). Space: O(n).

2179. Count Good Triplets in an Array

Hard · Binary Indexed Tree, Segment Tree, Array, Binary Search, Divide and Conquer, Ordered Set, Merge Sort

leetcode.com/problems/count-good-triplets-in-an-array

★ **TOP 10 PROBLEM** in Binary Indexed Tree (Fenwick Tree): master this one first

PROBLEM

You are given two **0-indexed** arrays `nums1` and `nums2` of length `n`, both of which are **permutations** of `[0, 1, ..., n - 1]`.

A **good triplet** is a set of `3` **distinct** values which are present in **increasing order** by position both in `nums1` and `nums2`. In other words, if we consider $pos1_v$ as the index of the value `v` in `nums1` and $pos2_v$ as the index of the value `v` in `nums2`, then a good triplet will be a set `(x, y, z)` where `0 <= x, y, z <= n - 1`, such that $pos1_x < pos1_y < pos1_z$ and $pos2_x < pos2_y < pos2_z$.

Return *the **total number** of good triplets*.

Example 1:

```
Input: nums1 = [2,0,1,3], nums2 = [0,1,2,3]
Output: 1
Explanation:
There are 4 triplets (x,y,z) such that pos1x < pos1y < pos1z. They are (2,0,1), (2,0,3), (2,1,3), and (0,1,3).
Out of those triplets, only the triplet (0,1,3) satisfies pos2x < pos2y < pos2z. Hence, there is only 1 good triplet.
```

Example 2:

```
Input: nums1 = [4,0,1,3,2], nums2 = [4,1,0,2,3]
Output: 4
Explanation: The 4 good triplets are (4,0,3), (4,0,2), (4,1,3), and (4,1,2).
```

Constraints:

- `n == nums1.length == nums2.length`
- `3 <= n <= 10^5`
- `0 <= nums1[i], nums2[i] <= n - 1`
- `nums1` and `nums2` are permutations of `[0, 1, ..., n - 1]`.

SOLUTIONS (PYTHON 3)

Solution 1: Binary Indexed Tree (Fenwick Tree)

How to think about it

A good triplet has the same relative order in both permutations. Enumerating triples is $O(n^3)$ and fails for $n \le 10^5$. With the middle value fixed, the left count is how many already seen in nums1 sit earlier in nums2; the right count is the symmetric unseen suffix. Walk nums1, query a Fenwick tree at the nums2 position for the prefix count and the unused suffix, and add the product. Positions are 1-based; update after each value.

For this problem, we first use `pos` to record the position of each number in `nums2`, and then process each element in `nums1` sequentially.

Consider the number of good triplets **with the current number as the middle number**. The first number must have already been traversed and must appear earlier than the current number in `nums2`. The third number must not yet have been traversed and must appear later than the current number in `nums2`.

Take `nums1 = [4,0,1,3,2]` and `nums2 = [4,1,0,2,3]` as an example. Consider the traversal process:

1. First, process `4`. At this point, the state of `nums2` is `[4,X,X,X,X]`. The number of values before `4` is `0`, and the number of values after `4` is `4`. Therefore, `4` as the middle number forms `0` good triplets.
2. Next, process `0`. The state of `nums2` becomes `[4,X,0,X,X]`. The number of values before `0` is `1`, and the number of values after `0` is `2`. Therefore, `0` as the middle number forms `2` good triplets.
3. Next, process `1`. The state of `nums2` becomes `[4,1,0,X,X]`. The number of values before `1` is `1`, and the number of values after `1` is `2`. Therefore, `1` as the middle number forms `2` good triplets.
4. ...
5. Finally, process `2`. The state of `nums2` becomes `[4,1,0,2,3]`. The number of values before `2` is `4`, and the number of values after `2` is `0`. Therefore, `2` as the middle number forms `0` good triplets.

We can use a **Binary Indexed Tree (Fenwick Tree)** to update the occurrence of numbers at each position in `nums2`, and quickly calculate the number of `1`s to the left of each number and the number of `0`s to the right of each number.

A Binary Indexed Tree, also known as a Fenwick Tree, efficiently supports the following operations:

1. **Point Update** `update(x, delta)`: Add a value `delta` to the number at position `x` in the sequence.
2. **Prefix Sum Query** `query(x)`: Query the sum of the sequence in the range `[1, ..., x]`, i.e., the prefix sum at position `x`.

Both operations have a time complexity of O(log n). Therefore, the overall time complexity is O(n log n), where n is the length of the array nums1. The space complexity is O(n).

Python 3

```python
class BinaryIndexedTree:
    def __init__(self, n):
        self.n = n
        self.c = [0] * (n + 1)

    @staticmethod
    def lowbit(x):
        return x & -x

    def update(self, x, delta):
        while x <= self.n:
            self.c[x] += delta
            x += BinaryIndexedTree.lowbit(x)

    def query(self, x):
        s = 0
        while x > 0:
            s += self.c[x]
            x -= BinaryIndexedTree.lowbit(x)
        return s

class Solution:
    def goodTriplets(self, nums1: List[int], nums2: List[int]) -> int:
        pos = {v: i for i, v in enumerate(nums2, 1)}
        ans = 0
        n = len(nums1)
        tree = BinaryIndexedTree(n)
        for num in nums1:
            p = pos[num]
            left = tree.query(p)
            right = n - p - (tree.query(n) - tree.query(p))
            ans += left * right
            tree.update(p, 1)
        return ans
```

Solution 2: Segment Tree

> **How to think about it**
>
> Solution 1 stores prefix insertion counts in a Fenwick tree. A segment tree with point adds and range sums supports the same queries at the same asymptotic cost. Each node stores how many values in its interval have appeared; query [1,p] and the unused count of (p,n], add the product, then increment that point. The write-up records the segment-tree implementation.

We can also use a segment tree to solve this problem. A segment tree is a data structure that efficiently supports range queries and updates. The basic idea is to divide an interval into multiple subintervals, with each subinterval represented by a node.

The segment tree divides the entire interval into multiple non-overlapping subintervals, with the number of subintervals not exceeding `log(width)`. To update the value of an element, we only need to update `log(width)` intervals, all of which are contained within a larger interval that includes the element.

- Each node of the segment tree represents an interval.
- The segment tree has a unique root node, representing the entire range, such as `[1, N]`.
- Each leaf node of the segment tree represents a unit interval `[x, x]`.
- For each internal node `[l, r]`, its left child represents `[l, mid]`, and its right child represents `[mid + 1, r]`, where `mid = ⌊(l + r) / 2⌋` (floor division).

The time complexity is O(n log n), where n is the length of the array nums1. The space complexity is O(n).

Python 3

```python
class Node:
    __slots__ = ("l", "r", "v")

    def __init__(self):
        self.l = 0
        self.r = 0
        self.v = 0

class SegmentTree:
    def __init__(self, n):
        self.tr = [Node() for _ in range(4 * n)]
        self.build(1, 1, n)

    def build(self, u, l, r):
        self.tr[u].l = l
        self.tr[u].r = r
        if l == r:
            return
        mid = (l + r) >> 1
        self.build(u << 1, l, mid)
        self.build(u << 1 | 1, mid + 1, r)

    def modify(self, u, x, v):
        if self.tr[u].l == x and self.tr[u].r == x:
            self.tr[u].v += v
            return
        mid = (self.tr[u].l + self.tr[u].r) >> 1
        if x <= mid:
            self.modify(u << 1, x, v)
        else:
            self.modify(u << 1 | 1, x, v)
        self.pushup(u)

    def pushup(self, u):
        self.tr[u].v = self.tr[u << 1].v + self.tr[u << 1 | 1].v

    def query(self, u, l, r):
        if self.tr[u].l >= l and self.tr[u].r <= r:
            return self.tr[u].v
        mid = (self.tr[u].l + self.tr[u].r) >> 1
        v = 0
        if l <= mid:
            v += self.query(u << 1, l, r)
        if r > mid:
            v += self.query(u << 1 | 1, l, r)
        return v

2926. Maximum Balanced Subsequence Sum

Hard · Binary Indexed Tree, Segment Tree, Array, Binary Search, Dynamic Programming

leetcode.com/problems/maximum-balanced-subsequence-sum

PROBLEM

You are given a **0-indexed** integer array `nums`.

A **subsequence** of `nums` having length `k` and consisting of **indices** $i_0 < i_1 < \ldots < i_{k-1}$ is **balanced** if the following holds:

- $nums[i_j] - nums[i_{j-1}] >= i_j - i_{j-1}$, for every j in the range `[1, k - 1]`.

A **subsequence** of `nums` having length `1` is considered balanced.

Return *an integer denoting the **maximum** possible **sum of elements** in a **balanced** subsequence of* `nums`.

A **subsequence** of an array is a new **non-empty** array that is formed from the original array by deleting some (**possibly none**) of the elements without disturbing the relative positions of the remaining elements.

Example 1:

```
Input: nums = [3,3,5,6]
Output: 14
Explanation: In this example, the subsequence [3,5,6] consisting of indices 0, 2, and 3 can be
selected.
nums[2] - nums[0] >= 2 - 0.
nums[3] - nums[2] >= 3 - 2.
Hence, it is a balanced subsequence, and its sum is the maximum among the balanced subsequences of
nums.
The subsequence consisting of indices 1, 2, and 3 is also valid.
It can be shown that it is not possible to get a balanced subsequence with a sum greater than 14.
```

Example 2:

```
Input: nums = [5,-1,-3,8]
Output: 13
Explanation: In this example, the subsequence [5,8] consisting of indices 0 and 3 can be selected.
nums[3] - nums[0] >= 3 - 0.
Hence, it is a balanced subsequence, and its sum is the maximum among the balanced subsequences of
nums.
It can be shown that it is not possible to get a balanced subsequence with a sum greater than 13.
```

Example 3:

```
Input: nums = [-2,-1]
Output: -1
Explanation: In this example, the subsequence [-1] can be selected.
It is a balanced subsequence, and its sum is the maximum among the balanced subsequences of nums.
```

Constraints:

- $1 <= nums.length <= 10^5$
- $-10^9 <= nums[i] <= 10^9$

SOLUTION (PYTHON 3)

Solution 1: Dynamic Programming + Binary Indexed Tree

How to think about it

Balance nums[i]-nums[j] ≥ i-j rewrites as nums[i]-i ≥ nums[j]-j. On arr[t]=nums[t]-t we want a nondecreasing index sequence maximizing the sum of nums. The naive f[i]=nums[i]+max$_{j<i,\ arr[j]\le arr[i]}$ f[j] (or just nums[i]) is O(n^2) for n ≤ 10^5. After compressing arr, a Fenwick tree stores the best f among values up to a threshold. Scan in index order, query, then insert; a final prefix maximum is the answer.

According to the problem description, we can transform the inequality nums[i] - nums[j] ≥ i - j into nums[i] - i ≥ nums[j] - j. Therefore, we consider defining a new array arr, where arr[i] = nums[i] - i. A balanced subsequence satisfies that for any j < i, arr[j] ≤ arr[i]. The problem is transformed into selecting an increasing subsequence in arr such that the corresponding sum in nums is maximized.

Suppose i is the index of the last element in the subsequence, then we consider the index j of the second to last element in the subsequence. If arr[j] ≤ arr[i], we can consider whether to add j to the subsequence.

Therefore, we define f[i] as the maximum sum of nums when the index of the last element in the subsequence is i. The answer is max$_{i=0}^{n-1}$ f[i].

The state transition equation is:

$$f[i] = \max(\max_{j=0}^{i-1} f[j], 0) + nums[i]$$

where j satisfies arr[j] ≤ arr[i].

We can use a Binary Indexed Tree to maintain the maximum value of the prefix, i.e., for each arr[i], we maintain the maximum value of f[i] in the prefix arr[0..i].

The time complexity is O(n × log n), and the space complexity is O(n). Here, n is the length of the array nums.

Python 3

```python
class BinaryIndexedTree:
    def __init__(self, n: int):
        self.n = n
        self.c = [-inf] * (n + 1)

    def update(self, x: int, v: int):
        while x <= self.n:
            self.c[x] = max(self.c[x], v)
            x += x & -x

    def query(self, x: int) -> int:
        mx = -inf
        while x:
            mx = max(mx, self.c[x])
            x -= x & -x
        return mx

class Solution:
    def maxBalancedSubsequenceSum(self, nums: List[int]) -> int:
        arr = [x - i for i, x in enumerate(nums)]
        s = sorted(set(arr))
        tree = BinaryIndexedTree(len(s))
        for i, x in enumerate(nums):
            j = bisect_left(s, x - i) + 1
            v = max(tree.query(j), 0) + x
            tree.update(j, v)
        return tree.query(len(s))
```

1862. Sum of Floored Pairs

Hard · Array, Math, Binary Search, Counting, Enumeration, Prefix Sum

leetcode.com/problems/sum-of-floored-pairs

PROBLEM

Given an integer array `nums`, return the sum of `floor(nums[i] / nums[j])` for all pairs of indices `0 <= i, j < nums.length` in the array. Since the answer may be too large, return it **modulo** $10^9 + 7$.

The `floor()` function returns the integer part of the division.

Example 1:

```
Input: nums = [2,5,9]
Output: 10
Explanation:
floor(2 / 5) = floor(2 / 9) = floor(5 / 9) = 0
floor(2 / 2) = floor(5 / 5) = floor(9 / 9) = 1
floor(5 / 2) = 2
floor(9 / 2) = 4
floor(9 / 5) = 1
We calculate the floor of the division for every pair of indices in the array then sum them up.
```

Example 2:

```
Input: nums = [7,7,7,7,7,7,7]
Output: 49
```

Constraints:

- `1 <= nums.length <=` 10^5
- `1 <= nums[i] <=` 10^5

SOLUTION (PYTHON 3)

Solution 1: Prefix Sum of Value Range + Optimized Enumeration

How to think about it

We need $\sum_{i,j}$floor(nums[i]/nums[j]). Pair enumeration is $O(n^2)$ and too slow for n≤ 10^5. Values are at most 10^5, so build a prefix of frequencies. For each denominator y and quotient d, the count of numerators in [dy,dy+y) is a prefix difference, multiplied by cnt[y]· d. The harmonic enumeration is O(Mlog M).

First, we count the occurrences of each element in the array nums and record them in the array cnt. Then, we calculate the prefix sum of the array cnt and record it in the array s, i.e., s[i] represents the count of elements less than or equal to i.

Next, we enumerate the denominator y and the quotient d. Using the prefix sum array, we can calculate the count of the numerator s[min(mx, d × y + y - 1)] - s[d × y - 1], where mx represents the maximum value in the array nums. Then, we multiply the count of the numerator by the count of the denominator cnt[y], and then multiply by the quotient d. This gives us the value of all fractions that meet the conditions. By summing these values, we can get the answer.

The time complexity is O(M × log M), and the space complexity is O(M). Here, M is the maximum value in the array nums.

Python 3

```
class Solution:
    def sumOfFlooredPairs(self, nums: List[int]) -> int:
        mod = 10**9 + 7
        cnt = Counter(nums)
        mx = max(nums)
        s = [0] * (mx + 1)
        for i in range(1, mx + 1):
            s[i] = s[i - 1] + cnt[i]
        ans = 0
        for y in range(1, mx + 1):
            if cnt[y]:
                d = 1
                while d * y <= mx:
                    ans += cnt[y] * d * (s[min(mx, d * y + y - 1)] - s[d * y - 1])
                    ans %= mod
                    d += 1
        return ans
```

```

PATTERN 41 · BINARY INDEXED TREE (FENWICK TREE) · PROBLEM 20 OF 20

3187. Peaks in Array

Hard · Binary Indexed Tree, Segment Tree, Array

leetcode.com/problems/peaks-in-array

PROBLEM

A **peak** in an array `arr` is an element that is **greater** than its previous and next element in `arr`.

You are given an integer array `nums` and a 2D integer array `queries`.

You have to process queries of two types:

- `queries[i] = [1, l_i, r_i]`, determine the count of **peak** elements in the subarray `nums[l_i..r_i]`. notionvc: 73b20b7c-e1ab-4dac-86d0-13761094a9ae
- `queries[i] = [2, index_i, val_i]`, change `nums[index_i]` to `val_i`.

Return an array `answer` containing the results of the queries of the first type in order. notionvc: a9ccef22-4061-4b5a-b4cc-a2b2a0e12f30

Notes:

- The **first** and the **last** element of an array or a subarray notionvc: fcffef72-deb5-47cb-8719-3a3790102f73 **cannot** be a peak.

Example 1:

Input: nums = [3,1,4,2,5], queries = [[2,3,4],[1,0,4]]

Output: [0]

Explanation:

First query: We change `nums[3]` to 4 and `nums` becomes `[3,1,4,4,5]`.

Second query: The number of peaks in the `[3,1,4,4,5]` is 0.

Example 2:

Input: nums = [4,1,4,2,1,5], queries = [[2,2,4],[1,0,2],[1,0,4]]

Output: [0,1]

Explanation:

First query: `nums[2]` should become 4, but it is already set to 4.

Second query: The number of peaks in the `[4,1,4]` is 0.

Third query: The second 4 is a peak in the `[4,1,4,2,1]`.

Constraints:

- `3 <= nums.length <= 10^5`
- `1 <= nums[i] <= 10^5`
- `1 <= queries.length <= 10^5`
- `queries[i][0] == 1` or `queries[i][0] == 2`
- For all `i` that:
  - `queries[i][0] == 1: 0 <= queries[i][1] <= queries[i][2] <= nums.length - 1`
  - `queries[i][0] == 2: 0 <= queries[i][1] <= nums.length - 1, 1 <= queries[i][2] <= 10^5`

SOLUTION (PYTHON 3)

Solution 1: Binary Indexed Tree

How to think about it

A peak is an interior index strictly above both neighbors. Range peak counts plus point updates make rebuilding O(nq). Peaks are 0/1 indicators, so a Fenwick tree range-sums them. An assignment at idx only changes peaks at idx-1,idx,idx+1. Insert the initial peaks. A query sums (l+1,r-1). An update subtracts the three old flags, writes the new value, and adds the new flags.

According to the problem description, for $0 < i < n - 1$, if it satisfies $nums[i - 1] < nums[i]$ and $nums[i] > nums[i + 1]$, we can consider $nums[i]$ as 1, otherwise as 0. Thus, for operation 1, i.e., querying the number of peak elements in the subarray $nums[l..r]$, it is equivalent to querying the number of 1s in the interval $[l + 1, r - 1]$. We can use a binary indexed tree to maintain the number of 1s in the interval $[1, n - 1]$.

For operation 1, i.e., updating $nums[idx]$ to val, it will only affect the values at positions $idx - 1$, idx, and $idx + 1$, so we only need to update these three positions. Specifically, we can first remove the peak elements at these three positions, then update the value of $nums[idx]$, and finally add back the peak elements at these three positions.

The time complexity is $O((n + q) \times \log n)$, and the space complexity is $O(n)$. Here, n and q are the lengths of the array `nums` and the query array `queries`, respectively.

Python 3

```python
class BinaryIndexedTree:
    __slots__ = "n", "c"

    def __init__(self, n: int):
        self.n = n
        self.c = [0] * (n + 1)

    def update(self, x: int, delta: int) -> None:
        while x <= self.n:
            self.c[x] += delta
            x += x & -x

    def query(self, x: int) -> int:
        s = 0
        while x:
            s += self.c[x]
            x -= x & -x
        return s

class Solution:
    def countOfPeaks(self, nums: List[int], queries: List[List[int]]) -> List[int]:
        def update(i: int, val: int):
            if i <= 0 or i >= n - 1:
                return
            if nums[i - 1] < nums[i] and nums[i] > nums[i + 1]:
                tree.update(i, val)

        n = len(nums)
        tree = BinaryIndexedTree(n - 1)
        for i in range(1, n - 1):
            update(i, 1)
        ans = []
        for q in queries:
            if q[0] == 1:
                l, r = q[1] + 1, q[2] - 1
                ans.append(0 if l > r else tree.query(r) - tree.query(l - 1))
            else:
                idx, val = q[1:]
                for i in range(idx - 1, idx + 2):
                    update(i, -1)
                nums[idx] = val
                for i in range(idx - 1, idx + 2):
                    update(i, 1)
        return ans
```

PART 2

Extra Topics and More Practice

Fill the gaps: the rest of AlgoMaster's 600 problems

- 50 topic groups with 210 more problems that are not in Part 1, each on its own page with the statement, figures, Python 3 solutions and follow-up code.
- The groups follow AlgoMaster's 600 list (arrays, strings, linked lists, trees, graphs, shortest path, spanning trees, many kinds of DP, tries, line sweep ...).
- Each group page has a short note and lists the group's problems; it also shows which problems of the group are already in Part 1, with a link.
- Use it for the topics that Part 1 does not teach (minimum spanning tree, Eulerian paths, bitmask / digit / probability DP, tree DP) and for extra reps on the rest.

PART 2 · ARRAYS · PROBLEM 1 OF 9

163. Missing Ranges

Easy · Array

leetcode.com/problems/missing-ranges

★ **TOP 10 PROBLEM** in Arrays: master this one first

PROBLEM

You are given an inclusive range `[lower, upper]` and a **sorted unique** integer array `nums`, where all elements are within the inclusive range.

A number `x` is considered **missing** if `x` is in the range `[lower, upper]` and `x` is not in `nums`.

Return *the **shortest sorted** list of ranges that **exactly covers all the missing numbers***. That is, no element of `nums` is included in any of the ranges, and each missing number is covered by one of the ranges.

Example 1:

```
Input: nums = [0,1,3,50,75], lower = 0, upper = 99
Output: [[2,2],[4,49],[51,74],[76,99]]
Explanation: The ranges are:
[2,2]
[4,49]
[51,74]
[76,99]
```

Example 2:

```
Input: nums = [-1], lower = -1, upper = -1
Output: []
Explanation: There are no missing ranges since there are no missing numbers.
```

Constraints:

- -10^9 <= lower <= upper <= 10^9
- 0 <= nums.length <= 100
- lower <= nums[i] <= upper
- All the values of `nums` are **unique**.

SOLUTION (PYTHON 3)

Solution 1: Simulation

How to think about it

Report the ranges in [lower,upper] that nums does not cover. The array is sorted, distinct, and of length at most 100, so we simulate the gaps: before the first value, between neighbors, and after the last. A difference greater than 1 is a missing range.

We can simulate the problem directly according to the requirements.

The time complexity is O(n), where n is the length of the array nums. Ignoring the space consumption of the answer, the space complexity is O(1).

Python 3

```python
class Solution:
    def findMissingRanges(
        self, nums: List[int], lower: int, upper: int
    ) -> List[List[int]]:
        n = len(nums)
        if n == 0:
            return [[lower, upper]]
        ans = []
        if nums[0] > lower:
            ans.append([lower, nums[0] - 1])
        for a, b in pairwise(nums):
            if b - a > 1:
                ans.append([a + 1, b - 1])
        if nums[-1] < upper:
            ans.append([nums[-1] + 1, upper])
        return ans
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

# Time: O(n).  Space: O(1).
def count_missing_numbers(nums, lower, upper):
    total = 0
    previous = lower - 1
    for x in nums + [upper + 1]:
        total += max(0, x - previous - 1)
        previous = x
    return total
```

PART 2 · ARRAYS · PROBLEM 2 OF 9

169. Majority Element

Easy · Array, Hash Table, Divide and Conquer, Counting, Sorting, Boyer-Moore Voting

leetcode.com/problems/majority-element

★ **TOP 10 PROBLEM** in Arrays: master this one first

PROBLEM

Given an array `nums` of size `n`, return *the majority element*.

The majority element is the element that appears more than `⌊n / 2⌋` times. You may assume that the majority element always exists in the array.

Example 1:

```
Input: nums = [3,2,3]
Output: 3
```

Example 2:

```
Input: nums = [2,2,1,1,1,2,2]
Output: 2
```

Constraints:

- `n == nums.length`
- `1 <= n <= 5 * 10^4`
- `-10^9 <= nums[i] <= 10^9`
- The input is generated such that a majority element will exist in the array.

Follow-up:

Could you solve the problem in linear time and in

`O(1)`

space?

SOLUTION (PYTHON 3)

Solution 1: Moore Voting Algorithm

How to think about it

The majority value appears more than floor(n/2) times and is guaranteed. Counting or sorting works; the follow-up wants O(n) time and O(1) space. n≤ 5× 10^4. Boyer–Moore cancels distinct values in pairs. When the counter hits zero we change candidate. The majority cannot be fully cancelled, so the candidate after one pass is the answer; a second pass is unnecessary.

The basic steps of the Moore voting algorithm are as follows:

Initialize the element m and initialize the counter cnt = 0. Then, for each element x in the input list:

1. If cnt = 0, then m = x and cnt = 1;
1. Otherwise, if m = x, then cnt = cnt + 1, otherwise cnt = cnt - 1.

In general, the Moore voting algorithm requires **two passes** over the input list. In the first pass, we generate the candidate value m, and if there is a majority, the candidate value is the majority value. In the second pass, we simply compute the frequency of the candidate value to confirm whether it is the majority value. Since this problem has clearly stated that there is a majority value, we can directly return m after the first pass, without the need for a second pass to confirm whether it is the majority value.

The time complexity is O(n), where n is the length of the array nums. The space complexity is O(1).

Python 3

```python
class Solution:
    def majorityElement(self, nums: List[int]) -> int:
        cnt = m = 0
        for x in nums:
            if cnt == 0:
                m, cnt = x, 1
            else:
                cnt += 1 if m == x else -1
        return m
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

Built on the solutions above: helper functions, then the function for each follow-up. No tests and no restating of the question.

```python
# FOLLOW-UPS (answered below, in this order):
# 1. The majority element may not exist: return None then
# 2. Elements that appear more than n / k times

# ============================================================
# FOLLOW-UP 1: The majority element may not exist: return
# None then
# ============================================================

# ---- follow-up 1: function ----
# Answer: Boyer-Moore finds a candidate; a second pass
# checks that it really appears more than n / 2 times.
# Time: O(n).  Space: O(1).
def majority_or_none(nums):
    candidate = None
    count = 0
    for x in nums:
        if count == 0:
            candidate = x
        count += 1 if x == candidate else -1
    if nums.count(candidate) > len(nums) // 2:
        return candidate
    return None

# ============================================================
# FOLLOW-UP 2: Elements that appear more than n / k times
# ============================================================

# ---- follow-up 2: function ----
# Answer: Boyer-Moore generalised (Misra-Gries): keep at
# most k - 1 counters, and decrease all of them when there
# is no room.
# Time: O(n * k).  Space: O(k).
def more_than_n_over_k(nums, k):
    counters = {}
    for x in nums:
        if x in counters:
            counters[x] += 1
        elif len(counters) < k - 1:
            counters[x] = 1
        else:
            for key in list(counters):
                counters[key] -= 1
                if counters[key] == 0:
                    del counters[key]
    result = []
    for candidate in counters:
        if nums.count(candidate) > len(nums) // k:
            result.append(candidate)
```

```
    return result
```

414. Third Maximum Number

Easy · Array, Sorting

leetcode.com/problems/third-maximum-number

★ **TOP 10 PROBLEM** in Arrays: master this one first

PROBLEM

You are given an integer array `nums`.

Return the **third distinct maximum** number in this array. If the third **maximum** does not exist, return the **maximum** number.

Example 1:

```
Input: nums = [3,2,1]
Output: 1
Explanation:
The first distinct maximum is 3.
The second distinct maximum is 2.
The third distinct maximum is 1.
```

Example 2:

```
Input: nums = [1,2]
Output: 2
Explanation:
The first distinct maximum is 2.
The second distinct maximum is 1.
The third distinct maximum does not exist, so the maximum (2) is returned instead.
```

Example 3:

```
Input: nums = [2,2,3,1]
Output: 1
Explanation:
The first distinct maximum is 3.
The second distinct maximum is 2 (both 2's are counted together since they have the same value).
The third distinct maximum is 1.
```

Constraints:

- $1 \le nums.length \le 10^4$
- $-2^{31} \le nums[i] \le 2^{31} - 1$

Follow up:

Can you find an

$O(n)$

solution?

SOLUTION (PYTHON 3)

Solution 1: Single Pass

> **How to think about it**
>
> We need the third distinct maximum. Sorting and unique-ing works, but the follow-up asks for a linear scan and constant extra memory. Keep $m_1 > m_2 > m_3$, skip a value already stored, and shift the triple when inserting. If m_3 stays at the sentinel, fewer than three distinct values exist and the maximum is the answer. Duplicates must be skipped, or one number would occupy all three slots.

We can use three variables m_1, m_2, and m_3 to represent the first, second, and third largest numbers in the array respectively. Initially, we set these three variables to negative infinity.

Then, we iterate through each number in the array. For each number:

- If it equals any of m_1, m_2, or m_3, we skip this number.
- If it is greater than m_1, we update the values of m_1, m_2, and m_3 to m_2, m_3, and this number respectively.
- If it is greater than m_2, we update the values of m_2 and m_3 to m_3 and this number respectively.
- If it is greater than m_3, we update the value of m_3 to this number.

Finally, if the value of m_3 has not been updated, it means that there is no third largest number in the array, so we return m_1. Otherwise, we return m_3.

The time complexity is O(n), where n is the length of the array `nums`. The space complexity is O(1).

Python 3

```python
class Solution:
    def thirdMax(self, nums: List[int]) -> int:
        m1 = m2 = m3 = -inf
        for num in nums:
            if num in [m1, m2, m3]:
                continue
            if num > m1:
                m3, m2, m1 = m2, m1, num
            elif num > m2:
                m3, m2 = m2, num
            elif num > m3:
                m3 = num
        return m3 if m3 != -inf else m1
```

PART 2 · ARRAYS · PROBLEM 4 OF 9

485. Max Consecutive Ones

Easy · Array

leetcode.com/problems/max-consecutive-ones

★ **TOP 10 PROBLEM** in Arrays: master this one first

PROBLEM

Given a binary array `nums`, return *the maximum number of consecutive* `1`*'s in the array*.

Example 1:

```
Input: nums = [1,1,0,1,1,1]
Output: 3
Explanation: The first two digits or the last three digits are consecutive 1s. The maximum number of consecutive 1s is 3.
```

Example 2:

```
Input: nums = [1,0,1,1,0,1]
Output: 2
```

Constraints:

- `1 <= nums.length <= 10^5`
- `nums[i]` is either `0` or `1`.

SOLUTION (PYTHON 3)

Solution 1: Single Pass

How to think about it

Longest run of ones. Checking every subarray is $O(n^2)$; one scan is enough. A 1 grows the current run and updates the answer; a 0 resets the counter. Zeros separate runs, so the counter never joins two blocks.

We can iterate through the array, using a variable cnt to record the current number of consecutive 1s, and another variable ans to record the maximum number of consecutive 1s.

When we encounter a 1, we increment cnt by one, and then update ans to be the maximum of cnt and ans itself, i.e., ans = max(ans, cnt). Otherwise, we reset cnt to 0.

After the iteration ends, we return the value of ans.

The time complexity is O(n), where n is the length of the array. The space complexity is O(1).

Python 3

```python
class Solution:
    def findMaxConsecutiveOnes(self, nums: List[int]) -> int:
        ans = cnt = 0
        for x in nums:
            if x:
                cnt += 1
                ans = max(ans, cnt)
            else:
                cnt = 0
        return ans
```

```

1470. Shuffle the Array

Easy · Array

leetcode.com/problems/shuffle-the-array

★ **TOP 10 PROBLEM** in Arrays: master this one first

PROBLEM

Given the array `nums` consisting of `2n` elements in the form $[x_1,x_2,...,x_n,y_1,y_2,...,y_n]$.

Return the array in the form $[x_1,y_1,x_2,y_2,...,x_n,y_n]$.

Example 1:

```
Input: nums = [2,5,1,3,4,7], n = 3
Output: [2,3,5,4,1,7]
Explanation: Since x1=2, x2=5, x3=1, y1=3, y2=4, y3=7 then the answer is [2,3,5,4,1,7].
```

Example 2:

```
Input: nums = [1,2,3,4,4,3,2,1], n = 4
Output: [1,4,2,3,3,2,4,1]
```

Example 3:

```
Input: nums = [1,1,2,2], n = 2
Output: [1,2,1,2]
```

Constraints:

- `1 <= n <= 500`
- `nums.length == 2n`
- `1 <= nums[i] <= 10^3`

SOLUTION (PYTHON 3)

Solution 1: Simulation

How to think about it

Interleave $[x_1,...,x_n]$ with $[y_1,...,y_n]$. Zip the two halves and flatten.

We traverse the indices i in the range [0, n). Each time, we take nums[i] and nums[i+n] and place them sequentially into the answer array.

After the traversal is complete, we return the answer array.

The time complexity is O(n), and the space complexity is O(n). Here, n is the length of the array nums.

Python 3

```python
class Solution:
    def shuffle(self, nums: List[int], n: int) -> List[int]:
        return [x for pair in zip(nums[:n], nums[n:]) for x in pair]
```

```

31. Next Permutation

Medium · Array, Two Pointers

leetcode.com/problems/next-permutation

★ **TOP 10 PROBLEM** in Arrays: master this one first

PROBLEM

A **permutation** of an array of integers is an arrangement of its members into a sequence or linear order.

- For example, for `arr = [1,2,3]`, the following are all the permutations of `arr`: `[1,2,3]`, `[1,3,2]`, `[2, 1, 3]`, `[2, 3, 1]`, `[3,1,2]`, `[3,2,1]`.

The **next permutation** of an array of integers is the next lexicographically greater permutation of its integer. More formally, if all the permutations of the array are sorted in one container according to their lexicographical order, then the **next permutation** of that array is the permutation that follows it in the sorted container. If such arrangement is not possible, the array must be rearranged as the lowest possible order (i.e., sorted in ascending order).

- For example, the next permutation of `arr = [1,2,3]` is `[1,3,2]`.
- Similarly, the next permutation of `arr = [2,3,1]` is `[3,1,2]`.
- While the next permutation of `arr = [3,2,1]` is `[1,2,3]` because `[3,2,1]` does not have a lexicographical larger rearrangement.

Given an array of integers `nums`, *find the next permutation of* `nums`.

The replacement must be **in place** and use only constant extra memory.

Example 1:

```
Input: nums = [1,2,3]
Output: [1,3,2]
```

Example 2:

```
Input: nums = [3,2,1]
Output: [1,2,3]
```

Example 3:

```
Input: nums = [1,1,5]
Output: [1,5,1]
```

Constraints:

- `1 <= nums.length <= 100`
- `0 <= nums[i] <= 100`

SOLUTION (PYTHON 3)

Solution 1: Two traversals

How to think about it

The first idea is to generate every permutation and take the one after the current sequence. Correct, but n! is impossible at n ≤ 100, and the problem requires an in-place, constant-extra-space update. We do not need the full set, only the next sequence in lexicographic order: strictly larger, changing as far right as possible, and by the smallest amount. The longest non-increasing suffix is already the largest arrangement of that tail; the element just before it, nums[i], is the pivot we must raise. The smallest larger replacement sits at the right end of that suffix. After the swap, reverse the suffix so it becomes increasing. If the whole array is non-increasing, no larger permutation exists and we reverse everything.

We first traverse the array from back to front and find the first position i where nums[i] < nums[i + 1].

Then traverse the array from back to front again and find the first position j where nums[j] > nums[i]. Swap nums[i] and nums[j], and then reverse the elements from nums[i + 1] to nums[n - 1], the next permutation can be obtained.

The time complexity is O(n) and the space complexity is O(1). Where n is the length of the array.

Python 3

```
class Solution:
    def nextPermutation(self, nums: List[int]) -> None:
        n = len(nums)
        i = next((i for i in range(n - 2, -1, -1) if nums[i] < nums[i + 1]), -1)
        if ~i:
            j = next((j for j in range(n - 1, i, -1) if nums[j] > nums[i]))
            nums[i], nums[j] = nums[j], nums[i]
        nums[i + 1 :] = nums[i + 1 :][::-1]
```

```

PART 2 · ARRAYS · PROBLEM 7 OF 9

229. Majority Element II

Medium · Array, Hash Table, Counting, Sorting, Boyer-Moore Voting

leetcode.com/problems/majority-element-ii

★ **TOP 10 PROBLEM** in Arrays: master this one first

PROBLEM

Given an integer array of size `n`, find all elements that appear more than `⌊n / 3⌋` times.

Example 1:

```
Input: nums = [3,2,3]
Output: [3]
```

Example 2:

```
Input: nums = [1]
Output: [1]
```

Example 3:

```
Input: nums = [1,2]
Output: [1,2]
```

Constraints:

- `1 <= nums.length <= 5 * 10^4`
- `-10^9 <= nums[i] <= 10^9`

Follow up: Could you solve the problem in linear time and in `O(1)` space?

SOLUTION (PYTHON 3)

Solution 1

How to think about it

At most two values can appear more than floor(n/3) times. Hashing works but uses extra memory. Boyer–Moore can keep two candidates and their offsetting counts. A match increments a count; otherwise both counts decrement when they are positive. A second pass verifies the true frequencies.

Python 3

```python
class Solution:
    def majorityElement(self, nums: List[int]) -> List[int]:
        n1 = n2 = 0
        m1, m2 = 0, 1
        for m in nums:
            if m == m1:
                n1 += 1
            elif m == m2:
                n2 += 1
            elif n1 == 0:
                m1, n1 = m, 1
            elif n2 == 0:
                m2, n2 = m, 1
            else:
                n1, n2 = n1 - 1, n2 - 1
        return [m for m in [m1, m2] if nums.count(m) > len(nums) // 3]
```

Complexity. Time: O(n). Space: O(1).

```

334. Increasing Triplet Subsequence

Medium · Greedy, Array, Longest Increasing Subsequence

leetcode.com/problems/increasing-triplet-subsequence

★ **TOP 10 PROBLEM** in Arrays: master this one first

PROBLEM

Given an integer array `nums`, return `true` *if there exists a triple of indices* `(i, j, k)` *such that* `i < j < k` *and* `nums[i] < nums[j] < nums[k]`. If no such indices exists, return `false`.

Example 1:

```
Input: nums = [1,2,3,4,5]
Output: true
Explanation: Any triplet where i < j < k is valid.
```

Example 2:

```
Input: nums = [5,4,3,2,1]
Output: false
Explanation: No triplet exists.
```

Example 3:

```
Input: nums = [2,1,5,0,4,6]
Output: true
Explanation: One of the valid triplet is (1, 4, 5), because nums[1] == 1 < nums[4] == 4 < nums[5] == 6.
```

Constraints:

- `1 <= nums.length <= 5 * 10^5`
- `-2^31 <= nums[i] <= 2^31 - 1`

Follow up:

Could you implement a solution that runs in

`O(n)`

time complexity and

`O(1)`

space complexity?

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Decide whether an increasing triplet of indices exists. Trying every middle index is O(n^2). We only need a smaller left value and a candidate second value. Keep mi<mid. A value above mid finishes the triplet; otherwise update mi if it is no larger, else update mid. The old index of mid need not be stored: it already sits after a smaller mi.

Python 3

```python
class Solution:
    def increasingTriplet(self, nums: List[int]) -> bool:
        mi, mid = inf, inf
        for num in nums:
            if num > mid:
                return True
            if num <= mi:
                mi = num
            else:
                mid = num
        return False
```

2348. Number of Zero-Filled Subarrays

Medium · Array, Math

leetcode.com/problems/number-of-zero-filled-subarrays

★ **TOP 10 PROBLEM** in Arrays: master this one first

PROBLEM

Given an integer array `nums`, return *the number of **subarrays** filled with* `0`.

A **subarray** is a contiguous non-empty sequence of elements within an array.

Example 1:

```
Input: nums = [1,3,0,0,2,0,0,4]
Output: 6
Explanation:
There are 4 occurrences of [0] as a subarray.
There are 2 occurrences of [0,0] as a subarray.
There is no occurrence of a subarray with a size more than 2 filled with 0. Therefore, we return 6.
```

Example 2:

```
Input: nums = [0,0,0,2,0,0]
Output: 9
Explanation:
There are 5 occurrences of [0] as a subarray.
There are 3 occurrences of [0,0] as a subarray.
There is 1 occurrence of [0,0,0] as a subarray.
There is no occurrence of a subarray with a size more than 3 filled with 0. Therefore, we return 9.
```

Example 3:

```
Input: nums = [2,10,2019]
Output: 0
Explanation: There is no subarray filled with 0. Therefore, we return 0.
```

Constraints:

- `1 <= nums.length <= 10^5`
- `-10^9 <= nums[i] <= 10^9`

SOLUTION (PYTHON 3)

Solution 1: Traversal and Counting

How to think about it

Zero-filled subarrays live inside runs of zeros. n ≤ 10^5, so we count by run instead of endpoints. Keep the current run length cnt. A zero increments cnt and adds it to the answer (subarrays ending here); a nonzero resets cnt.

We traverse the array nums and use a variable cnt to record the current number of consecutive 0s. For the current element x we are traversing, if x is 0, then cnt is incremented by 1, and the number of all-zero subarrays ending with the current x is cnt, which we add to the answer. Otherwise, we set cnt to 0.

After the traversal, we return the answer.

Time complexity O(n), where n is the length of the array nums. Space complexity O(1).

Similar problems:

- 413. Arithmetic Slices

- 1513. Number of Substrings With Only 1s

Python 3

```python
class Solution:
    def zeroFilledSubarray(self, nums: List[int]) -> int:
        ans = cnt = 0
        for x in nums:
            if x == 0:
                cnt += 1
                ans += cnt
            else:
                cnt = 0
        return ans
```

58. Length of Last Word

Easy · String

leetcode.com/problems/length-of-last-word

★ **TOP 10 PROBLEM** in Strings: master this one first

PROBLEM

Given a string `s` consisting of words and spaces, return *the length of the **last** word in the string.*

A **word** is a maximal substring consisting of non-space characters only.

Example 1:

```
Input: s = "Hello World"
Output: 5
Explanation: The last word is "World" with length 5.
```

Example 2:

```
Input: s = " fly me to the moon "
Output: 4
Explanation: The last word is "moon" with length 4.
```

Example 3:

```
Input: s = "luffy is still joyboy"
Output: 6
Explanation: The last word is "joyboy" with length 6.
```

Constraints:

- `1 <= s.length <= 10^4`
- `s` consists of only English letters and spaces `' '`.
- There will be at least one word in `s`.

SOLUTION (PYTHON 3)

Solution 1: Reverse Traversal + Two Pointers

How to think about it

The first idea is to split on spaces and take the last token. n ≤ 10^4 would pass, but we scan the whole string and allocate substrings. The waste is every earlier word. The last word sits at the end (possibly behind trailing spaces). So scan from the right: skip trailing spaces to get i, then walk to the word's left edge j; the length is i-j.

We start traversing from the end of the string s, find the first character that is not a space, which is the last character of the last word, and mark the index as i. Then continue to traverse forward, find the first character that is a space, which is the character before the first character of the last word, and mark it as j. Then the length of the last word is i - j.

The time complexity is O(n), where n is the length of the string s. The space complexity is O(1).

Python 3

```
class Solution:
    def lengthOfLastWord(self, s: str) -> int:
        i = len(s) - 1
        while i >= 0 and s[i] == ' ':
            i -= 1
        j = i
        while j >= 0 and s[j] != ' ':
            j -= 1
        return i - j
```

```

PART 2 · STRINGS · PROBLEM 2 OF 8

392. Is Subsequence

Easy · Two Pointers, String, Dynamic Programming

leetcode.com/problems/is-subsequence

★ **TOP 10 PROBLEM** in Strings: master this one first

PROBLEM

Given two strings `s` and `t`, return `true` *if* `s` *is a* ***subsequence*** *of* `t`*, or* `false` *otherwise*.

A **subsequence** of a string is a new string that is formed from the original string by deleting some (can be none) of the characters without disturbing the relative positions of the remaining characters. (i.e., `"ace"` is a subsequence of `"abcde"` while `"aec"` is not).

Example 1:

```
Input: s = "abc", t = "ahbgdc"
Output: true
```

Example 2:

```
Input: s = "axc", t = "ahbgdc"
Output: false
```

Constraints:

- `0 <= s.length <= 100`
- `0 <= t.length <= 10^4`
- `s` and `t` consist only of lowercase English letters.

Follow up:

Suppose there are lots of incoming

`s`

, say

`s_1, s_2, ..., s_k`

where

`k >= 10^9`

, and you want to check one by one to see if

`t`

has its subsequence. In this scenario, how would you change your code?

SOLUTION (PYTHON 3)

Solution 1: Two Pointers

How to think about it

Is s a subsequence of t? Each character of s needs a later match in t. Two pointers in one scan. i walks s, j walks t; on a match advance i. s is a subsequence iff i reaches the end.

We define two pointers i and j to point to the initial position of the string s and t respectively. Each time we compare the two characters pointed to by the two pointers, if they are the same, both pointers move right at the same time; if they are not the same, only j moves right. When the pointer i moves to the end of the string s, it means that s is the subsequence of t.

The time complexity is O(m + n), where m and n are the lengths of the strings s and t respectively. The space complexity is O(1).

Python 3

```python
class Solution:
    def isSubsequence(self, s: str, t: str) -> bool:
        i = j = 0
        while i < len(s) and j < len(t):
            if s[i] == t[j]:
                i += 1
            j += 1
        return i == len(s)
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

# FOLLOW-UPS (answered below, in this order):
# 1. Many strings s are checked against the same long t
# 2. Return the indices of t that match s

# ============================================================
# FOLLOW-UP 1: Many strings s are checked against the same
# long t
# ============================================================

# ---- follow-up 1: function ----
# Answer: Store the positions of every letter of t; for
# each s, binary search the next position after the last
# match.
# Time: build O(|t|), each check O(|s| log |t|).  Space:
# O(|t|).
import bisect

class SubsequenceChecker:
    def __init__(self, t):
        self.positions = {}
        for i, ch in enumerate(t):
            self.positions.setdefault(ch, []).append(i)

    def is_subsequence(self, s):
        previous = -1
        for ch in s:
            spots = self.positions.get(ch, [])
            k = bisect.bisect_right(spots, previous)
            if k == len(spots):
                return False
            previous = spots[k]
        return True

# ============================================================
# FOLLOW-UP 2: Return the indices of t that match s
# ============================================================

# ---- follow-up 2: function ----
# Answer: Greedy walk through t, recording the index of
# each matched letter.
# Time: O(|t|).  Space: O(|s|).
def matching_indices(s, t):
    indices = []
    i = 0
    for j in range(len(t)):
        if i < len(s) and s[i] == t[j]:
            indices.append(j)
            i += 1
```

```
    if i == len(s):
        return indices
    return None
```

796. Rotate String

Easy · String, String Matching

leetcode.com/problems/rotate-string

★ **TOP 10 PROBLEM** in Strings: master this one first

PROBLEM

Given two strings `s` and `goal`, return `true` *if and only if* `s` *can become* `goal` *after some number of* ***shifts*** *on* `s`.

A **shift** on `s` consists of moving the leftmost character of `s` to the rightmost position.

- For example, if `s = "abcde"`, then it will be `"bcdea"` after one shift.

Example 1:

Input: s = "abcde", goal = "cdeab"

Output: true

Explanation:

Rotating `s` to the left by 2 positions moves `"ab"` to the end, resulting in `"cdeab"`, which is equal to `goal`.

Example 2:

Input: s = "abcde", goal = "abced"

Output: false

Explanation:

No sequence of rotations of `s` can produce `"abced"`. The characters appear in a different relative order, so `goal` is not a rotation of `s`.

Constraints:

- `1 <= s.length, goal.length <= 100`
- `s` and `goal` consist of lowercase English letters.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Is goal a rotation of s? Unequal lengths fail; otherwise goal is a substring of s+s.

Python 3

```python
class Solution:
    def rotateString(self, s: str, goal: str) -> bool:
        return len(s) == len(goal) and goal in s + s
```

Complexity. Time: O(n) (substring search on 2n characters). Space: O(n).

    if len(s) != len(goal):
        return -1
    return (s + s).find(goal)

# ============================================================
# FOLLOW-UP 2: How many different rotations does s have
# ============================================================

# ---- follow-up 2: function ----
# Answer: The smallest period p of s with p dividing n
# gives p different rotations.
# Time: O(n).  Space: O(n).
def distinct_rotations(s):
    n = len(s)
    position = (s + s).find(s, 1)
    return position if position != -1 and position < n else n
```

PART 2 · STRINGS · PROBLEM 4 OF 8

151. Reverse Words in a String

Medium · Two Pointers, String

leetcode.com/problems/reverse-words-in-a-string

★ **TOP 10 PROBLEM** in Strings: master this one first

PROBLEM

Given an input string `s`, reverse the order of the **words**.

A **word** is defined as a sequence of non-space characters. The **words** in `s` will be separated by at least one space.

Return *a string of the words in reverse order concatenated by a single space.*

Note that `s` may contain leading or trailing spaces or multiple spaces between two words. The returned string should only have a single space separating the words. Do not include any extra spaces.

Example 1:

```
Input: s = "the sky is blue"
Output: "blue is sky the"
```

Example 2:

```
Input: s = " hello world "
Output: "world hello"
Explanation: Your reversed string should not contain leading or trailing spaces.
```

Example 3:

```
Input: s = "a good example"
Output: "example good a"
Explanation: You need to reduce multiple spaces between two words to a single space in the reversed
string.
```

Constraints:

- `1 <= s.length <= 10^4`
- `s` contains English letters (upper-case and lower-case), digits, and spaces `' '`.
- There is **at least one** word in `s`.

Follow-up: If the string data type is mutable in your language, can you solve it **in-place** with `O(1)` extra space?

SOLUTIONS (PYTHON 3)

Solution 1: Two Pointers

How to think about it

Reverse the word order and collapse extra spaces. n≤ 10^4. Two pointers skip spaces, cut out each word, then reverse the list and join. Leading, trailing, and repeated spaces disappear.

We can use two pointers i and j to find each word, add it to the result list, then reverse the result list, and finally concatenate it into a string.

The time complexity is O(n), and the space complexity is O(n). Where n is the length of the string.

Python 3

```python
class Solution:
    def reverseWords(self, s: str) -> str:
        words = []
        i, n = 0, len(s)
        while i < n:
            while i < n and s[i] == " ":
                i += 1
            if i < n:
                j = i
                while j < n and s[j] != " ":
                    j += 1
                words.append(s[i:j])
                i = j
        return " ".join(words[::-1])
```

Solution 2: String Split

> **How to think about it**
>
> Solution 1 splits words by hand. A built-in split on whitespace already drops extra spaces; reverse that list and join. Shorter code, same complexity.

We can use the built-in string split function to split the string into a list of words by spaces, then reverse the list, and finally concatenate it into a string.

The time complexity is O(n), and the space complexity is O(n). Where n is the length of the string.

Python 3

```python
class Solution:
    def reverseWords(self, s: str) -> str:
        return " ".join(reversed(s.split()))
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

```

161. One Edit Distance

Medium · Two Pointers, String

leetcode.com/problems/one-edit-distance

★ **TOP 10 PROBLEM** in Strings: master this one first

PROBLEM

Given two strings `s` and `t`, return `true` if they are both one edit distance apart, otherwise return `false`.

A string `s` is said to be one distance apart from a string `t` if you can:

- Insert **exactly one** character into `s` to get `t`.
- Delete **exactly one** character from `s` to get `t`.
- Replace **exactly one** character of `s` with **a different character** to get `t`.

Example 1:

```
Input: s = "ab", t = "acb"
Output: true
Explanation: We can insert 'c' into s to get t.
```

Example 2:

```
Input: s = "", t = ""
Output: false
Explanation: We cannot get t from s by only one step.
```

Constraints:

- `0 <= s.length, t.length <= 10^4`
- `s` and `t` consist of lowercase letters, uppercase letters, and digits.

SOLUTION (PYTHON 3)

Solution 1: Discuss Different Cases

How to think about it

Exactly one insert, delete, or replace should turn s into t. A length gap above 1 is impossible. n≤ 10^4. Assume s is at least as long as t. At the first mismatch: equal lengths compare the suffixes (replace); unequal lengths compare s without that character to the rest of t (delete). If they match throughout, s must be exactly one character longer.

Let m represent the length of string s, and n represent the length of string t. We can assume that m is always greater than or equal to n.

If m-n > 1, return false directly;

Otherwise, iterate through s and t, if s[i] is not equal to t[i]:

- If m ≠ n, compare s[i+1:] with t[i:], return true if they are equal, otherwise return false;
- If m = n, compare s[i:] with t[i:], return true if they are equal, otherwise return false.

If the iteration ends, it means that all the characters of s and t that have been iterated are equal, at this time it needs to satisfy m=n+1.

The time complexity is O(m), where m is the length of string s. The space complexity is O(1).

Python 3

```
class Solution:
    def isOneEditDistance(self, s: str, t: str) -> bool:
        if len(s) < len(t):
            return self.isOneEditDistance(t, s)
        m, n = len(s), len(t)
        if m - n > 1:
            return False
        for i, c in enumerate(t):
            if c != s[i]:
                return s[i + 1 :] == t[i + 1 :] if m == n else s[i + 1 :] == t[i:]
        return m == n + 1
```

616. Add Bold Tag in String

Medium · Trie, Array, Hash Table, String, String Matching, Aho-Corasick

leetcode.com/problems/add-bold-tag-in-string

★ **TOP 10 PROBLEM** in Strings: master this one first

PROBLEM

You are given a string `s` and an array of strings `words`.

You should add a closed pair of bold tag `<b>` and `</b>` to wrap the substrings in `s` that exist in `words`.

- If two such substrings overlap, you should wrap them together with only one pair of closed bold-tag.
- If two substrings wrapped by bold tags are consecutive, you should combine them.

Return `s` *after adding the bold tags*.

Example 1:

```
Input: s = "abcxyz123", words = ["abc","123"]
Output: "<b>abc</b>xyz<b>123</b>"
Explanation: The two strings of words are substrings of s as following: "abcxyz123".
We add <b> before each substring and </b> after each substring.
```

Example 2:

```
Input: s = "aaabbb", words = ["aa","b"]
Output: "<b>aaabbb</b>"
Explanation:
"aa" appears as a substring two times: "aaabbb" and "aaabbb".
"b" appears as a substring three times: "aaabbb", "aaabbb", and "aaabbb".
We add <b> before each substring and </b> after each substring:
"<b>a<b>a</b>a</b><b>b</b><b>b</b><b>b</b>".
Since the first two <b>'s overlap, we merge them: "<b>aaa</b><b>b</b><b>b</b><b>b</b>".
Since now the four <b>'s are consecutive, we merge them: "<b>aaabbb</b>".
```

Constraints:

- `1 <= s.length <= 1000`
- `0 <= words.length <= 100`
- `1 <= words[i].length <= 1000`
- `s` and `words[i]` consist of English letters and digits.
- All the values of `words` are **unique**.

Note: This question is the same as 758. Bold Words in String.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Every occurrence of a word in s must be wrapped, and intervals may overlap. Naive matching per word repeats work and still needs a merge pass. Insert words into a trie and walk from every start index to collect end positions. Merge overlapping intervals, then splice `<b>` around them.

Python 3

```
class Trie:
    def __init__(self):
        self.children = [None] * 128
        self.is_end = False

    def insert(self, word):
        node = self
        for c in word:
            idx = ord(c)
            if node.children[idx] is None:
                node.children[idx] = Trie()
            node = node.children[idx]
        node.is_end = True

class Solution:
    def addBoldTag(self, s: str, words: List[str]) -> str:
        trie = Trie()
        for w in words:
            trie.insert(w)
        n = len(s)
        pairs = []
        for i in range(n):
            node = trie
            for j in range(i, n):
                idx = ord(s[j])
                if node.children[idx] is None:
                    break
                node = node.children[idx]
                if node.is_end:
                    pairs.append([i, j])
        if not pairs:
            return s
        st, ed = pairs[0]
        t = []
        for a, b in pairs[1:]:
            if ed + 1 < a:
                t.append([st, ed])
                st, ed = a, b
            else:
                ed = max(ed, b)
        t.append([st, ed])

        ans = []
        i = j = 0
        while i < n:
            if j == len(t):
                ans.append(s[i:])
                break
            st, ed = t[j]
            if i < st:
                ans.append(s[i:st])
            ans.append('<b>')
            ans.append(s[st : ed + 1])
            ans.append('</b>')
            j += 1
            i = ed + 1

        return ''.join(ans)
```

Complexity. Time: O(n * m + L), m = longest word, L = total letters. Space: O(128 * L).

1657. Determine if Two Strings Are Close

Medium · Hash Table, String, Counting, Sorting

leetcode.com/problems/determine-if-two-strings-are-close

★ **TOP 10 PROBLEM** in Strings: master this one first

PROBLEM

Two strings are considered **close** if you can attain one from the other using the following operations:

- Operation 1: Swap any two **existing** characters.
  - For example, `abcde -> aecdb`
- Operation 2: Transform **every** occurrence of one **existing** character into another **existing** character, and do the same with the other character.
  - For example, `aacabb -> bbcbaa` (all `a`'s turn into `b`'s, and all `b`'s turn into `a`'s)

You can use the operations on either string as many times as necessary.

Given two strings, `word1` and `word2`, return `true` *if* `word1` *and* `word2` *are* ***close****, and* `false` *otherwise.*

Example 1:

```
Input: word1 = "abc", word2 = "bca"
Output: true
Explanation: You can attain word2 from word1 in 2 operations.
Apply Operation 1: "abc" -> "acb"
Apply Operation 1: "acb" -> "bca"
```

Example 2:

```
Input: word1 = "a", word2 = "aa"
Output: false
Explanation: It is impossible to attain word2 from word1, or vice versa, in any number of operations.
```

Example 3:

```
Input: word1 = "cabbba", word2 = "abbccc"
Output: true
Explanation: You can attain word2 from word1 in 3 operations.
Apply Operation 1: "cabbba" -> "caabbb"
Apply Operation 2: "caabbb" -> "baaccc"
Apply Operation 2: "baaccc" -> "abbccc"
```

Constraints:

- `1 <= word1.length, word2.length <= 10^5`
- `word1` and `word2` contain only lowercase English letters.

SOLUTION (PYTHON 3)

Solution 1: Counting + Sorting

How to think about it

Swapping two characters and renaming one letter globally preserve the set of letters and the multiset of frequencies (the latter up to permuting values among those letters). Hence the strings are close iff they use the same letters and their frequency lists match after sorting. Count both strings and compare key sets plus sorted value lists.

According to the problem description, two strings are close if they meet the following two conditions simultaneously:

1. The strings `word1` and `word2` must contain the same types of letters.

2. The arrays obtained by sorting the counts of all characters in `word1` and `word2` must be the same.

Therefore, we can first use an array or hash table to count the occurrences of each letter in `word1` and `word2` respectively, and then compare whether they are the same. If they are not the same, return `false` early.

Otherwise, we sort the corresponding counts, and then compare whether the counts at the corresponding positions are the same. If they are not the same, return `false`.

At the end of the traversal, return `true`.

The time complexity is O(m + n + C × log C), and the space complexity is O(C). Here, m and n are the lengths of the strings `word1` and `word2` respectively, and C is the number of letter types. In this problem, C=26.

Python 3

```
class Solution:
    def closeStrings(self, word1: str, word2: str) -> bool:
        cnt1, cnt2 = Counter(word1), Counter(word2)
        return sorted(cnt1.values()) == sorted(cnt2.values()) and set(
            cnt1.keys()
        ) == set(cnt2.keys())
```

    if len(word1) != len(word2) or set(word1) != set(word2):
        return False
    forward = {}
    backward = {}
    for a, b in zip(word1, word2):
        if forward.setdefault(a, b) != b or backward.setdefault(b, a) != a:
            return False
    return True
```

843. Guess the Word

Hard · Minimax, Array, Math, String, Game Theory, Interactive

leetcode.com/problems/guess-the-word

★ **TOP 10 PROBLEM** in Strings: master this one first

PROBLEM

You are given an array of unique strings `words` where `words[i]` is six letters long. One word of `words` was chosen as a secret word.

You are also given the helper object `Master`. You may call `Master.guess(word)` where `word` is a six-letter-long string, and it must be from `words`. `Master.guess(word)` returns:

- `-1` if `word` is not from `words`, or
- an integer representing the number of exact matches (value and position) of your guess to the secret word.

There is a parameter `allowedGuesses` for each test case where `allowedGuesses` is the maximum number of times you can call `Master.guess(word)`.

For each test case, you should call `Master.guess` with the secret word without exceeding the maximum number of allowed guesses. You will get:

- `"Either you took too many guesses, or you did not find the secret word."` if you called `Master.guess` more than `allowedGuesses` times or if you did not call `Master.guess` with the secret word, or
- `"You guessed the secret word correctly."` if you called `Master.guess` with the secret word with the number of calls to `Master.guess` less than or equal to `allowedGuesses`.

The test cases are generated such that you can guess the secret word with a reasonable strategy (other than using the bruteforce method).

Example 1:

```
Input: secret = "acckzz", words = ["acckzz","ccbazz","eiowzz","abcczz"], allowedGuesses = 10
Output: You guessed the secret word correctly.
Explanation:
master.guess("aaaaaa") returns -1, because "aaaaaa" is not in words.
master.guess("acckzz") returns 6, because "acckzz" is secret and has all 6 matches.
master.guess("ccbazz") returns 3, because "ccbazz" has 3 matches.
master.guess("eiowzz") returns 2, because "eiowzz" has 2 matches.
master.guess("abcczz") returns 4, because "abcczz" has 4 matches.
We made 5 calls to master.guess, and one of them was the secret, so we pass the test case.
```

Example 2:

```
Input: secret = "hamada", words = ["hamada","khaled"], allowedGuesses = 10
Output: You guessed the secret word correctly.
Explanation: Since there are two words, you can guess both.
```

Constraints:

- `1 <= words.length <= 100`
- `words[i].length == 6`
- `words[i]` consist of lowercase English letters.
- All the strings of `words` are **unique**.
- `secret` exists in `words`.
- `10 <= allowedGuesses <= 30`

SOLUTION (PYTHON 3)

Solution 1

How to think about it

The secret must be found in at most 30 guesses, each returning a match count. There are only 100 length-6 words, yet random guesses need not shrink the candidate set. Keep the words still consistent with all answers, and filter by the match count after each guess. Even without implementation code here, the core is using that count to reduce the search to a manageable set.

Python 3 (written for this guide: the doocs page has an empty Python tab)

```
class Solution:
    def findSecretWord(self, words: List[str], master: "Master") -> None:
        def match(a: str, b: str) -> int:
            return sum(x == y for x, y in zip(a, b))

        candidates = words[:]
        for _ in range(10):
            # Choose the guess that splits the remaining candidates best. Any word of the list may be
guessed,
            # even one that is already ruled out: compare the groups of candidates by how many letters
            # they share with the guess, prefer the smallest biggest group, then the smallest sum of
            # squares, then a word that can still be the secret.
            still_possible = set(candidates)
            best_word, best_key = None, None
            for guess in words:
                groups = {}
                for other in candidates:
                    k = match(guess, other)
                    groups[k] = groups.get(k, 0) + 1
                key = (max(groups.values()), sum(v * v for v in groups.values()), guess not in
still_possible)
                if best_key is None or key < best_key:
                    best_word, best_key = guess, key
            hits = master.guess(best_word)
            if hits == 6:
                return
            # the secret shares exactly `hits` letters with the guess, so keep only such words
            candidates = [w for w in candidates if match(best_word, w) == hits]
```

Complexity. Time: O(10 * N^2) (each of the 10 rounds compares every word with every candidate). Space: O(N).

Easy · Bit Manipulation, Recursion, Math

leetcode.com/problems/power-of-two

★ **TOP 10 PROBLEM** in Bit Manipulation: master this one first

PROBLEM

Given an integer `n`, return `true` *if it is a power of two. Otherwise, return* `false`.

An integer `n` is a power of two, if there exists an integer `x` such that $n == 2^x$.

Example 1:

```
Input: n = 1
Output: true
Explanation: 20 = 1
```

Example 2:

```
Input: n = 16
Output: true
Explanation: 24 = 16
```

Example 3:

```
Input: n = 3
Output: false
```

Constraints:

- $-2^{31} <= n <= 2^{31} - 1$

Follow up:

Could you solve it without loops/recursion?

SOLUTIONS (PYTHON 3)

Solution 1: Bit Manipulation

How to think about it

Repeated division by 2 works, but one bit test is enough. A power of two has a single 1 bit, i.e. n>0 and n&(n-1)=0.

According to the properties of bit manipulation, executing n&(n-1) can eliminate the last bit 1 in the binary form of n. Therefore, if n > 0 and n&(n-1) results in 0, then n is a power of 2.

The time complexity is O(1), and the space complexity is O(1).

Python 3

```python
class Solution:
    def isPowerOfTwo(self, n: int) -> bool:
        return n > 0 and (n & (n - 1)) == 0
```

Solution 2: Lowbit

> **How to think about it**
>
> Clearing the lowest set bit is equivalent to taking lowbit. If n>0 and n=n&(-n), that single bit is the whole number.

According to the definition of lowbit, we know that lowbit(x) = x & (-x), which can get the decimal number represented by the last bit 1 of n. Therefore, if n > 0 and lowbit(n) equals n, then n is a power of 2.

The time complexity is O(1), and the space complexity is O(1).

Python 3

```python
class Solution:
    def isPowerOfTwo(self, n: int) -> bool:
        return n > 0 and n == n & (-n)
```

    return n + 1
```

PART 2 · BIT MANIPULATION · PROBLEM 2 OF 2

461. Hamming Distance

Easy · Bit Manipulation

leetcode.com/problems/hamming-distance

★ **TOP 10 PROBLEM** in Bit Manipulation: master this one first

PROBLEM

The Hamming distance between two integers is the number of positions at which the corresponding bits are different.

Given two integers `x` and `y`, return *the **Hamming distance** between them*.

Example 1:

```
Input: x = 1, y = 4
Output: 2
Explanation:
1 (0 0 0 1)
4 (0 1 0 0)
       ↑ ↑
The above arrows point to positions where the corresponding bits are different.
```

Example 2:

```
Input: x = 3, y = 1
Output: 1
```

Constraints:

- `0 <= x, y <= 2^31 - 1`

Note: This question is the same as 2220: Minimum Bit Flips to Convert Number.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Hamming distance is the number of differing bits. Comparing bit by bit needs a 32-step loop. The 1-bits of xxor y are exactly those positions; bit_count returns their number. XOR folds the comparison into one word operation; popcount is then a hardware instruction or a short loop.

Python 3

```python
class Solution:
    def hammingDistance(self, x: int, y: int) -> int:
        return (x ^ y).bit_count()
```

Complexity. Time: O(1). Space: O(1).

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

219. Contains Duplicate II

Easy · Array, Hash Table, Sliding Window

leetcode.com/problems/contains-duplicate-ii

★ **TOP 10 PROBLEM** in Hash Tables: master this one first

PROBLEM

Given an integer array `nums` and an integer `k`, return `true` *if there are two* ***distinct indices*** `i` *and* `j` *in the array such that* `nums[i] == nums[j]` ***and*** `abs(i - j) <= k`.

Example 1:

```
Input: nums = [1,2,3,1], k = 3
Output: true
```

Example 2:

```
Input: nums = [1,0,1,1], k = 1
Output: true
```

Example 3:

```
Input: nums = [1,2,3,1,2,3], k = 2
Output: false
```

Constraints:

- `1 <= nums.length <= 10^5`
- `-10^9 <= nums[i] <= 10^9`
- `0 <= k <= 10^5`

SOLUTION (PYTHON 3)

Solution 1: Hash Table

How to think about it

We need equal values whose indices differ by at most k. Sorting would scramble indices. A hash map stores the last index of each value; on a repeat we only check the gap.

We use a hash table d to store the recently traversed numbers and their corresponding indices.

Traverse the array nums. For the current element nums[i], if it exists in the hash table and the difference between the indices is no more than k, return true. Otherwise, add the current element to the hash table.

After traversing, return false.

The time complexity is O(n), and the space complexity is O(n). Here, n is the length of the array nums.

Python 3

```python
class Solution:
    def containsNearbyDuplicate(self, nums: List[int], k: int) -> bool:
        d = {}
        for i, x in enumerate(nums):
            if x in d and i - d[x] <= k:
                return True
            d[x] = i
        return False
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

# Time: O(n).  Space: O(k).
def count_close_equal_pairs(nums, k):
    window = {}
    total = 0
    for i, x in enumerate(nums):
        total += window.get(x, 0)
        window[x] = window.get(x, 0) + 1
        if i >= k:
            old = nums[i - k]
            window[old] -= 1
    return total
```

350. Intersection of Two Arrays II

Easy · Array, Hash Table, Two Pointers, Binary Search, Sorting

leetcode.com/problems/intersection-of-two-arrays-ii

★ **TOP 10 PROBLEM** in Hash Tables: master this one first

PROBLEM

Given two integer arrays `nums1` and `nums2`, return *an array of their intersection*. Each element in the result must appear as many times as it shows in both arrays and you may return the result in **any order**.

Example 1:

```
Input: nums1 = [1,2,2,1], nums2 = [2,2]
Output: [2,2]
```

Example 2:

```
Input: nums1 = [4,9,5], nums2 = [9,4,9,8,4]
Output: [4,9]
Explanation: [9,4] is also accepted.
```

Constraints:

- `1 <= nums1.length, nums2.length <= 1000`
- `0 <= nums1[i], nums2[i] <= 1000`

Follow up:

- What if the given array is already sorted? How would you optimize your algorithm?
- What if `nums1`'s size is small compared to `nums2`'s size? Which algorithm is better?
- What if elements of `nums2` are stored on disk, and the memory is limited such that you cannot load all elements into the memory at once?

SOLUTION (PYTHON 3)

Solution 1: Hash Table

How to think about it

The intersection must keep multiplicities, the min of the two counts. Unlike 349, we cannot unique the values. Count nums1, then scan nums2: while a remainder exists, emit it and decrement. The length is the sum of those minima.

We can use a hash table cnt to count the occurrences of each element in the array nums1. Then, we iterate through the array nums2. If an element x is in cnt and the occurrence of x is greater than 0, we add x to the answer and then decrement the occurrence of x by one.

After the iteration is finished, we return the answer array.

The time complexity is O(m + n), and the space complexity is O(m). Here, m and n are the lengths of the arrays nums1 and nums2, respectively.

Python 3

```python
class Solution:
    def intersect(self, nums1: List[int], nums2: List[int]) -> List[int]:
        cnt = Counter(nums1)
        ans = []
        for x in nums2:
            if cnt[x]:
                ans.append(x)
                cnt[x] -= 1
        return ans
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

Built on the solutions above: helper functions, then the function for each follow-up. No tests and no restating of the question.

```python
# FOLLOW-UPS (answered below, in this order):
# 1. Both arrays are sorted: use no extra memory
# 2. The intersection of k arrays (with multiplicity)

# ============================================================
# FOLLOW-UP 1: Both arrays are sorted: use no extra memory
# ============================================================

# ---- follow-up 1: function ----
# Answer: Two pointers: advance the smaller one, collect
# equal numbers.
# Time: O(a + b).  Space: O(1) extra besides the result.
def intersect_sorted(a, b):
    i = j = 0
    result = []
    while i < len(a) and j < len(b):
        if a[i] < b[j]:
            i += 1
        elif a[i] > b[j]:
            j += 1
        else:
            result.append(a[i])
            i += 1
            j += 1
    return result

# ============================================================

    return sorted(common.elements())
```

387. First Unique Character in a String

Easy · Queue, Hash Table, String, Counting

leetcode.com/problems/first-unique-character-in-a-string

★ **TOP 10 PROBLEM** in Hash Tables: master this one first

PROBLEM

Given a string `s`, find the **first** non-repeating character in it and return its index. If it **does not** exist, return `-1`.

Example 1:

Input: s = "leetcode"

Output: 0

Explanation:

The character `'l'` at index 0 is the first character that does not occur at any other index.

Example 2:

Input: s = "loveleetcode"

Output: 2

Example 3:

Input: s = "aabb"

Output: -1

Constraints:

- `1 <= s.length <= 10^5`
- `s` consists of only lowercase English letters.

SOLUTION (PYTHON 3)

Solution 1: Counting

How to think about it

Index of the first unique character. One left-to-right pass cannot know about later repeats. Count, then scan for frequency 1; else -1. Two linear passes, alphabet space.

We use a hash table or an array of length 26 cnt to store the frequency of each character. Then, we traverse each character s[i] from the beginning. If cnt[s[i]] is 1, we return i.

If no such character is found after the traversal, we return -1.

The time complexity is O(n), where n is the length of the string. The space complexity is O(|Σ|), where Σ is the character set. In this problem, the character set consists of lowercase letters, so |Σ|=26.

Python 3

```python
class Solution:
    def firstUniqChar(self, s: str) -> int:
        cnt = Counter(s)
        for i, c in enumerate(s):
            if cnt[c] == 1:
                return i
        return -1
```

```

1189. Maximum Number of Balloons

Easy · Hash Table, String, Counting

leetcode.com/problems/maximum-number-of-balloons

★ **TOP 10 PROBLEM** in Hash Tables: master this one first

PROBLEM

Given a string `text`, you want to use the characters of `text` to form as many instances of the word **"balloon"** as possible.

You can use each character in `text` **at most once**. Return the maximum number of instances that can be formed.

Example 1:

```
Input: text = "nlaebolko"
Output: 1
```

Example 2:

```
Input: text = "loonbalxballpoon"
Output: 2
```

Example 3:

```
Input: text = "leetcode"
Output: 0
```

Constraints:

- `1 <= text.length <= 10^4`
- `text` consists of lower case English letters only.

Note: This question is the same as 2287: Rearrange Characters to Make Target String.

SOLUTION (PYTHON 3)

Solution 1: Counting

How to think about it

`balloon` needs b,a, two l, two o, and n. After counting `text`, halve l and o and take the min over b,a,l,o,n. There is no need to delete letters from the string repeatedly.

We count the frequency of each letter in the string `text`, and then divide the frequency of the letters 'o' and 'l' by 2, because the word `balloon` contains the letters 'o' and 'l' twice.

Next, we traverse each letter in the word `balon`, and find the minimum frequency of each letter in the string `text`. This minimum frequency is the maximum number of times the word `balloon` can appear in the string `text`.

The time complexity is O(n), and the space complexity is O(C). Here, n is the length of the string `text`, and C is the size of the character set. In this problem, C = 26.

Python 3

```python
class Solution:
    def maxNumberOfBalloons(self, text: str) -> int:
        cnt = Counter(text)
        cnt['o'] >>= 1
        cnt['l'] >>= 1
        return min(cnt[c] for c in 'balon')
```

    return "".join(sorted(ch * c for ch, c in left.items() if c > 0))
```

535. Encode and Decode TinyURL

Medium · Design, Hash Table, String, Hash Function

leetcode.com/problems/encode-and-decode-tinyurl

★ **TOP 10 PROBLEM** in Hash Tables: master this one first

PROBLEM

Note: This is a companion problem to the

System Design

problem:

Design TinyURL

.

TinyURL is a URL shortening service where you enter a URL such as `https://leetcode.com/problems/design-tinyurl` and it returns a short URL such as `http://tinyurl.com/4e9iAk`. Design a class to encode a URL and decode a tiny URL.

There is no restriction on how your encode/decode algorithm should work. You just need to ensure that a URL can be encoded to a tiny URL and the tiny URL can be decoded to the original URL.

Implement the `Solution` class:

- `Solution()` Initializes the object of the system.
- `String encode(String longUrl)` Returns a tiny URL for the given `longUrl`.
- `String decode(String shortUrl)` Returns the original long URL for the given `shortUrl`. It is guaranteed that the given `shortUrl` was encoded by the same object.

Example 1:

```
Input: url = "https://leetcode.com/problems/design-tinyurl"
Output: "https://leetcode.com/problems/design-tinyurl"

Explanation:
Solution obj = new Solution();
string tiny = obj.encode(url); // returns the encoded tiny url.
string ans = obj.decode(tiny); // returns the original url after decoding it.
```

Constraints:

- `1 <= url.length <= 10^4`
- `url` is guranteed to be a valid URL.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

We need a reversible short URL. Hashing to a fixed string can collide and needs a conflict table. The short code need not be unpredictable, so a monotonic id suffices. A map stores `id -> long URL`; the short form is the domain plus that id, and decode reads the last path segment. Both operations are constant time.

Python 3

```
class Codec:
    def __init__(self):
        self.m = defaultdict()
        self.idx = 0
        self.domain = 'https://tinyurl.com/'

    def encode(self, longUrl: str) -> str:
        """Encodes a URL to a shortened URL."""
        self.idx += 1
        self.m[str(self.idx)] = longUrl
        return f'{self.domain}{self.idx}'

    def decode(self, shortUrl: str) -> str:
        """Decodes a shortened URL to its original URL."""
        idx = shortUrl.split('/')[-1]
        return self.m[idx]

# Your Codec object will be instantiated and called as such:
# codec = Codec()
# codec.decode(codec.encode(url))
```

Complexity. Time: O(1) per call. Space: O(n), n = stored urls.

```

```
        return self.table.get(short_url.rsplit("/", 1)[1])
```

659. Split Array into Consecutive Subsequences

Medium · Greedy, Array, Hash Table, Heap (Priority Queue)

leetcode.com/problems/split-array-into-consecutive-subsequences

★ **TOP 10 PROBLEM** in Hash Tables: master this one first

PROBLEM

You are given an integer array `nums` that is **sorted in non-decreasing order**.

Determine if it is possible to split `nums` into **one or more subsequences** such that **both** of the following conditions are true:

- Each subsequence is a **consecutive increasing sequence** (i.e. each integer is **exactly one** more than the previous integer).
- All subsequences have a length of `3` **or more**.

Return `true` *if you can split* `nums` *according to the above conditions, or* `false` *otherwise*.

A **subsequence** of an array is a new array that is formed from the original array by deleting some (can be none) of the elements without disturbing the relative positions of the remaining elements. (i.e., `[1,3,5]` is a subsequence of `[1,2,3,4,5]` while `[1,3,2]` is not).

Example 1:

```
Input: nums = [1,2,3,3,4,5]
Output: true
Explanation: nums can be split into the following subsequences:
[1,2,3,3,4,5] --> 1, 2, 3
[1,2,3,3,4,5] --> 3, 4, 5
```

Example 2:

```
Input: nums = [1,2,3,3,4,4,5,5]
Output: true
Explanation: nums can be split into the following subsequences:
[1,2,3,3,4,4,5,5] --> 1, 2, 3, 4, 5
[1,2,3,3,4,4,5,5] --> 3, 4, 5
```

Example 3:

```
Input: nums = [1,2,3,4,4,5]
Output: false
Explanation: It is impossible to split nums into consecutive increasing subsequences of length 3 or
more.
```

Constraints:

- `1 <= nums.length <= 10^4`
- `-1000 <= nums[i] <= 1000`
- `nums` is sorted in **non-decreasing** order.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Split the array into consecutive increasing subsequences of length at least 3. Always starting a new sequence can leave short ones stranded. A hash map stores min-heaps of lengths ending at each value. Append v to the shortest sequence ending at v-1, or start a new one. Every heap minimum must be at least 3.

Python 3

```
class Solution:
    def isPossible(self, nums: List[int]) -> bool:
        d = defaultdict(list)
        for v in nums:
            if h := d[v - 1]:
                heappush(d[v], heappop(h) + 1)
            else:
                heappush(d[v], 1)
        return all(not v or v and v[0] > 2 for v in d.values())
```

Complexity. Time: O(n log n). Space: O(n).

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

```

1525. Number of Good Ways to Split a String

Medium · Bit Manipulation, Hash Table, String, Dynamic Programming, Prefix Sum

leetcode.com/problems/number-of-good-ways-to-split-a-string

★ **TOP 10 PROBLEM** in Hash Tables: master this one first

PROBLEM

You are given a string `s`.

A split is called **good** if you can split `s` into two non-empty strings s_{left} and s_{right} where their concatenation is equal to `s` (i.e., $s_{left} + s_{right} = s$) and the number of distinct letters in s_{left} and s_{right} is the same.

Return *the number of **good splits** you can make in* `s`.

Example 1:

```
Input: s = "aacaba"
Output: 2
Explanation: There are 5 ways to split "aacaba" and 2 of them are good.
("a", "acaba") Left string and right string contains 1 and 3 different letters respectively.
("aa", "caba") Left string and right string contains 1 and 3 different letters respectively.
("aac", "aba") Left string and right string contains 2 and 2 different letters respectively (good
split).
("aaca", "ba") Left string and right string contains 2 and 2 different letters respectively (good
split).
("aacab", "a") Left string and right string contains 3 and 1 different letters respectively.
```

Example 2:

```
Input: s = "abcd"
Output: 1
Explanation: Split the string as follows ("ab", "cd").
```

Constraints:

- `1 <= s.length <= 10^5`
- `s` consists of only lowercase English letters.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Count splits where the two sides have equally many distinct characters. n≤ 10^5, so rescanning both sides at every cut is quadratic. The right-hand alphabet starts as a global frequency map; the left-hand set only grows. Moving the cut to the right inserts the current character on the left and decrements it on the right, dropping the key when the count hits zero. Whenever the two maps have the same size, the split is good. One pass suffices.

Python 3

```
class Solution:
    def numSplits(self, s: str) -> int:
        cnt = Counter(s)
        vis = set()
        ans = 0
        for c in s:
            vis.add(c)
            cnt[c] -= 1
            if cnt[c] == 0:
                cnt.pop(c)
            ans += len(vis) == len(cnt)
        return ans
```

Complexity. Time: O(n). Space: O(C), C = 26 letters.

    return total
```

1647. Minimum Deletions to Make Character Frequencies Unique

Medium · Greedy, Hash Table, String, Sorting

leetcode.com/problems/minimum-deletions-to-make-character-frequencies-unique

★ **TOP 10 PROBLEM** in Hash Tables: master this one first

PROBLEM

A string `s` is called **good** if there are no two different characters in `s` that have the same **frequency**.

Given a string `s`, return *the **minimum** number of characters you need to delete to make* `s` ***good***.

The **frequency** of a character in a string is the number of times it appears in the string. For example, in the string `"aab"`, the **frequency** of `'a'` is `2`, while the **frequency** of `'b'` is `1`.

Example 1:

```
Input: s = "aab"
Output: 0
Explanation: s is already good.
```

Example 2:

```
Input: s = "aaabbbcc"
Output: 2
Explanation: You can delete two 'b's resulting in the good string "aaabcc".
Another way it to delete one 'b' and one 'c' resulting in the good string "aaabbc".
```

Example 3:

```
Input: s = "ceabaacb"
Output: 2
Explanation: You can delete both 'c's resulting in the good string "eabaab".
Note that we only care about characters that are still in the string at the end (i.e. frequency of 0 is ignored).
```

Constraints:

- `1 <= s.length <= 10^5`
- `s` contains only lowercase English letters.

SOLUTIONS (PYTHON 3)

Solution 1: Array + Sorting

How to think about it

Frequencies must become unique and we may only delete characters. With 26 letters, sort frequencies decreasingly so each value occupies at most one integer slot. Keep the next free upper bound pre. If v ≥ pre, delete down to pre-1 (or delete all once pre is 0). Otherwise keep v and set pre=v.

First, we use an array cnt of length 26 to count the occurrences of each letter in the string s.

Then, we sort the array cnt in descending order. We define a variable pre to record the current number of occurrences of the letter.

Next, we traverse each element v in the array cnt. If the current pre is 0, we directly add v to the answer. Otherwise, if v ≥ pre, we add v - pre + 1 to the answer and decrement pre by 1. Otherwise, we directly update pre to v. Then, we continue to the next element.

After traversing, we return the answer.

The time complexity is O(n + |Σ| × log |Σ|), and the space complexity is O(|Σ|). Here, n is the length of the string s, and |Σ| is the size of the alphabet. In this problem, |Σ| = 26.

Python 3

```python
class Solution:
    def minDeletions(self, s: str) -> int:
        cnt = Counter(s)
        ans, pre = 0, inf
        for v in sorted(cnt.values(), reverse=True):
            if pre == 0:
                ans += v
            elif v >= pre:
                ans += v - pre + 1
                pre -= 1
            else:
                pre = v
        return ans
```

Solution 2: Greedy (Adjacent Decrement)

> **How to think about it**
>
> Solution 1 enforces a global upper bound. Equivalently, after sorting, force adjacent frequencies to decrease: while the next is not smaller, decrement it and count deletions. The implementation matches “neighbors differ” and has the same complexity.

Count frequencies and sort them in descending order. Walking adjacent frequencies, decrement the current one until it is strictly smaller than the previous.

The time complexity is O(n + |Σ| × log |Σ| + n), and the space complexity is O(|Σ|), where n is the length of s.

Python 3

```python
class Solution:
    def minDeletions(self, s: str) -> int:
        cnt = Counter(s)
        vals = sorted(cnt.values(), reverse=True)
        ans = 0
        for i in range(1, len(vals)):
            while vals[i] >= vals[i - 1] and vals[i] > 0:
                vals[i] -= 1
                ans += 1
        return ans
```

408. Valid Word Abbreviation

Easy · Two Pointers, String

leetcode.com/problems/valid-word-abbreviation

★ **TOP 10 PROBLEM** in Two Pointers: master this one first

PROBLEM

A string can be **abbreviated** by replacing any number of **non-adjacent**, **non-empty** substrings with their lengths. The lengths **should not** have leading zeros.

For example, a string such as `"substitution"` could be abbreviated as (but not limited to):

- `"s10n"` (`"s ubstitutio n"`)
- `"sub4u4"` (`"sub stit u tion"`)
- `"12"` (`"substitution"`)
- `"su3i1u2on"` (`"su bst i t u ti on"`)
- `"substitution"` (no substrings replaced)

The following are **not valid** abbreviations:

- `"s55n"` (`"s ubsti tutio n"`, the replaced substrings are adjacent)
- `"s010n"` (has leading zeros)
- `"s0ubstitution"` (replaces an empty substring)

Given a string `word` and an abbreviation `abbr`, return *whether the string **matches** the given abbreviation*.

A **substring** is a contiguous **non-empty** sequence of characters within a string.

Example 1:

```
Input: word = "internationalization", abbr = "i12iz4n"
Output: true
Explanation: The word "internationalization" can be abbreviated as "i12iz4n" ("i nternational iz atio n").
```

Example 2:

```
Input: word = "apple", abbr = "a2e"
Output: false
Explanation: The word "apple" cannot be abbreviated as "a2e".
```

Constraints:

- `1 <= word.length <= 20`
- `word` consists of only lowercase English letters.
- `1 <= abbr.length <= 10`
- `abbr` consists of lowercase English letters and digits.
- All the integers in `abbr` will fit in a 32-bit integer.

SOLUTION (PYTHON 3)

Solution 1: Simulation

> **How to think about it**
>
> An abbreviation interleaves letters and skip lengths, and a number may not have a leading zero. Expanding the abbreviation into a new string is unnecessary and can be large. Two pointers scan abbr: digits accumulate a skip (rejecting a leading zero); a letter first applies the skip, then compares characters. At the end, the word pointer plus any leftover skip must land exactly on the last index. Skip and compare belong in one pass so overflow, mismatch, and unused length are checked together.

We can directly simulate character matching and replacement.

Assume the lengths of the string word and the string abbr are m and n respectively. We use two pointers i and j to point to the initial positions of the string word and the string abbr respectively, and use an integer variable x to record the current matched number in abbr.

Loop to match each character of the string word and the string abbr:

If the character abbr[j] pointed by the pointer j is a number, if abbr[j] is `'0'` and x is 0, it means that the number in abbr has leading zeros, so it is not a valid abbreviation, return `false`; otherwise, update x to x × 10 + abbr[j] - '0'.

If the character abbr[j] pointed by the pointer j is not a number, then we move the pointer i forward by x positions at this time, and then reset x to 0. If i ≥ m or word[i] ≠ abbr[j] at this time, it means that the two strings cannot match, return `false`; otherwise, move the pointer i forward by 1 position.

Then we move the pointer j forward by 1 position, repeat the above process, until i exceeds the length of the string word or j exceeds the length of the string abbr.

Finally, if i + x equals m and j equals n, it means that the string word can be abbreviated as the string abbr, return `true`; otherwise return `false`.

The time complexity is O(m + n), where m and n are the lengths of the string word and the string abbr respectively. The space complexity is O(1).

Python 3

```python
class Solution:
    def validWordAbbreviation(self, word: str, abbr: str) -> bool:
        m, n = len(word), len(abbr)
        i = j = x = 0
        while i < m and j < n:
            if abbr[j].isdigit():
                if abbr[j] == "0" and x == 0:
                    return False
                x = x * 10 + int(abbr[j])
            else:
                i += x
                x = 0
                if i >= m or word[i] != abbr[j]:
                    return False
                i += 1
            j += 1
        return i + x == m and j == n
```

PART 2 · TWO POINTERS · PROBLEM 2 OF 5

696. Count Binary Substrings

Easy · Two Pointers, String

leetcode.com/problems/count-binary-substrings

★ **TOP 10 PROBLEM** in Two Pointers: master this one first

PROBLEM

Given a binary string `s`, return the number of non-empty substrings that have the same number of `0`'s and `1`'s, and all the `0`'s and all the `1`'s in these substrings are grouped consecutively.

Substrings that occur multiple times are counted the number of times they occur.

Example 1:

```
Input: s = "00110011"
Output: 6
Explanation: There are 6 substrings that have equal number of consecutive 1's and 0's: "0011", "01",
"1100", "10", "0011", and "01".
Notice that some of these substrings repeat and are counted the number of times they occur.
Also, "00110011" is not a valid substring because all the 0's (and 1's) are not grouped together.
```

Example 2:

```
Input: s = "10101"
Output: 4
Explanation: There are 4 substrings: "10", "01", "10", "01" that have equal number of consecutive 1's
and 0's.
```

Constraints:

- `1 <= s.length <= 10^5`
- `s[i]` is either `'0'` or `'1'`.

SOLUTION (PYTHON 3)

Solution 1: Iteration and Counting

How to think about it

Count substrings made of a run of 0s next to a run of 1s of equal length. Checking every substring is quadratic. Split into runs. Adjacent runs contribute min(pre,cur) valid substrings. One pass over the runs is enough.

We can iterate through the string s, using a variable pre to record the count of the previous consecutive characters, and another variable cur to record the count of the current consecutive characters. The number of valid substrings ending with the current character is min(pre, cur). We accumulate min(pre, cur) to the answer, assign the value of cur to pre, and continue iterating through string s until the end.

The time complexity is O(n), where n is the length of string s. The space complexity is O(1).

Python 3

```
class Solution:
    def countBinarySubstrings(self, s: str) -> int:
        n = len(s)
        ans = i = 0
        pre = 0
        while i < n:
            j = i + 1
            while j < n and s[j] == s[i]:
                j += 1
            cur = j - i
            ans += min(pre, cur)
            pre = cur
            i = j
        return ans
```

```

PART 2 · TWO POINTERS · PROBLEM 3 OF 5

1768. Merge Strings Alternately

Easy · Two Pointers, String

leetcode.com/problems/merge-strings-alternately

★ **TOP 10 PROBLEM** in Two Pointers: master this one first

PROBLEM

You are given two strings `word1` and `word2`. Merge the strings by adding letters in alternating order, starting with `word1`. If a string is longer than the other, append the additional letters onto the end of the merged string.

Return *the merged string.*

Example 1:

```
Input: word1 = "abc", word2 = "pqr"
Output: "apbqcr"
Explanation: The merged string will be merged as so:
word1: a b c
word2: p q r
merged: a p b q c r
```

Example 2:

```
Input: word1 = "ab", word2 = "pqrs"
Output: "apbqrs"
Explanation: Notice that as word2 is longer, "rs" is appended to the end.
word1: a b
word2: p q r s
merged: a p b q r s
```

Example 3:

```
Input: word1 = "abcd", word2 = "pq"
Output: "apbqcd"
Explanation: Notice that as word1 is longer, "cd" is appended to the end.
word1: a b c d
word2: p q
merged: a p b q c d
```

Constraints:

- `1 <= word1.length, word2.length <= 100`
- `word1` and `word2` consist of lowercase English letters.

SOLUTION (PYTHON 3)

Solution 1: Direct Simulation

How to think about it

Merge by alternating characters and append the leftover of the longer string. One paired walk is enough. zip_longest yields corresponding characters (empty when missing); joining them is the merge.

We traverse the two strings `word1` and `word2`, take out the characters one by one, and append them to the result string. The Python code can be simplified into one line.

The time complexity is O(m + n), where m and n are the lengths of the two strings respectively. Ignoring the space consumption of the answer, the space complexity is O(1).

Python 3

```
class Solution:
    def mergeAlternately(self, word1: str, word2: str) -> str:
        return ''.join(a + b for a, b in zip_longest(word1, word2, fillvalue=''))
```

# ============================================================

# ---- follow-up 2: function ----
# Answer: The same walk, in chunks of c letters.
# Time: O(n + m).  Space: O(n + m).
def merge_in_chunks(word1, word2, c):
    result = []
    i = j = 0
    while i < len(word1) or j < len(word2):
        result.append(word1[i:i + c])
        i += c
        result.append(word2[j:j + c])
        j += c
    return "".join(result)
```

PART 2 · TWO POINTERS · PROBLEM 4 OF 5

15. 3Sum

Medium · Array, Two Pointers, Sorting

leetcode.com/problems/3sum

★ **TOP 10 PROBLEM** in Two Pointers: master this one first

PROBLEM

Given an integer array nums, return all the triplets `[nums[i], nums[j], nums[k]]` such that `i != j`, `i != k`, and `j != k`, and `nums[i] + nums[j] + nums[k] == 0`.

Notice that the solution set must not contain duplicate triplets.

Example 1:

```
Input: nums = [-1,0,1,2,-1,-4]
Output: [[-1,-1,2],[-1,0,1]]
Explanation:
nums[0] + nums[1] + nums[2] = (-1) + 0 + 1 = 0.
nums[1] + nums[2] + nums[4] = 0 + 1 + (-1) = 0.
nums[0] + nums[3] + nums[4] = (-1) + 2 + (-1) = 0.
The distinct triplets are [-1,0,1] and [-1,-1,2].
Notice that the order of the output and the order of the triplets does not matter.
```

Example 2:

```
Input: nums = [0,1,1]
Output: []
Explanation: The only possible triplet does not sum up to 0.
```

Example 3:

```
Input: nums = [0,0,0]
Output: [[0,0,0]]
Explanation: The only possible triplet sums up to 0.
```

Constraints:

- `3 <= nums.length <= 3000`
- -10^5 `<= nums[i] <=` 10^5

SOLUTION (PYTHON 3)

Solution 1: Sort + Two Pointers

How to think about it

The first idea is three nested loops plus a set for uniqueness. Correct, but $O(n^3)$. n≤ 3000 will not pass. Hashing two-sum for each i reaches $O(n^2)$, yet duplicates and extra space are messy. The bottleneck is finding two numbers that sum to the opposite of a fixed value, without repeating triplets. Sort first so duplicates sit together and are easy to skip; two-sum on a sorted array is two pointers in O(n). If nums[i]>0, everything after it is positive, so the sum cannot be 0 anymore. So we sort, enumerate the first number, and squeeze the rest with two pointers.

We notice that the problem does not require us to return the triplet in order, so we might as well sort the array first, which makes it easy to skip duplicate elements.

Next, we enumerate the first element of the triplet nums[i], where 0 ≤ i < n - 2. For each i, we can find j and k satisfying nums[i] + nums[j] + nums[k] = 0 by maintaining two pointers j = i + 1 and k = n - 1. In the enumeration process, we need to skip duplicate elements to avoid duplicate triplets.

The specific judgment logic is as follows:

If i > 0 and nums[i] = nums[i - 1], it means that the element currently enumerated is the same as the previous element, we can skip it directly, because it will not produce new results.

If nums[i] > 0, it means that the element currently enumerated is greater than 0, so the sum of three numbers must not be equal to 0, and the enumeration ends.

Otherwise, we let the left pointer j = i + 1, and the right pointer k = n - 1. When j < k, the loop is executed, and the sum of three numbers x = nums[i] + nums[j] + nums[k] is calculated and compared with 0:

- If x < 0, it means that nums[j] is too small, we need to move j to the right.
- If x > 0, it means that nums[k] is too large, we need to move k to the left.
- Otherwise, it means that we have found a valid triplet, add it to the answer, move j to the right, move k to the left, and skip all duplicate elements to continue looking for the next valid triplet.

After the enumeration is over, we can get the answer to the triplet.

The time complexity is $O(n^2)$, and the space complexity is O(log n). The n is the length of the array.

Python 3

```python
class Solution:
    def threeSum(self, nums: List[int]) -> List[List[int]]:
        nums.sort()
        n = len(nums)
        ans = []
        for i in range(n - 2):
            if nums[i] > 0:
                break
            if i and nums[i] == nums[i - 1]:
                continue
            j, k = i + 1, n - 1
            while j < k:
                x = nums[i] + nums[j] + nums[k]
                if x < 0:
                    j += 1
                elif x > 0:
                    k -= 1
                else:
                    ans.append([nums[i], nums[j], nums[k]])
                    j, k = j + 1, k - 1
                    while j < k and nums[j] == nums[j - 1]:
                        j += 1
                    while j < k and nums[k] == nums[k + 1]:
                        k -= 1
        return ans
```

    return go(0, k, target)
```

PART 2 · TWO POINTERS · PROBLEM 5 OF 5

443. String Compression

Medium · Two Pointers, String

leetcode.com/problems/string-compression

★ **TOP 10 PROBLEM** in Two Pointers: master this one first

PROBLEM

Given an array of characters `chars`, compress it using the following algorithm:

Begin with an empty string `s`. For each group of **consecutive repeating characters** in `chars`:

- If the group's length is `1`, append the character to `s`.
- Otherwise, append the character followed by the group's length.

The compressed string `s` **should not be returned separately**, but instead, be stored **in the input character array** `chars`. Note that group lengths that are `10` or longer will be split into multiple characters in `chars`.

After you are done **modifying the input array,** return *the new length of the array*.

You must write an algorithm that uses only constant extra space.

Note: The characters in the array beyond the returned length do not matter and should be ignored.

Example 1:

```
Input: chars = ["a","a","b","b","c","c","c"]
Output: 6
Explanation: The groups are "aa", "bb", and "ccc". This compresses to "a2b2c3".
After modifying the input array in-place, the first 6 characters of chars should be
["a","2","b","2","c","3"].
```

Example 2:

```
Input: chars = ["a"]
Output: 1
Explanation: The only group is "a", which remains uncompressed since it is a single character.
After modifying the input array in-place, the first character of chars should be ["a"].
```

Example 3:

```
Input: chars = ["a","b","b","b","b","b","b","b","b","b","b","b","b"]
Output: 4
Explanation: The groups are "a" and "bbbbbbbbbbbb". This compresses to "ab12".
After modifying the input array in-place, the first 4 characters of chars should be ["a","b","1","2"].
```

Constraints:

- `1 <= chars.length <= 2000`
- `chars[i]` is a lowercase English letter, uppercase English letter, digit, or symbol.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

A run becomes the character plus its count (when the count is greater than 1), written in place. A second buffer would break the space bound. Read pointer i finds a run; write pointer k stores the character and, if needed, the decimal digits. Then i jumps to the next run. The write pointer never passes the read pointer: a compressed prefix is never longer than the original, so overwriting from the left is safe. Return k as the new length.

Python 3

```python
class Solution:
    def compress(self, chars: List[str]) -> int:
        i, k, n = 0, 0, len(chars)
        while i < n:
            j = i + 1
            while j < n and chars[j] == chars[i]:
                j += 1
            chars[k] = chars[i]
            k += 1
            if j - i > 1:
                cnt = str(j - i)
                for c in cnt:
                    chars[k] = c
                    k += 1
            i = j
        return k
```

Complexity. Time: O(n). Space: O(1).

1480. Running Sum of 1d Array

Easy · Array, Prefix Sum

leetcode.com/problems/running-sum-of-1d-array

★ **TOP 10 PROBLEM** in Prefix Sum: master this one first

PROBLEM

Given an array `nums`. We define a running sum of an array as `runningSum[i] = sum(nums[0]…nums[i])`.

Return the running sum of `nums`.

Example 1:

```
Input: nums = [1,2,3,4]
Output: [1,3,6,10]
Explanation: Running sum is obtained as follows: [1, 1+2, 1+2+3, 1+2+3+4].
```

Example 2:

```
Input: nums = [1,1,1,1,1]
Output: [1,2,3,4,5]
Explanation: Running sum is obtained as follows: [1, 1+1, 1+1+1, 1+1+1+1, 1+1+1+1+1].
```

Example 3:

```
Input: nums = [3,1,2,10,1]
Output: [3,4,6,16,17]
```

Constraints:

- `1 <= nums.length <= 1000`
- `-10^6 <= nums[i] <= 10^6`

SOLUTION (PYTHON 3)

Solution 1: Prefix Sum

How to think about it

Each output entry is a prefix sum. n≤ 1000, so one `accumulate` pass is enough.

We directly traverse the array. For the current element nums[i], we add it with the prefix sum nums[i-1] to get the prefix sum nums[i] of the current element.

The time complexity is O(n), where n is the length of the array. The space complexity is O(1).

Python 3

```python
class Solution:
    def runningSum(self, nums: List[int]) -> List[int]:
        return list(accumulate(nums))
```

        result.append(total)
    return result
```

PART 2 · PREFIX SUM · PROBLEM 2 OF 5

1854. Maximum Population Year

Easy · Array, Counting, Prefix Sum

leetcode.com/problems/maximum-population-year

★ **TOP 10 PROBLEM** in Prefix Sum: master this one first

PROBLEM

You are given a 2D integer array `logs` where each `logs[i] = [birth_i, death_i]` indicates the birth and death years of the i^{th} person.

The **population** of some year `x` is the number of people alive during that year. The i^{th} person is counted in year `x`'s population if `x` is in the **inclusive** range `[birth_i, death_i - 1]`. Note that the person is **not** counted in the year that they die.

Return *the **earliest** year with the **maximum population***.

Example 1:

```
Input: logs = [[1993,1999],[2000,2010]]
Output: 1993
Explanation: The maximum population is 1, and 1993 is the earliest year with this population.
```

Example 2:

```
Input: logs = [[1950,1961],[1960,1971],[1970,1981]]
Output: 1960
Explanation:
The maximum population is 2, and it had happened in years 1960 and 1970.
The earlier year between them is 1960.
```

Constraints:

- `1 <= logs.length <= 100`
- `1950 <= birth_i < death_i <= 2050`

SOLUTION (PYTHON 3)

Solution 1: Difference Array

How to think about it

We need the earliest year with the maximum population; years lie in [1950,2050]. Recounting every life for every year repeats work. The domain is tiny, so a difference array adds 1 at birth and subtracts 1 at death. A prefix-sum scan yields the population of each year; the first maximum, shifted back by 1950, is the answer.

We notice that the range of years is [1950,..2050]. Therefore, we can map these years to an array d of length 101, where the index of the array represents the value of the year minus 1950.

Next, we traverse logs. For each person, we increment d[$birth_i$ - 1950] by 1 and decrement d[$death_i$ - 1950] by 1. Finally, we traverse the array d, find the maximum value of the prefix sum, which is the year with the most population, and add 1950 to get the answer.

The time complexity is O(n), and the space complexity is O(C). Where n is the length of the array logs, and C is the range size of the years, i.e., 2050 - 1950 + 1 = 101.

Python 3

```python
class Solution:
    def maximumPopulation(self, logs: List[List[int]]) -> int:
        d = [0] * 101
        offset = 1950
        for a, b in logs:
            a, b = a - offset, b - offset
            d[a] += 1
            d[b] -= 1
        s = mx = j = 0
        for i, x in enumerate(d):
            s += x
            if mx < s:
                mx, j = s, i
        return j + offset
```

370. Range Addition

Medium · Array, Prefix Sum

leetcode.com/problems/range-addition

★ **TOP 10 PROBLEM** in Prefix Sum: master this one first

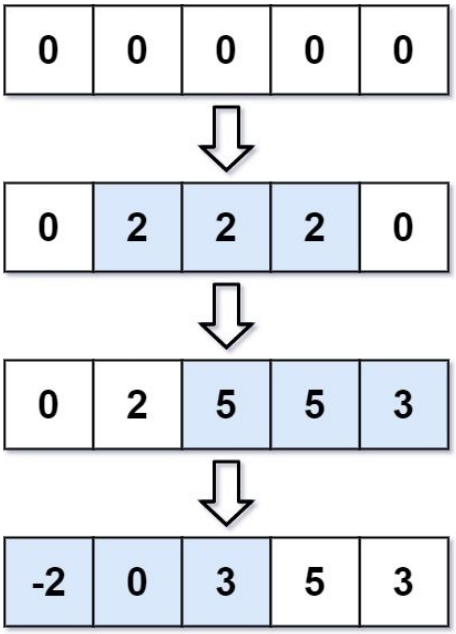
PROBLEM

You are given an integer `length` and an array `updates` where `updates[i] = [startIdx`$_i$`, endIdx`$_i$`, inc`$_i$`]`.

You have an array `arr` of length `length` with all zeros, and you have some operation to apply on `arr`. In the `i`th operation, you should increment all the elements `arr[startIdx`$_i$`], arr[startIdx`$_i$` + 1], ..., arr[endIdx`$_i$`]` by `inc`$_i$.

Return `arr` *after applying all the* `updates`.

Example 1:



```
Input: length = 5, updates = [[1,3,2],[2,4,3],[0,2,-2]]
Output: [-2,0,3,5,3]
```

Example 2:

```
Input: length = 10, updates = [[2,4,6],[5,6,8],[1,9,-4]]
Output: [0,-4,2,2,2,4,4,-4,-4,-4]
```

Constraints:

- `1 <= length <= 10`^{5}
- `0 <= updates.length <= 10`^{4}
- `0 <= startIdx`$_i$ `<= endIdx`$_i$ `< length`
- `-1000 <= inc`$_i$ `<= 1000`

SOLUTIONS (PYTHON 3)

Solution 1: Difference Array

> **How to think about it**
>
> Many range-add updates, then the final array. Touching each range in O(n) does not scale. A difference array turns a range add into two point writes. Add c at l and -c at r+1, then prefix-sum. Each update is O(1).

This is a template problem for difference arrays.

We define d as the difference array. To add c to each number in the interval [l,..r], we set d[l] += c and d[r+1] -= c. Finally, we compute the prefix sum of the difference array to obtain the original array.

The time complexity is O(n), and the space complexity is O(n). Here, n is the length of the array.

Python 3

```python
class Solution:
    def getModifiedArray(self, length: int, updates: List[List[int]]) -> List[int]:
        d = [0] * length
        for l, r, c in updates:
            d[l] += c
            if r + 1 < length:
                d[r + 1] -= c
        return list(accumulate(d))
```

Solution 2: Binary Indexed Tree + Difference Array

> **How to think about it**
>
> The difference array is already linear. A Fenwick tree encodes the same two-point updates; a prefix query recovers the value. An extra log n buys online queries later.

The time complexity is O(n × log n).

A Binary Indexed Tree (BIT), also known as a Fenwick Tree, can efficiently perform the following two operations:

1. **Point Update** `update(x, delta)`: Add a value delta to the number at position x in the sequence.
2. **Prefix Sum Query** `query(x)`: Query the sum of the interval [1, ... , x] in the sequence, i.e., the prefix sum up to position x.

The time complexity for both operations is O(log n).

Python 3

```python
class BinaryIndexedTree:
    __slots__ = "n", "c"

    def __init__(self, n: int):
        self.n = n
        self.c = [0] * (n + 1)

    def update(self, x: int, delta: int) -> None:
        while x <= self.n:
            self.c[x] += delta
            x += x & -x

    def query(self, x: int) -> int:
        s = 0
        while x:
            s += self.c[x]
            x -= x & -x
        return s

class Solution:
    def getModifiedArray(self, length: int, updates: List[List[int]]) -> List[int]:
        tree = BinaryIndexedTree(length)
        for l, r, c in updates:
            tree.update(l + 1, c)
            tree.update(r + 2, -c)
        return [tree.query(i + 1) for i in range(length)]
```

PART 2 · PREFIX SUM · PROBLEM 4 OF 5

974. Subarray Sums Divisible by K

Medium · Array, Hash Table, Prefix Sum

leetcode.com/problems/subarray-sums-divisible-by-k

★ **TOP 10 PROBLEM** in Prefix Sum: master this one first

PROBLEM

Given an integer array `nums` and an integer `k`, return *the number of non-empty **subarrays** that have a sum divisible by* `k`.

A **subarray** is a **contiguous** part of an array.

Example 1:

```
Input: nums = [4,5,0,-2,-3,1], k = 5
Output: 7
Explanation: There are 7 subarrays with a sum divisible by k = 5:
[4, 5, 0, -2, -3, 1], [5], [5, 0], [5, 0, -2, -3], [0], [0, -2, -3], [-2, -3]
```

Example 2:

```
Input: nums = [5], k = 9
Output: 0
```

Constraints:

- `1 <= nums.length <= 3 * 10^4`
- `-10^4 <= nums[i] <= 10^4`
- `2 <= k <= 10^4`

SOLUTION (PYTHON 3)

Solution 1: Hash Table + Prefix Sum

How to think about it

A subarray sum is divisible by k iff the two prefix sums are congruent modulo k. Enumerating intervals is quadratic. While scanning, a counter of residues tells how many earlier prefixes share the current s, which is the number of good subarrays ending here. Start with cnt[0]=1 for the empty prefix.

Suppose there exists $i \le j$ such that the sum of nums[i,..j] is divisible by k. If we let s_i represent the sum of nums[0,..i] and s_j represent the sum of nums[0,..j], then $s_j - s_i$ is divisible by k, i.e., $(s_j - s_i) \bmod k = 0$, which means $s_j \bmod k = s_i \bmod k$. Therefore, we can use a hash table to count the number of prefix sums modulo k, allowing us to quickly determine if there exists a subarray that meets the condition.

We use a hash table cnt to count the number of prefix sums modulo k, where cnt[i] represents the number of prefix sums with a modulo k value of i. Initially, cnt[0] = 1. We use a variable s to represent the prefix sum, initially s = 0.

Next, we traverse the array nums from left to right. For each element x, we calculate s = (s + x) mod k, then update the answer ans = ans + cnt[s], where cnt[s] represents the number of prefix sums with a modulo k value of s. Finally, we increment the value of cnt[s] by 1 and continue to the next element.

In the end, we return the answer ans.

Note: Since the value of s can be negative, we can add k to the result of s mod k and then take modulo k again to ensure that the value of s is non-negative.

The time complexity is O(n), and the space complexity is O(n). Here, n is the length of the array nums.

Python 3

```python
class Solution:
    def subarraysDivByK(self, nums: List[int], k: int) -> int:
        cnt = Counter({0: 1})
        ans = s = 0
        for x in nums:
            s = (s + x) % k
            ans += cnt[s]
            cnt[s] += 1
        return ans
```

        seen[total] = seen.get(total, 0) + 1
    return count
```

2536. Increment Submatrices by One

Medium · Array, Matrix, Prefix Sum

leetcode.com/problems/increment-submatrices-by-one

★ **TOP 10 PROBLEM** in Prefix Sum: master this one first

PROBLEM

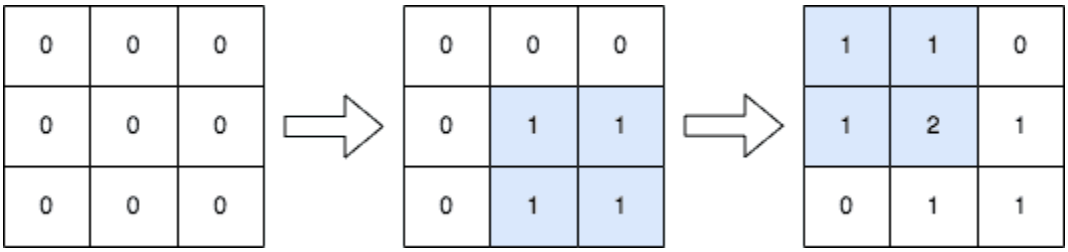
You are given a positive integer `n`, indicating that we initially have an `n x n` **0-indexed** integer matrix `mat` filled with zeroes.

You are also given a 2D integer array `query`. For each `query[i] = [row1_i, col1_i, row2_i, col2_i]`, you should do the following operation:

- Add `1` to **every element** in the submatrix with the **top left** corner `(row1_i, col1_i)` and the **bottom right** corner `(row2_i, col2_i)`. That is, add `1` to `mat[x][y]` for all `row1_i <= x <= row2_i` and `col1_i <= y <= col2_i`.

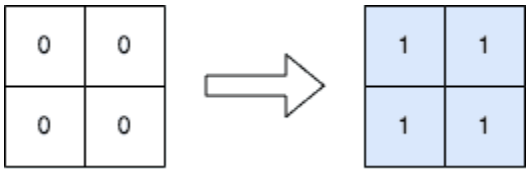
Return *the matrix* `mat` *after performing every query.*

Example 1:



```
Input: n = 3, queries = [[1,1,2,2],[0,0,1,1]]
Output: [[1,1,0],[1,2,1],[0,1,1]]
Explanation: The diagram above shows the initial matrix, the matrix after the first query, and the
matrix after the second query.
- In the first query, we add 1 to every element in the submatrix with the top left corner (1, 1) and
bottom right corner (2, 2).
- In the second query, we add 1 to every element in the submatrix with the top left corner (0, 0) and
bottom right corner (1, 1).
```

Example 2:



```
Input: n = 2, queries = [[0,0,1,1]]
Output: [[1,1],[1,1]]
Explanation: The diagram above shows the initial matrix and the matrix after the first query.
- In the first query we add 1 to every element in the matrix.
```

Constraints:

- `1 <= n <= 500`
- `1 <= queries.length <= 10^4`
- `0 <= row1_i <= row2_i < n`
- `0 <= col1_i <= col2_i < n`

SOLUTION (PYTHON 3)

Solution 1: 2D Difference Array

> **How to think about it**
>
> Several submatrices must be incremented by one. Walking every cell of every query is heavy when both q and n reach 500. A 2D difference array turns one rectangle increment into four O(1) corner updates: +1 at the top-left, +1 just past the bottom-right, and -1 at the other two corners. A 2D prefix sum restores the matrix after all queries.

A 2D difference array is a technique used to efficiently handle range updates on 2D arrays. We can implement fast updates on submatrices by maintaining a difference matrix of the same size as the original matrix.

Suppose we have a 2D difference matrix diff, initially with all elements set to 0. For each query [row1, col1, row2, col2], we can update the difference matrix through the following steps:

1. Increment position (row1, col1) by 1.
2. Decrement position (row2 + 1, col1) by 1, provided that row2 + 1 < n.
3. Decrement position (row1, col2 + 1) by 1, provided that col2 + 1 < n.
4. Increment position (row2 + 1, col2 + 1) by 1, provided that row2 + 1 < n and col2 + 1 < n.

After completing all queries, we need to convert the difference matrix back to the original matrix using prefix sums. That is, for each position (i, j), we calculate:

$$\text{mat}[i][j] = \text{diff}[i][j] + (\text{mat}[i-1][j] \text{ if } i > 0 \text{ else } 0) + (\text{mat}[i][j-1] \text{ if } j > 0 \text{ else } 0) - (\text{mat}[i-1][j-1] \text{ if } i > 0 \text{ and } j > 0 \text{ else } 0)$$

The time complexity is $O(m + n^2)$, where m and n are the length of queries and the given n, respectively. Ignoring the space consumed by the answer, the space complexity is O(1).

Python 3

```python
class Solution:
    def rangeAddQueries(self, n: int, queries: List[List[int]]) -> List[List[int]]:
        mat = [[0] * n for _ in range(n)]
        for x1, y1, x2, y2 in queries:
            mat[x1][y1] += 1
            if x2 + 1 < n:
                mat[x2 + 1][y1] -= 1
            if y2 + 1 < n:
                mat[x1][y2 + 1] -= 1
            if x2 + 1 < n and y2 + 1 < n:
                mat[x2 + 1][y2 + 1] += 1

        for i in range(n):
            for j in range(n):
                if i:
                    mat[i][j] += mat[i - 1][j]
                if j:
                    mat[i][j] += mat[i][j - 1]
                if i and j:
                    mat[i][j] -= mat[i - 1][j - 1]
        return mat
```

2461. Maximum Sum of Distinct Subarrays With Length K

Medium · Array, Hash Table, Sliding Window

leetcode.com/problems/maximum-sum-of-distinct-subarrays-with-length-k

★ **TOP 10 PROBLEM** in Sliding Window - Fixed Size: master this one first

PROBLEM

You are given an integer array `nums` and an integer `k`. Find the maximum subarray sum of all the subarrays of `nums` that meet the following conditions:

- The length of the subarray is `k`, and
- All the elements of the subarray are **distinct**.

Return *the maximum subarray sum of all the subarrays that meet the conditions.* If no subarray meets the conditions, return `0`.

*A **subarray** is a contiguous non-empty sequence of elements within an array.*

Example 1:

```
Input: nums = [1,5,4,2,9,9,9], k = 3
Output: 15
Explanation: The subarrays of nums with length 3 are:
- [1,5,4] which meets the requirements and has a sum of 10.
- [5,4,2] which meets the requirements and has a sum of 11.
- [4,2,9] which meets the requirements and has a sum of 15.
- [2,9,9] which does not meet the requirements because the element 9 is repeated.
- [9,9,9] which does not meet the requirements because the element 9 is repeated.
We return 15 because it is the maximum subarray sum of all the subarrays that meet the conditions
```

Example 2:

```
Input: nums = [4,4,4], k = 3
Output: 0
Explanation: The subarrays of nums with length 3 are:
- [4,4,4] which does not meet the requirements because the element 4 is repeated.
We return 0 because no subarrays meet the conditions.
```

Constraints:

- `1 <= k <= nums.length <=` 10^5
- `1 <= nums[i] <=` 10^5

SOLUTION (PYTHON 3)

Solution 1: Sliding Window + Hash Table

How to think about it

Maximum sum of a length-k window with distinct values, n≤ 10^5. Slide a window of sum and frequencies; when the map size equals k, update the answer. Drop a key when its count hits zero.

We maintain a sliding window of length k, use a hash table cnt to record the count of each number in the window, and use a variable s to record the sum of all numbers in the window. Each time we slide the window, if all numbers in the window are unique, we update the answer.

The time complexity is O(n), and the space complexity is O(n). Here, n is the length of the array nums.

Python 3

```python
class Solution:
    def maximumSubarraySum(self, nums: List[int], k: int) -> int:
        cnt = Counter(nums[:k])
        s = sum(nums[:k])
        ans = s if len(cnt) == k else 0
        for i in range(k, len(nums)):
            cnt[nums[i]] += 1
            cnt[nums[i - k]] -= 1
            if cnt[nums[i - k]] == 0:
                cnt.pop(nums[i - k])
            s += nums[i] - nums[i - k]
            if len(cnt) == k:
                ans = max(ans, s)
        return ans
```

30. Substring with Concatenation of All Words

Hard · Hash Table, String, Sliding Window

leetcode.com/problems/substring-with-concatenation-of-all-words

★ **TOP 10 PROBLEM** in Sliding Window - Fixed Size: master this one first

PROBLEM

You are given a string `s` and an array of strings `words`. All the strings of `words` are of **the same length**.

A **concatenated string** is a string that exactly contains all the strings of any permutation of `words` concatenated.

- For example, if `words = ["ab","cd","ef"]`, then `"abcdef"`, `"abefcd"`, `"cdabef"`, `"cdefab"`, `"efabcd"`, and `"efcdab"` are all concatenated strings. `"acdbef"` is not a concatenated string because it is not the concatenation of any permutation of `words`.

Return an array of *the starting indices* of all the concatenated substrings in `s`. You can return the answer in **any order**.

Example 1:

Input: s = "barfoothefoobarman", words = ["foo","bar"]

Output: [0,9]

Explanation:

The substring starting at 0 is `"barfoo"`. It is the concatenation of `["bar","foo"]` which is a permutation of `words`.
The substring starting at 9 is `"foobar"`. It is the concatenation of `["foo","bar"]` which is a permutation of `words`.

Example 2:

Input: s = "wordgoodgoodgoodbestword", words = ["word","good","best","word"]

Output: []

Explanation:

There is no concatenated substring.

Example 3:

Input: s = "barfoofoobarthefoobarman", words = ["bar","foo","the"]

Output: [6,9,12]

Explanation:

The substring starting at 6 is `"foobarthe"`. It is the concatenation of `["foo","bar","the"]`.
The substring starting at 9 is `"barthefoo"`. It is the concatenation of `["bar","the","foo"]`.
The substring starting at 12 is `"thefoobar"`. It is the concatenation of `["the","foo","bar"]`.

Constraints:

- `1 <= s.length <= 10^4`
- `1 <= words.length <= 5000`
- `1 <= words[i].length <= 30`
- `s` and `words[i]` consist of lowercase English letters.

SOLUTION (PYTHON 3)

Solution 1: Hash Table + Sliding Window

How to think about it

The first idea is to try every start and test whether the length-n· k window is some permutation of words. With m ≤ 10^4, n ≤ 5000, k ≤ 30, slicing n words per start is worst-case O(mnk) and will not pass. The bottleneck is recounting heavily overlapping windows from scratch. Words share one length k, so the window slides in steps of k and frequencies can be maintained incrementally in a hash map. There are only k alignments (starts 0,1,…,k-1). In each, the right end eats a length-k token: a word outside cnt resets the window; an over-used word is spat out from the left until counts are legal; exactly n words means we record the left index. Each character enters and leaves a window a constant number of times, so the total is O(mk).

We use a hash table cnt to count the number of times each word appears in words, and use a hash table cnt1 to count the number of times each word appears in the current sliding window. We denote the length of the string s as m, the number of words in the string array words as n, and the length of each word as k.

We can enumerate the starting point i of the sliding window, where 0 < i < k. For each starting point, we maintain a sliding window with the left boundary as l, the right boundary as r, and the number of words in the sliding window as t. Additionally, we use a hash table cnt1 to count the number of times each word appears in the sliding window.

Each time, we extract the string s[r:r+k]. If s[r:r+k] is not in the hash table cnt, it means that the words in the current sliding window are not valid. We update the left boundary l to r, clear the hash table cnt1, and reset the word count t to 0. If s[r:r+k] is in the hash table cnt, it means that the words in the current sliding window are valid. We increase the word count t by 1, and increase the count of s[r:r+k] in the hash table cnt1 by 1. If cnt1[s[r:r+k]] is greater than cnt[s[r:r+k]], it means that s[r:r+k] appears too many times in the current sliding window. We need to move the left boundary l to the right until cnt1[s[r:r+k]] = cnt[s[r:r+k]]. If t = n, it means that the words in the current sliding window are exactly valid, and we add the left boundary l to the answer array.

The time complexity is O(m × k), and the space complexity is O(n × k). Here, m and n are the lengths of the string s and the string array words respectively, and k is the length of the words in the string array words.

Python 3

```python
class Solution:
    def findSubstring(self, s: str, words: List[str]) -> List[int]:
        cnt = Counter(words)
        m, n = len(s), len(words)
        k = len(words[0])
        ans = []
        for i in range(k):
            l = r = i
            cnt1 = Counter()
            while r + k <= m:
                t = s[r : r + k]
                r += k
                if cnt[t] == 0:
                    l = r
                    cnt1.clear()
                    continue
                cnt1[t] += 1
                while cnt1[t] > cnt[t]:
                    rem = s[l : l + k]
                    l += k
                    cnt1[rem] -= 1
                if r - l == n * k:
                    ans.append(l)
        return ans
```

159. Longest Substring with At Most Two Distinct Characters

Medium · Hash Table, String, Sliding Window

leetcode.com/problems/longest-substring-with-at-most-two-distinct-characters

★ **TOP 10 PROBLEM** in Sliding Window - Dynamic Size: master this one first

PROBLEM

Given a string `s`, return *the length of the longest substring that contains at most **two distinct characters***.

Example 1:

```
Input: s = "eceba"
Output: 3
Explanation: The substring is "ece" which its length is 3.
```

Example 2:

```
Input: s = "ccaabbb"
Output: 5
Explanation: The substring is "aabbb" which its length is 5.
```

Constraints:

- `1 <= s.length <= 10^5`
- `s` consists of English letters.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Longest substring with at most two distinct characters. n≤ 10^5, so enumerating endpoints is O(n^2). The distinct count grows with the right end and shrinks with the left. Extend right while counting; when there are more than two kinds, move left. Update the answer on a valid window.

Python 3

```python
class Solution:
    def lengthOfLongestSubstringTwoDistinct(self, s: str) -> int:
        cnt = Counter()
        ans = j = 0
        for i, c in enumerate(s):
            cnt[c] += 1
            while len(cnt) > 2:
                cnt[s[j]] -= 1
                if cnt[s[j]] == 0:
                    cnt.pop(s[j])
                j += 1
            ans = max(ans, i - j + 1)
        return ans
```

PART 2 · SLIDING WINDOW - DYNAMIC SIZE · PROBLEM 2 OF 3

340. Longest Substring with At Most K Distinct Characters

Medium · Hash Table, String, Sliding Window

leetcode.com/problems/longest-substring-with-at-most-k-distinct-characters

★ **TOP 10 PROBLEM** in Sliding Window - Dynamic Size: master this one first

PROBLEM

Given a string `s` and an integer `k`, return *the length of the longest substring of* `s` *that contains at most* `k` ***distinct*** *characters*.

Example 1:

```
Input: s = "eceba", k = 2
Output: 3
Explanation: The substring is "ece" with length 3.
```

Example 2:

```
Input: s = "aa", k = 1
Output: 2
Explanation: The substring is "aa" with length 2.
```

Constraints:

- `1 <= s.length <= 5 * 10^4`
- `0 <= k <= 50`

SOLUTION (PYTHON 3)

Solution 1: Sliding Window + Hash Table

How to think about it

Longest substring with at most k distinct characters. Checking every pair of ends is O(n^2). Distinctness grows with the right end and shrinks when the left advances, so a sliding window works. Admit the right character; while the map has more than k keys, drop the left. The window is always the longest legal suffix of the prefix, and the length is n-l.

We can use the idea of a sliding window, with a hash table cnt to record the occurrence count of each character within the window, and l to denote the left boundary of the window.

Iterate through the string, adding the character at the right boundary to the hash table each time. If the number of distinct characters in the hash table exceeds k, remove the character at the left boundary from the hash table, then update the left boundary l.

Finally, return the length of the string minus the length of the left boundary.

The time complexity is O(n), and the space complexity is O(k). Here, n is the length of the string.

Python 3

```python
class Solution:
    def lengthOfLongestSubstringKDistinct(self, s: str, k: int) -> int:
        l = 0
        cnt = Counter()
        for c in s:
            cnt[c] += 1
            if len(cnt) > k:
                cnt[s[l]] -= 1
                if cnt[s[l]] == 0:
                    del cnt[s[l]]
                l += 1
        return len(s) - l
```

        return total

    return at_most(k) - at_most(k - 1)
```

395. Longest Substring with At Least K Repeating Characters

Medium · Hash Table, String, Divide and Conquer, Sliding Window

leetcode.com/problems/longest-substring-with-at-least-k-repeating-characters

★ **TOP 10 PROBLEM** in Sliding Window - Dynamic Size: master this one first

PROBLEM

Given a string `s` and an integer `k`, return *the length of the longest substring of* `s` *such that the frequency of each character in this substring is greater than or equal to* `k`.

if no such substring exists, return 0.

Example 1:

```
Input: s = "aaabb", k = 3
Output: 3
Explanation: The longest substring is "aaa", as 'a' is repeated 3 times.
```

Example 2:

```
Input: s = "ababbc", k = 2
Output: 5
Explanation: The longest substring is "ababb", as 'a' is repeated 2 times and 'b' is repeated 3 times.
```

Constraints:

- `1 <= s.length <= 10^4`
- `s` consists of only lowercase English letters.
- `1 <= k <= 10^5`

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Longest substring in which every present character occurs at least k times. A distinct-count window does not capture "all ≥ k". A character that appears fewer than k times in the whole range cannot appear in any legal substring, so it is a split point. Count the range, split on a rare character, and recurse; if none exists the range is legal. Depth is at most 26.

Python 3

```python
class Solution:
    def longestSubstring(self, s: str, k: int) -> int:
        def dfs(l, r):
            cnt = Counter(s[l : r + 1])
            split = next((c for c, v in cnt.items() if v < k), '')
            if not split:
                return r - l + 1
            i = l
            ans = 0
            while i <= r:
                while i <= r and s[i] == split:
                    i += 1
                if i >= r:
                    break
                j = i
                while j <= r and s[j] != split:
                    j += 1
                t = dfs(i, j - 1)
                ans = max(ans, t)
                i = j
            return ans

        return dfs(0, len(s) - 1)
```

Complexity. Time: O(n * C), C = 26 letters (the recursion splits at most C times deep). Space: O(C).

918. Maximum Sum Circular Subarray

Medium · Queue, Array, Divide and Conquer, Dynamic Programming, Monotonic Queue

leetcode.com/problems/maximum-sum-circular-subarray

★ **TOP 10 PROBLEM** in Kadane's Algorithm: master this one first

PROBLEM

Given a **circular integer array** `nums` of length `n`, return *the maximum possible sum of a non-empty* ***subarray*** *of* `nums`.

A **circular array** means the end of the array connects to the beginning of the array. Formally, the next element of `nums[i]` is `nums[(i + 1) % n]` and the previous element of `nums[i]` is `nums[(i - 1 + n) % n]`.

A **subarray** may only include each element of the fixed buffer `nums` at most once. Formally, for a subarray `nums[i], nums[i + 1], ..., nums[j]`, there does not exist `i <= k1, k2 <= j` with `k1 % n == k2 % n`.

Example 1:

```
Input: nums = [1,-2,3,-2]
Output: 3
Explanation: Subarray [3] has maximum sum 3.
```

Example 2:

```
Input: nums = [5,-3,5]
Output: 10
Explanation: Subarray [5,5] has maximum sum 5 + 5 = 10.
```

Example 3:

```
Input: nums = [-3,-2,-3]
Output: -2
Explanation: Subarray [-2] has maximum sum -2.
```

Constraints:

- `n == nums.length`
- `1 <= n <= 3 * 10^4`
- `-3 * 10^4 <= nums[i] <= 3 * 10^4`

SOLUTION (PYTHON 3)

Solution 1: Maintain Prefix Maximum

How to think about it

A circular maximum subarray is either a normal Kadane segment, or the total sum minus a minimum segment that wraps around. One scan maintains the prefix minimum and prefix maximum to obtain both quantities, then returns the larger of ans and s-smi.

The maximum sum of a circular subarray can be divided into two cases:

- Case 1: The subarray with the maximum sum does not include the circular part, which is the ordinary maximum subarray sum;
- Case 2: The subarray with the maximum sum includes the circular part, which can be transformed into: the total sum of the array minus the minimum subarray sum.

Therefore, we maintain the following variables:

- The minimum prefix sum pmi, initially 0;
- The maximum prefix sum pmx, initially -∞;

- The prefix sum s, initially 0;
- The minimum subarray sum smi, initially ∞;
- The answer ans, initially -∞.

Next, we only need to traverse the array nums. For the current element x we are traversing, we perform the following update operations:

- Update the prefix sum s = s + x;
- Update the answer ans = max(ans, s - pmi), which is the answer for Case 1 (the prefix sum s minus the minimum prefix sum pmi can give the maximum subarray sum);
- Update smi = min(smi, s - pmx), which is the minimum subarray sum for Case 2;
- Update pmi = min(pmi, s), which is the minimum prefix sum;
- Update pmx = max(pmx, s), which is the maximum prefix sum.

After the traversal, we return the maximum value of ans and s - smi as the answer.

The time complexity is O(n), where n is the length of the array. The space complexity is O(1).

Python 3

```python
class Solution:
    def maxSubarraySumCircular(self, nums: List[int]) -> int:
        pmi, pmx = 0, -inf
        ans, s, smi = -inf, 0, inf
        for x in nums:
            s += x
            ans = max(ans, s - pmi)
            smi = min(smi, s - pmx)
            pmi = min(pmi, s)
            pmx = max(pmx, s)
        return max(ans, s - smi)
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

        best_max_here = max(x, best_max_here + x)
        best_max = max(best_max, best_max_here)
    if best_max == total:
        return best_min
    return min(best_min, total - best_max)
```

PART 2 · KADANE'S ALGORITHM · PROBLEM 2 OF 5

978. Longest Turbulent Subarray

Medium · Array, Dynamic Programming, Sliding Window

leetcode.com/problems/longest-turbulent-subarray

★ **TOP 10 PROBLEM** in Kadane's Algorithm: master this one first

PROBLEM

Given an integer array `arr`, return *the length of a maximum size turbulent subarray of* `arr`.

A subarray is **turbulent** if the comparison sign flips between each adjacent pair of elements in the subarray.

More formally, a subarray `[arr[i], arr[i + 1], ..., arr[j]]` of `arr` is said to be turbulent if and only if:

- For `i <= k < j`:
  - `arr[k] > arr[k + 1]` when `k` is odd, and
  - `arr[k] < arr[k + 1]` when `k` is even.
- Or, for `i <= k < j`:
  - `arr[k] > arr[k + 1]` when `k` is even, and
  - `arr[k] < arr[k + 1]` when `k` is odd.

Example 1:

```
Input: arr = [9,4,2,10,7,8,8,1,9]
Output: 5
Explanation: arr[1] > arr[2] < arr[3] > arr[4] < arr[5]
```

Example 2:

```
Input: arr = [4,8,12,16]
Output: 2
```

Example 3:

```
Input: arr = [100]
Output: 1
```

Constraints:

- `1 <= arr.length <= 4 * 10^4`
- `0 <= arr[i] <= 10^9`

SOLUTION (PYTHON 3)

Solution 1: Dynamic Programming

How to think about it

A turbulent subarray alternates strict comparisons. Checking every subarray is quadratic. Ending at i, we only need the longest rise-ending and fall-ending lengths, each extending the opposite state of i-1, or resetting to 1 on a tie. Two rolling variables suffice.

We define f[i] as the length of the longest turbulent subarray ending at nums[i] with an increasing state, and g[i] as the length of the longest turbulent subarray ending at nums[i] with a decreasing state. Initially, f[0] = 1, g[0] = 1. The answer is max(f[i], g[i]).

For i > 0, if nums[i] > nums[i - 1], then f[i] = g[i - 1] + 1, otherwise f[i] = 1; if nums[i] < nums[i - 1], then g[i] = f[i - 1] + 1, otherwise g[i] = 1.

Since f[i] and g[i] are only related to f[i - 1] and g[i - 1], two variables can be used instead of arrays.

The time complexity is O(n), where n is the length of the array. The space complexity is O(1).

Python 3

```python
class Solution:
    def maxTurbulenceSize(self, arr: List[int]) -> int:
        ans = f = g = 1
        for a, b in pairwise(arr):
            ff = g + 1 if a < b else 1
            gg = f + 1 if a > b else 1
            f, g = ff, gg
            ans = max(ans, f, g)
        return ans
```

    return total
```

PART 2 · KADANE'S ALGORITHM · PROBLEM 3 OF 5

1014. Best Sightseeing Pair

Medium · Array, Dynamic Programming

leetcode.com/problems/best-sightseeing-pair

★ **TOP 10 PROBLEM** in Kadane's Algorithm: master this one first

PROBLEM

You are given an integer array `values` where values[i] represents the value of the i^{th} sightseeing spot. Two sightseeing spots `i` and `j` have a **distance** `j - i` between them.

The score of a pair (`i < j`) of sightseeing spots is `values[i] + values[j] + i - j`: the sum of the values of the sightseeing spots, minus the distance between them.

Return *the maximum score of a pair of sightseeing spots*.

Example 1:

```
Input: values = [8,1,5,2,6]
Output: 11
Explanation: i = 0, j = 2, values[i] + values[j] + i - j = 8 + 5 + 0 - 2 = 11
```

Example 2:

```
Input: values = [1,2]
Output: 2
```

Constraints:

- `2 <= values.length <= 5 * 10^4`
- `1 <= values[i] <= 1000`

SOLUTION (PYTHON 3)

Solution 1: Enumeration

How to think about it

Evaluating values[i]+values[j]+i-j for every i<j is quadratic. Rewriting it as (values[i]+i)+(values[j]-j) shows that a fixed j only needs the best values[i]+i to its left. Scanning j from left to right, one variable stores that prefix maximum, giving the best pair at j in constant time before we fold in values[j]+j. Each index is used once as a right endpoint and once as a left candidate, so the scan is linear.

We can enumerate j from left to right while maintaining the maximum value of values[i] + i for elements to the left of j, denoted as mx. For each j, the maximum score is mx + values[j] - j. The answer is the maximum of these maximum scores for all positions.

The time complexity is O(n), where n is the length of the array values. The space complexity is O(1).

Python 3

```python
class Solution:
    def maxScoreSightseeingPair(self, values: List[int]) -> int:
        ans = mx = 0
        for j, x in enumerate(values):
            ans = max(ans, mx + x - j)
            mx = max(mx, x + j)
        return ans
```

```

1186. Maximum Subarray Sum with One Deletion

Medium · Array, Dynamic Programming

leetcode.com/problems/maximum-subarray-sum-with-one-deletion

★ **TOP 10 PROBLEM** in Kadane's Algorithm: master this one first

PROBLEM

Given an array of integers, return the maximum sum for a **non-empty** subarray (contiguous elements) with at most one element deletion. In other words, you want to choose a subarray and optionally delete one element from it so that there is still at least one element left and the sum of the remaining elements is maximum possible.

Note that the subarray needs to be **non-empty** after deleting one element.

Example 1:

```
Input: arr = [1,-2,0,3]
Output: 4
Explanation: Because we can choose [1, -2, 0, 3] and drop -2, thus the subarray [1, 0, 3] becomes the maximum value.
```

Example 2:

```
Input: arr = [1,-2,-2,3]
Output: 3
Explanation: We just choose [3] and it's the maximum sum.
```

Example 3:

```
Input: arr = [-1,-1,-1,-1]
Output: -1
Explanation: The final subarray needs to be non-empty. You can't choose [-1] and delete -1 from it, then get an empty subarray to make the sum equals to 0.
```

Constraints:

- $1 <= arr.length <= 10^5$
- $-10^4 <= arr[i] <= 10^4$

SOLUTION (PYTHON 3)

Solution 1: Preprocessing + Enumeration

How to think about it

A subarray may drop at most one element. Kadane from each end yields the best segment ending or starting at an index; with no deletion the answer is their maximum. Deleting arr[i] adds the best left ending at i-1 to the best right starting at i+1. After filling left and right, enumerate interior deletion points.

We can preprocess the array arr to find the maximum subarray sum ending and starting with each element, storing them in arrays left and right, respectively.

If we do not delete any element, then the maximum subarray sum is the maximum value in left[i] or right[i]; if we delete an element, we can enumerate each position i in [1..n-2], calculate the value of left[i-1] + right[i+1], and take the maximum value.

The time complexity is O(n), and the space complexity is O(n). Here, n is the length of the array arr.

Python 3

```python
class Solution:
    def maximumSum(self, arr: List[int]) -> int:
        n = len(arr)
        left = [0] * n
        right = [0] * n
        s = 0
        for i, x in enumerate(arr):
            s = max(s, 0) + x
            left[i] = s
        s = 0
        for i in range(n - 1, -1, -1):
            s = max(s, 0) + arr[i]
            right[i] = s
        ans = max(left)
        for i in range(1, n - 1):
            ans = max(ans, left[i - 1] + right[i + 1])
        return ans
```

PART 2 · KADANE'S ALGORITHM · PROBLEM 5 OF 5

1749. Maximum Absolute Sum of Any Subarray

Medium · Array, Dynamic Programming

leetcode.com/problems/maximum-absolute-sum-of-any-subarray

★ **TOP 10 PROBLEM** in Kadane's Algorithm: master this one first

PROBLEM

You are given an integer array `nums`. The **absolute sum** of a subarray $[nums_l, nums_{l+1}, ..., nums_{r-1}, nums_r]$ is $abs(nums_l + nums_{l+1} + ... + nums_{r-1} + nums_r)$.

Return *the **maximum** absolute sum of any **(possibly empty)** subarray of* `nums`.

Note that `abs(x)` is defined as follows:

- If `x` is a negative integer, then `abs(x) = -x`.
- If `x` is a non-negative integer, then `abs(x) = x`.

Example 1:

```
Input: nums = [1,-3,2,3,-4]
Output: 5
Explanation: The subarray [2,3] has absolute sum = abs(2+3) = abs(5) = 5.
```

Example 2:

```
Input: nums = [2,-5,1,-4,3,-2]
Output: 8
Explanation: The subarray [-5,1,-4] has absolute sum = abs(-5+1-4) = abs(-8) = 8.
```

Constraints:

- $1 <= nums.length <= 10^5$
- $-10^4 <= nums[i] <= 10^4$

SOLUTION (PYTHON 3)

Solution 1: Dynamic Programming

How to think about it

The maximum absolute subarray sum is the larger of the maximum subarray sum and the absolute minimum subarray sum. Kadane tracks the best and worst sums f,g ending here; the answer is the global max of f and |g|.

We define f[i] to represent the maximum value of the subarray ending with nums[i], and define g[i] to represent the minimum value of the subarray ending with nums[i]. Then the state transition equation of f[i] and g[i] is as follows:

aligned f[i] &= max(f[i - 1], 0) + nums[i] \ g[i] &= min(g[i - 1], 0) + nums[i] aligned

The final answer is the maximum value of max(f[i], |g[i]|).

Since f[i] and g[i] are only related to f[i - 1] and g[i - 1], we can use two variables to replace the array, reducing the space complexity to O(1).

Time complexity O(n), space complexity O(1), where n is the length of the array nums.

Python 3

```python
class Solution:
    def maxAbsoluteSum(self, nums: List[int]) -> int:
        f = g = 0
        ans = 0
        for x in nums:
            f = max(f, 0) + x
            g = min(g, 0) + x
            ans = max(ans, f, abs(g))
        return ans
```

36. Valid Sudoku

Medium · Array, Hash Table, Matrix

leetcode.com/problems/valid-sudoku

★ **TOP 10 PROBLEM** in Matrix (2D Array): master this one first

PROBLEM

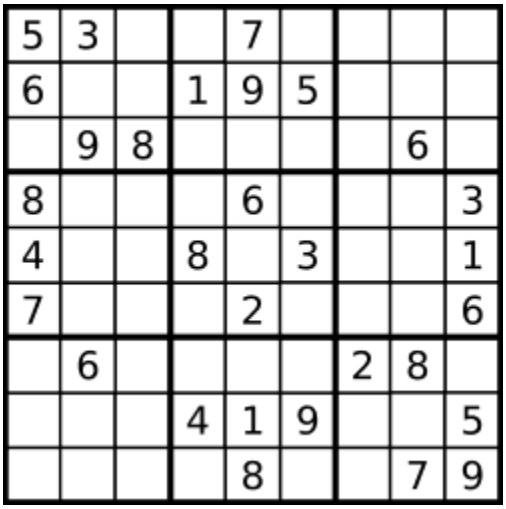
Determine if a `9 x 9` Sudoku board is valid. Only the filled cells need to be validated **according to the following rules**:

1. Each row must contain the digits `1-9` without repetition.
2. Each column must contain the digits `1-9` without repetition.
3. Each of the nine `3 x 3` sub-boxes of the grid must contain the digits `1-9` without repetition.

Note:

- A Sudoku board (partially filled) could be valid but is not necessarily solvable.
- Only the filled cells need to be validated according to the mentioned rules.

Example 1:



```
Input: board =
[["5","3",".",".","7",".",".",".","."]
,["6",".",".","1","9","5",".",".","."]
,[".","9","8",".",".",".",".","6","."]
,["8",".",".",".","6",".",".",".","3"]
,["4",".",".","8",".","3",".",".","1"]
,["7",".",".",".","2",".",".",".","6"]
,[".","6",".",".",".",".",".","2","8","."]
,[".",".",".","4","1","9",".",".","5"]
,[".",".",".",".","8",".",".","7","9"]]
Output: true
```

Example 2:

```
Input: board =
[["8","3",".",".","7",".",".",".","."]
,["6",".",".","1","9","5",".",".","."]
,[".","9","8",".",".",".",".","6","."]
,["8",".",".",".","6",".",".",".","3"]
,["4",".",".","8",".","3",".",".","1"]
,["7",".",".",".","2",".",".",".","6"]
,[".","6",".",".",".",".","2","8","."]
,[".",".",".","4","1","9",".",".","5"]
,[".",".",".",".","8",".",".","7","9"]]
Output: false
Explanation: Same as Example 1, except with the 5 in the top left corner being modified to 8. Since there are two 8's in the top left 3x3 sub-box, it is invalid.
```

Constraints:

- `board.length == 9`
- `board[i].length == 9`
- `board[i][j]` is a digit `1-9` or `'.'`.

SOLUTION (PYTHON 3)

Solution 1: Traversal once

How to think about it

The first idea is, for each filled digit, to rescan its row, column, and box. The board is only 9 × 9, so that would pass. The bottleneck is rescanning the same row, column, and box. We only need to remember whether digit v has already appeared in that unit. One pass is enough: three boolean tables row[i][v], col[j][v], and sub[k][v], with box index k = floor(i/3) × 3 + floor(j/3). A second hit of the same digit returns false immediately.

The valid sudoku satisfies the following three conditions:

- The digits are not repeated in each row;
- The digits are not repeated in each column;
- The digits are not repeated in each 3 × 3 box.

Traverse the sudoku, for each digit, check whether the row, column and 3 × 3 box it is in have appeared the digit. If it is, return `false`. If the traversal is over, return `true`.

The time complexity is O(C) and the space complexity is O(C), where C is the number of empty spaces in the sudoku. In this question, C=81.

Python 3

```python
class Solution:
    def isValidSudoku(self, board: List[List[str]]) -> bool:
        row = [[False] * 9 for _ in range(9)]
        col = [[False] * 9 for _ in range(9)]
        sub = [[False] * 9 for _ in range(9)]
        for i in range(9):
            for j in range(9):
                c = board[i][j]
                if c == '.':
                    continue
                num = int(c) - 1
                k = i // 3 * 3 + j // 3
                if row[i][num] or col[j][num] or sub[k][num]:
                    return False
                row[i][num] = True
                col[j][num] = True
                sub[k][num] = True
        return True
```

82. Remove Duplicates from Sorted List II

Medium · Linked List, Two Pointers

leetcode.com/problems/remove-duplicates-from-sorted-list-ii

★ **TOP 10 PROBLEM** in Linked List: master this one first

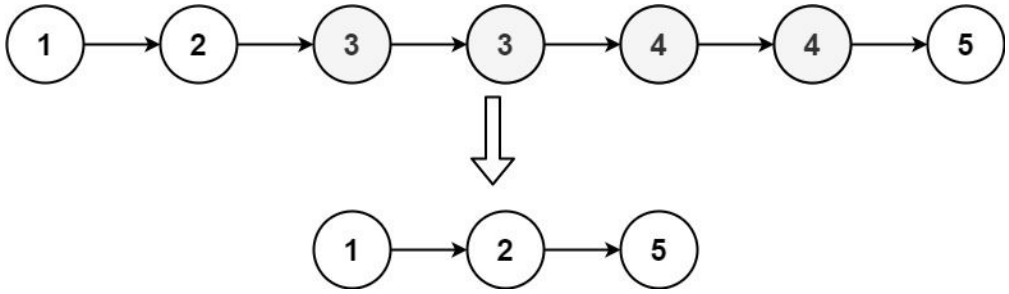
PROBLEM

You are given the `head` of a **sorted** linked list.

Delete all nodes that have **duplicate** numbers, leaving only **distinct** numbers from the original list.

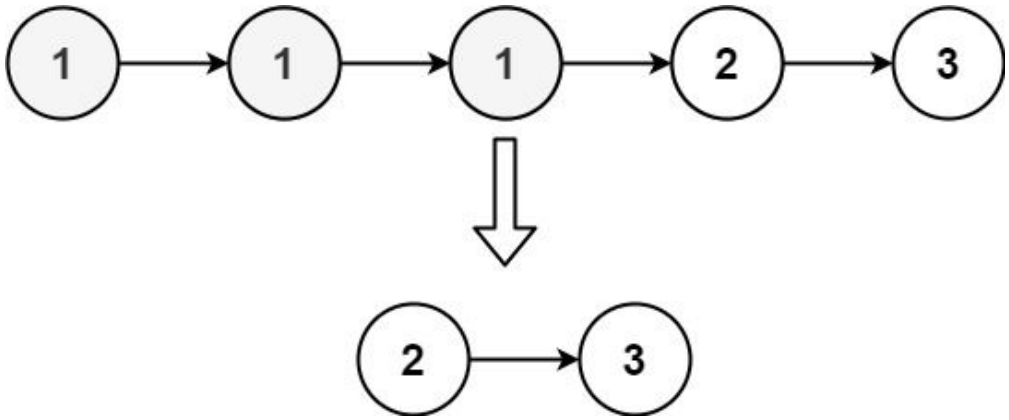
Return the linked list **sorted** as well.

Example 1:



```
Input: head = [1,2,3,3,4,4,5]
Output: [1,2,5]
```

Example 2:



```
Input: head = [1,1,1,2,3]
Output: [2,3]
```

Constraints:

- The number of nodes in the list is in the range `[0, 300]`.
- `-100 <= Node.val <= 100`
- The list is guaranteed to be **sorted** in ascending order.

SOLUTION (PYTHON 3)

Solution 1: Single Pass

How to think about it

The first idea is count frequencies, then rebuild a list of values that appear once. Correct, and n ≤ 300 is tiny, but that wastes “already sorted, so duplicates are adjacent” and uses extra O(n) space. The bottleneck is not using adjacency. Equal values form a contiguous run; one pass decides whether the whole run stays. The head may be deleted, so we need a dummy. And when a run is dropped, the predecessor must not advance into it. Keep pre on the last kept node and slide cur over the current value: if pre.next is still cur, the run has length one and pre moves; otherwise skip the whole run.

First, we create a dummy head node dummy, and set dummy.next = head. Then we create a pointer pre pointing to dummy, and a pointer cur pointing to head, and start traversing the linked list.

When the node value pointed by cur is the same as the node value pointed by cur.next, we let cur keep moving forward until the node value pointed by cur is different from the node value pointed by cur.next. At this point, we check whether pre.next is equal to cur. If they are equal, it means there are no duplicate nodes between pre and cur, so we move pre to the position of cur; otherwise, it means there are duplicate nodes between pre and cur, so we set pre.next to cur.next. Then we continue to move cur forward. Continue the above operation until cur is null, and the traversal ends.

Finally, return dummy.next.

The time complexity is O(n), and the space complexity is O(1). Here, n is the length of the linked list.

Python 3

```python
# Definition for singly-linked list.
# class ListNode:
#     def __init__(self, val=0, next=None):
#         self.val = val
#         self.next = next
class Solution:
    def deleteDuplicates(self, head: Optional[ListNode]) -> Optional[ListNode]:
        dummy = pre = ListNode(next=head)
        cur = head
        while cur:
            while cur.next and cur.next.val == cur.val:
                cur = cur.next
            if pre.next == cur:
                pre = cur
            else:
                pre.next = cur.next
            cur = cur.next
        return dummy.next
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

            tail.next = ListNode(node.val)
            tail = tail.next
        node = node.next
    return dummy.next
```

237. Delete Node in a Linked List

Medium · Linked List

leetcode.com/problems/delete-node-in-a-linked-list

★ **TOP 10 PROBLEM** in Linked List: master this one first

PROBLEM

There is a singly-linked list `head` and we want to delete a node `node` in it.

You are given the node to be deleted `node`. You will **not be given access** to the first node of `head`.

All the values of the linked list are **unique**, and it is guaranteed that the given node `node` is not the last node in the linked list.

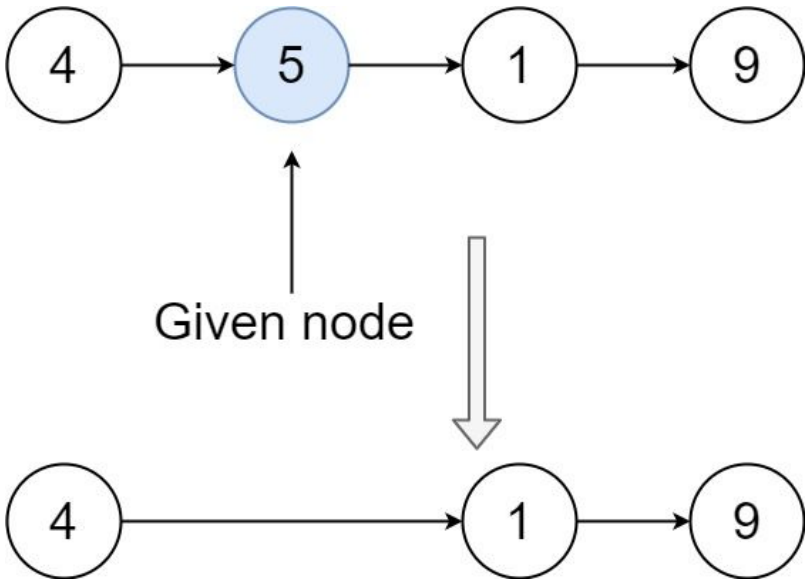
Delete the given node. Note that by deleting the node, we do not mean removing it from memory. We mean:

- The value of the given node should not exist in the linked list.
- The number of nodes in the linked list should decrease by one.
- All the values before `node` should be in the same order.
- All the values after `node` should be in the same order.

Custom testing:

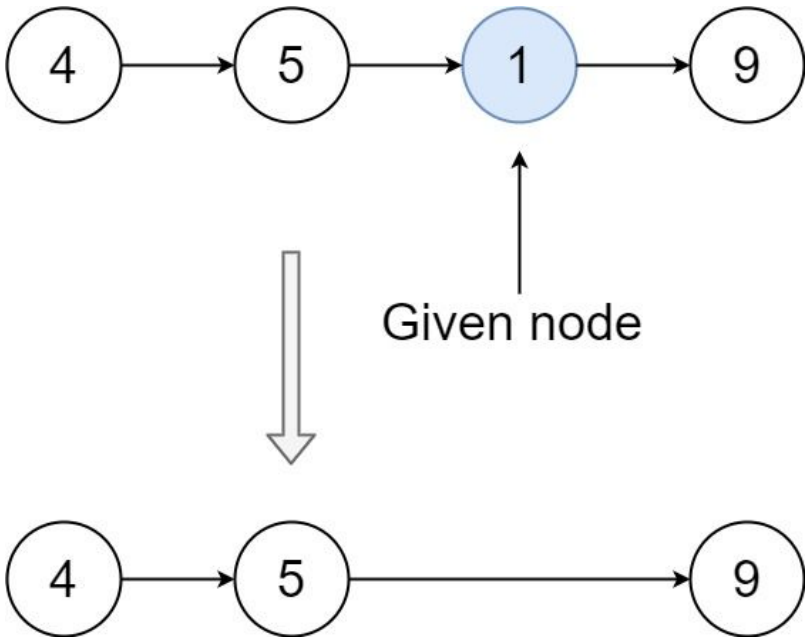
- For the input, you should provide the entire linked list `head` and the node to be given `node`. `node` should not be the last node of the list and should be an actual node in the list.
- We will build the linked list and pass the node to your function.
- The output will be the entire list after calling your function.

Example 1:



```
Input: head = [4,5,1,9], node = 5
Output: [4,1,9]
Explanation: You are given the second node with value 5, the linked list should become 4 -> 1 -> 9
after calling your function.
```

Example 2:



```
Input: head = [4,5,1,9], node = 1
Output: [4,5,9]
Explanation: You are given the third node with value 1, the linked list should become 4 -> 5 -> 9 after calling your function.
```

Constraints:

- The number of the nodes in the given list is in the range `[2, 1000]`.
- `-1000 <= Node.val <= 1000`
- The value of each node in the list is **unique**.
- The `node` to be deleted is **in the list** and is **not a tail** node.

SOLUTION (PYTHON 3)

Solution 1: Node assignment

> **How to think about it**
>
> We are given only the node to delete, so the predecessor's next cannot be rewritten. Copy the successor's value into the current node and skip the successor, which is equivalent to deleting it.

We can replace the value of the current node with the value of the next node, and then delete the next node. This can achieve the purpose of deleting the current node.

Time complexity O(1), space complexity O(1).

Python 3

```
# Definition for singly-linked list.
# class ListNode:
#     def __init__(self, x):
#         self.val = x
#         self.next = None

class Solution:
    def deleteNode(self, node):
        """
        :type node: ListNode
        :rtype: void Do not return anything, modify node in-place instead.
        """
        node.val = node.next.val
        node.next = node.next.next
```

```

```
    return dummy.next
```

708. Insert into a Sorted Circular Linked List

Medium · Linked List

leetcode.com/problems/insert-into-a-sorted-circular-linked-list

★ **TOP 10 PROBLEM** in Linked List: master this one first

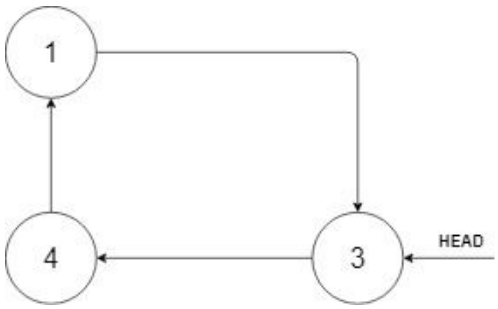
PROBLEM

Given a Circular Linked List node, which is sorted in non-descending order, write a function to insert a value `insertVal` into the list such that it remains a sorted circular list. The given node can be a reference to any single node in the list and may not necessarily be the smallest value in the circular list.

If there are multiple suitable places for insertion, you may choose any place to insert the new value. After the insertion, the circular list should remain sorted.

If the list is empty (i.e., the given node is `null`), you should create a new single circular list and return the reference to that single node. Otherwise, you should return the originally given node.

Example 1:



```
Input: head = [3,4,1], insertVal = 2
Output: [3,4,1,2]
Explanation: In the figure above, there is a sorted circular list of three elements. You are given a reference to the node with value 3, and we need to insert 2 into the list. The new node should be inserted between node 1 and node 3. After the insertion, the list should look like this, and we should still return node 3.
```

Example 2:

```
Input: head = [], insertVal = 1
Output: [1]
Explanation: The list is empty (given head is null). We create a new single circular list and return the reference to that single node.
```

Example 3:

```
Input: head = [1], insertVal = 0
Output: [1,0]
```

Constraints:

- The number of nodes in the list is in the range `[0, 5 * 10^4]`.
- `-10^6 <= Node.val, insertVal <= 10^6`

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Insert into a non-decreasing circular list. Up to 5×10^4 nodes, so we must find the gap in one lap. An empty list becomes a self-loop. A sorted ring has a single drop from the maximum back to the minimum. The insert either sits inside a non-decreasing run, or straddles that drop when the value is at least the max or at most the min. Walk adjacent prev and curr until one of those holds; if the list is globally non-decreasing we land on the last pair. Link the new node and return the original head.

Python 3

```
"""
# Definition for a Node.
class Node:
    def __init__(self, val=None, next=None):
        self.val = val
        self.next = next
"""

class Solution:
    def insert(self, head: 'Optional[Node]', insertVal: int) -> 'Node':
        node = Node(insertVal)
        if head is None:
            node.next = node
            return node
        prev, curr = head, head.next
        while curr != head:
            if prev.val <= insertVal <= curr.val or (
                prev.val > curr.val and (insertVal >= prev.val or insertVal <= curr.val)
            ):
                break
            prev, curr = curr, curr.next
        prev.next = node
        node.next = curr
        return head
```

Complexity. Time: O(n). Space: O(1).

PART 2 · STACKS · PROBLEM 1 OF 5

1614. Maximum Nesting Depth of the Parentheses

Easy · Stack, String, Parentheses

leetcode.com/problems/maximum-nesting-depth-of-the-parentheses

★ **TOP 10 PROBLEM** in Stacks: master this one first

PROBLEM

Given a **valid parentheses string** `s`, return the **nesting depth** of `s`. The nesting depth is the **maximum** number of nested parentheses.

Example 1:

Input: s = "(1+(2*3)+((8)/4))+1"

Output: 3

Explanation:

Digit 8 is inside of 3 nested parentheses in the string.

Example 2:

Input: s = "(1)+((2))+(((3)))"

Output: 3

Explanation:

Digit 3 is inside of 3 nested parentheses in the string.

Example 3:

Input: s = "()(())((()()))"

Output: 3

Constraints:

- `1 <= s.length <= 100`
- `s` consists of digits `0-9` and characters `'+'`, `'-'`, `'*'`, `'/'`, `'('`, and `')'`.
- It is guaranteed that parentheses expression `s` is a VPS.

SOLUTION (PYTHON 3)

Solution 1: Traversal

How to think about it

The string is valid and at most length 100. Nesting depth is the maximum number of unmatched opening parentheses during a scan. Digits and operators do not affect depth; only parentheses matter. A counter d increases on `(`, updates the answer, and decreases on `)`. One pass suffices.

We use a variable d to record the current depth, initially d = 0.

Traverse the string s. When encountering a left parenthesis, increment the depth d by one and update the answer to be the maximum of the current depth d and the answer. When encountering a right parenthesis, decrement the depth d by one.

Finally, return the answer.

The time complexity is O(n), where n is the length of the string s. The space complexity is O(1).

Python 3

```python
class Solution:
    def maxDepth(self, s: str) -> int:
        ans = d = 0
        for c in s:
            if c == '(':
                d += 1
                ans = max(ans, d)
            elif c == ')':
                d -= 1
        return ans
```

```

PART 2 · STACKS · PROBLEM 2 OF 5

678. Valid Parenthesis String

Medium · Stack, Greedy, String, Dynamic Programming, Parentheses

leetcode.com/problems/valid-parenthesis-string

★ **TOP 10 PROBLEM** in Stacks: master this one first

PROBLEM

Given a string `s` containing only three types of characters: `'('`, `')'` and `'*'`, return `true` *if* `s` *is* ***valid***.

The following rules define a **valid** string:

- Any left parenthesis `'('` must have a corresponding right parenthesis `')'`.
- Any right parenthesis `')'` must have a corresponding left parenthesis `'('`.
- Left parenthesis `'('` must go before the corresponding right parenthesis `')'`.
- `'*'` could be treated as a single right parenthesis `')'` or a single left parenthesis `'('` or an empty string `""`.

Example 1:

```
Input: s = "()"
Output: true
```

Example 2:

```
Input: s = "(*)"
Output: true
```

Example 3:

```
Input: s = "(*))"
Output: true
```

Example 4:

```
Input: s = "("
Output: false
```

Constraints:

- `1 <= s.length <= 100`
- `s[i]` is `'('`, `')'` or `'*'`.

SOLUTIONS (PYTHON 3)

Solution 1: Dynamic Programming

How to think about it

`*` can be a left, right, or empty token. Backtracking three choices is heavy for length 100. Interval DP: dp[i][j] is whether s[i..j] is valid. A single `*` is valid; a longer span is a matching pair around a valid inside, or a split into two valid pieces.

Let `dp[i][j]` be true if and only if the interval `s[i], s[i+1], ..., s[j]` can be made valid. Then `dp[i][j]` is true only if:

- `s[i]` is `'*'`, and the interval `s[i+1], s[i+2], ..., s[j]` can be made valid;
- or, `s[i]` can be made to be `'('`, and there is some `k` in `[i+1, j]` such that `s[k]` can be made to be `')'`, plus the two intervals cut by `s[k]` (`s[i+1: k] and s[k+1: j+1]`) can be made valid;
- Time Complexity: $O(n^3)$, where n is the length of the string. There are $O(n^2)$ states corresponding to entries of dp, and we do an average of O(n) work on each state.

- Space Complexity: O(n^2).

Python 3

```python
class Solution:
    def checkValidString(self, s: str) -> bool:
        n = len(s)
        dp = [[False] * n for _ in range(n)]
        for i, c in enumerate(s):
            dp[i][i] = c == '*'
        for i in range(n - 2, -1, -1):
            for j in range(i + 1, n):
                dp[i][j] = (
                    s[i] in '(*' and s[j] in '*)' and (i + 1 == j or dp[i + 1][j - 1])
                )
                dp[i][j] = dp[i][j] or any(
                    dp[i][k] and dp[k + 1][j] for k in range(i, j)
                )
        return dp[0][-1]
```

Solution 2: Greedy

> **How to think about it**
>
> Cubic DP is more than we need. Scan left treating `(` and `*` as stock for `)`; scan right treating `)` and `*` as stock for `(`. Both passes must succeed.

Scan twice, first from left to right to make sure that each of the closing brackets is matched successfully, and second from right to left to make sure that each of the opening brackets is matched successfully.

- Time Complexity: O(n), where n is the length of the string.
- Space Complexity: O(1).

Python 3

```python
class Solution:
    def checkValidString(self, s: str) -> bool:
        x = 0
        for c in s:
            if c in '(*':
                x += 1
            elif x:
                x -= 1
            else:
                return False
        x = 0
        for c in s[::-1]:
            if c in '*)':
                x += 1
            elif x:
                x -= 1
            else:
                return False
        return True
```

        low = max(low, 0)
    return added + low
```

PART 2 · STACKS · PROBLEM 3 OF 5

1249. Minimum Remove to Make Valid Parentheses

Medium · Stack, String

leetcode.com/problems/minimum-remove-to-make-valid-parentheses

★ **TOP 10 PROBLEM** in Stacks: master this one first

PROBLEM

Given a string s of `'('` , `')'` and lowercase English characters.

Your task is to remove the minimum number of parentheses (`'('` or `')'`, in any positions) so that the resulting *parentheses string* is valid and return **any** valid string.

Formally, a *parentheses string* is valid if and only if:

- It is the empty string, contains only lowercase characters, or
- It can be written as `AB` (`A` concatenated with `B`), where `A` and `B` are valid strings, or
- It can be written as `(A)`, where `A` is a valid string.

Example 1:

```
Input: s = "lee(t(c)o)de)"
Output: "lee(t(c)o)de"
Explanation: "lee(t(co)de)" , "lee(t(c)ode)" would also be accepted.
```

Example 2:

```
Input: s = "a)b(c)d"
Output: "ab(c)d"
```

Example 3:

```
Input: s = "))(("
Output: ""
Explanation: An empty string is also valid.
```

Constraints:

- `1 <= s.length <= 10^5`
- `s[i]` is either `'('` , `')'`, or lowercase English letter.

SOLUTION (PYTHON 3)

Solution 1: Two Passes

How to think about it

We delete the fewest parentheses to make the string valid, n ≤ 10^5. A stack can mark illegal brackets; a counter also works: left to right we drop unmatched), then right to left we drop extra (. The first pass keeps every prefix from having more rights than lefts; the second pass is symmetric for lefts. Remaining brackets match; letters stay.

First, we scan from left to right and remove the extra right parentheses. Then, we scan from right to left and remove the extra left parentheses.

The time complexity is O(n), and the space complexity is O(n). Where n is the length of the string s.

Similar problems:

- 678. Valid Parenthesis String
- 2116. Check if a Parentheses String Can Be Valid

Python 3

```python
class Solution:
    def minRemoveToMakeValid(self, s: str) -> str:
        stk = []
        x = 0
        for c in s:
            if c == ')' and x == 0:
                continue
            if c == '(':
                x += 1
            elif c == ')':
                x -= 1
            stk.append(c)
        x = 0
        ans = []
        for c in stk[::-1]:
            if c == '(' and x == 0:
                continue
            if c == ')':
                x += 1
            elif c == '(':
                x -= 1
            ans.append(c)
        return ''.join(ans[::-1])
```

                removed.append(i)
    return sorted(removed + stack)
```

PART 2 · STACKS · PROBLEM 4 OF 5

2390. Removing Stars From a String

Medium · Stack, String, Simulation

leetcode.com/problems/removing-stars-from-a-string

★ **TOP 10 PROBLEM** in Stacks: master this one first

PROBLEM

You are given a string `s`, which contains stars `*`.

In one operation, you can:

- Choose a star in `s`.
- Remove the closest **non-star** character to its **left**, as well as remove the star itself.

Return *the string after **all** stars have been removed*.

Note:

- The input will be generated such that the operation is always possible.
- It can be shown that the resulting string will always be unique.

Example 1:

```
Input: s = "leet**cod*e"
Output: "lecoe"
Explanation: Performing the removals from left to right:
- The closest character to the 1st star is 't' in "leet**cod*e". s becomes "lee*cod*e".
- The closest character to the 2nd star is 'e' in "lee*cod*e". s becomes "lecod*e".
- The closest character to the 3rd star is 'd' in "lecod*e". s becomes "lecoe".
There are no more stars, so we return "lecoe".
```

Example 2:

```
Input: s = "erase*****"
Output: ""
Explanation: The entire string is removed, so we return an empty string.
```

Constraints:

- `1 <= s.length <= 10^5`
- `s` consists of lowercase English letters and stars `*`.
- The operation above can be performed on `s`.

SOLUTION (PYTHON 3)

Solution 1: Stack Simulation

How to think about it

A star deletes the closest letter to its left. n ≤ 10^5, so repeated scans would reshuffle the same characters. A stack keeps letters that still survive: push a letter, pop on a star. The join of the stack is the answer.

We can use a stack to simulate the operation process. Traverse the string s, and if the current character is not an asterisk, push it onto the stack; if the current character is an asterisk, pop the top element from the stack.

Finally, concatenate the elements in the stack into a string and return it.

The time complexity is O(n), where n is the length of the string s. Ignoring the space consumption of the answer string, the space complexity is O(1).

Python 3

```
class Solution:
    def removeStars(self, s: str) -> str:
        ans = []
        for c in s:
            if c == '*':
                ans.pop()
            else:
                ans.append(c)
        return ''.join(ans)
```

32. Longest Valid Parentheses

Hard · Stack, String, Dynamic Programming, Parentheses

leetcode.com/problems/longest-valid-parentheses

★ **TOP 10 PROBLEM** in Stacks: master this one first

PROBLEM

Given a string containing just the characters `'('` and `')'`, return *the length of the longest valid (well-formed) parentheses substring*.

Example 1:

```
Input: s = "(()"
Output: 2
Explanation: The longest valid parentheses substring is "()".
```

Example 2:

```
Input: s = ")()())"
Output: 4
Explanation: The longest valid parentheses substring is "()()".
```

Example 3:

```
Input: s = ""
Output: 0
```

Constraints:

- `0 <= s.length <= 3 * 10^4`
- `s[i]` is `'('`, or `')'`.

SOLUTIONS (PYTHON 3)

Solution 1: Dynamic Programming

How to think about it

The first idea is to test every substring with a stack. Correct, but $n \le 3 \times 10^4$ makes $O(n^2)$ or $O(n^3)$ too slow. The bottleneck is overlap: the longest valid run ending at a position can be built from shorter valid runs. A valid substring can only end with `)`. If it pairs with the previous character, the length is that of the prefix before this pair plus 2. If the previous character is also `)`, we skip the already-valid chunk ending there and check whether a `(` sits just before that chunk. So we let f[i] be the longest valid length ending at s[i-1], transfer on those two pairing cases, and take max f[i].

We define f[i] to be the length of the longest valid parentheses that ends with s[i-1], and the answer is max(f[i]).

When i < 2, the length of the string is less than 2, and there is no valid parentheses, so f[i] = 0.

When i ≥ 2, we consider the length of the longest valid parentheses that ends with s[i-1], that is, f[i]:

- If s[i-1] is a left parenthesis, then the length of the longest valid parentheses that ends with s[i-1] must be 0, so f[i] = 0.
- If s[i-1] is a right parenthesis, there are the following two cases:
  - If s[i-2] is a left parenthesis, then the length of the longest valid parentheses that ends with s[i-1] is f[i-2] + 2.
  - If s[i-2] is a right parenthesis, then the length of the longest valid parentheses that ends with s[i-1] is f[i-1] + 2, but we also need to consider whether s[i-f[i-1]-2] is a left parenthesis. If it is a left parenthesis, then the length of the longest valid parentheses that ends with s[i-1] is f[i-1] + 2 + f[i-f[i-1]-2].

Therefore, we can get the state transition equation:

cases f[i] = 0, & if s[i-1] = '(',\ f[i] = f[i-2] + 2, & if s[i-1] = ')' and s[i-2] = '(',\ f[i] = f[i-1] + 2 + f[i-f[i-1]-2], & if s[i-1] = ')' and s[i-2] = ')' and s[i-f[i-1]-2] = '(',\ cases

Finally, we only need to return max(f).

The time complexity is O(n), and the space complexity is O(n), where n is the length of the string.

Python 3

```
class Solution:
    def longestValidParentheses(self, s: str) -> int:
        n = len(s)
        f = [0] * (n + 1)
        for i, c in enumerate(s, 1):
            if c == ")":
                if i > 1 and s[i - 2] == "(":
                    f[i] = f[i - 2] + 2
                else:
                    j = i - f[i - 1] - 1
                    if j and s[j - 1] == "(":
                        f[i] = f[i - 1] + 2 + f[j - 1]
        return max(f)
```

Solution 2: Using Stack

> **How to think about it**
>
> Method 1 is already O(n), but the recurrence splits on whether the previous character is `(` and on pairing across an already-valid chunk, so the boundaries are easy to miss. What we still lack is not a better complexity, but a record that matches pairing more directly: indices of unmatched `(`, and where the last broken prefix starts. Seed the stack with -1 as a baseline, push on `(`, pop on `)`. An empty stack means the current `)` is a new baseline; otherwise the top of the stack updates the length. Time and space stay O(n); the matching process is just easier to see.

- Maintain a stack to store the indices of left parentheses. Initialize the bottom element of the stack with the value -1 to facilitate the calculation of the length of valid parentheses.
- Iterate through each element of the string:
  - If the character is a left parenthesis, push the index of the character onto the stack.
  - If the character is a right parenthesis, pop an element from the stack to represent that we have found a valid pair of parentheses.
  - If the stack is empty, it means we couldn't find a left parenthesis to match the right parenthesis. In this case, push the index of the character as a new starting point.
  - If the stack is not empty, calculate the length of the valid parentheses and update it.

Summary:

The key to this algorithm is to maintain a stack to store the indices of left parentheses and then update the length of the valid substring of parentheses by pushing and popping elements.

The time complexity is O(n), and the space complexity is O(n), where n is the length of the string.

Python 3

```python
class Solution:
    def longestValidParentheses(self, s: str) -> int:
        stack = [-1]
        ans = 0
        for i in range(len(s)):
            if s[i] == '(':
                stack.append(i)
            else:
                stack.pop()
                if not stack:
                    stack.append(i)
                else:
                    ans = max(ans, i - stack[-1])
        return ans
```

PART 2 · MONOTONIC STACK · PROBLEM 1 OF 6

1475. Final Prices With a Special Discount in a Shop

Easy · Stack, Array, Monotonic Stack

leetcode.com/problems/final-prices-with-a-special-discount-in-a-shop

★ **TOP 10 PROBLEM** in Monotonic Stack: master this one first

PROBLEM

You are given an integer array `prices` where `prices[i]` is the price of the i^{th} item in a shop.

There is a special discount for items in the shop. If you buy the i^{th} item, then you will receive a discount equivalent to `prices[j]` where `j` is the minimum index such that `j > i` and `prices[j] <= prices[i]`. Otherwise, you will not receive any discount at all.

Return an integer array `answer` where `answer[i]` is the final price you will pay for the i^{th} item of the shop, considering the special discount.

Example 1:

```
Input: prices = [8,4,6,2,3]
Output: [4,2,4,2,3]
Explanation:
For item 0 with price[0]=8 you will receive a discount equivalent to prices[1]=4, therefore, the final price you will pay is 8 - 4 = 4.
For item 1 with price[1]=4 you will receive a discount equivalent to prices[3]=2, therefore, the final price you will pay is 4 - 2 = 2.
For item 2 with price[2]=6 you will receive a discount equivalent to prices[3]=2, therefore, the final price you will pay is 6 - 2 = 4.
For items 3 and 4 you will not receive any discount at all.
```

Example 2:

```
Input: prices = [1,2,3,4,5]
Output: [1,2,3,4,5]
Explanation: In this case, for all items, you will not receive any discount at all.
```

Example 3:

```
Input: prices = [10,1,1,6]
Output: [9,0,1,6]
```

Constraints:

- `1 <= prices.length <= 500`
- `1 <= prices[i] <= 1000`

SOLUTION (PYTHON 3)

Solution 1: Monotonic Stack

How to think about it

The discount is the next price to the right that is at most the current one. n≤ 500 would allow a double loop; a monotonic stack finds the next smaller-or-equal in linear time. Scan right to left on an increasing stack and subtract in place.

The problem is essentially to find the first element on the right side that is smaller than each element. We can use a monotonic stack to solve this.

We traverse the array prices in reverse order, using the monotonic stack to find the nearest smaller element on the left side of the current element, and then calculate the discount.

The time complexity is O(n), and the space complexity is O(n). Here, n is the length of the array prices.

Python 3

```python
class Solution:
    def finalPrices(self, prices: List[int]) -> List[int]:
        stk = []
        for i in reversed(range(len(prices))):
            x = prices[i]
            while stk and x < stk[-1]:
                stk.pop()
            if stk:
                prices[i] -= stk[-1]
            stk.append(x)
        return prices
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

Built on the solutions above: helper functions, then the function for each follow-up. No tests and no restating of the question.

    for p in prices:
        while stack and stack[-1] > p:
            stack.pop()
        result.append(p - stack[-1] if stack else p)
        stack.append(p)
    return result
```

PART 2 · MONOTONIC STACK · PROBLEM 2 OF 6

581. Shortest Unsorted Continuous Subarray

Medium · Stack, Greedy, Array, Two Pointers, Sorting, Monotonic Stack

leetcode.com/problems/shortest-unsorted-continuous-subarray

★ **TOP 10 PROBLEM** in Monotonic Stack: master this one first

PROBLEM

Given an integer array `nums`, you need to find one **continuous subarray** such that if you only sort this subarray in non-decreasing order, then the whole array will be sorted in non-decreasing order.

Return *the shortest such subarray and output its length*.

Example 1:

```
Input: nums = [2,6,4,8,10,9,15]
Output: 5
Explanation: You need to sort [6, 4, 8, 10, 9] in ascending order to make the whole array sorted in ascending order.
```

Example 2:

```
Input: nums = [1,2,3,4]
Output: 0
```

Example 3:

```
Input: nums = [1]
Output: 0
```

Constraints:

- `1 <= nums.length <= 10^4`
- `-10^5 <= nums[i] <= 10^5`

Follow up:

Can you solve it in

`O(n)`

time complexity?

SOLUTIONS (PYTHON 3)

Solution 1: Sorting

How to think about it

The shortest unsorted subarray is the one that, once sorted, makes the whole array sorted. Sort a copy and compare: the first and last mismatches bound that interval. $n \le 10^4$ allows a sort. If nothing mismatches, the array is already sorted and the length is 0.

We can first sort the array, and then compare the sorted array with the original array to find the leftmost and rightmost positions where they differ. The length between them is the length of the shortest unsorted continuous subarray.

The time complexity is O(n × log n), and the space complexity is O(n). Here, n is the length of the array.

Python 3

```python
class Solution:
    def findUnsortedSubarray(self, nums: List[int]) -> int:
        arr = sorted(nums)
        l, r = 0, len(nums) - 1
        while l <= r and nums[l] == arr[l]:
            l += 1
        while l <= r and nums[r] == arr[r]:
            r -= 1
        return r - l + 1
```

Solution 2: Maintaining the Maximum Value on the Left and the Minimum Value on the Right

> **How to think about it**
>
> Sorting adds a log factor. A left-to-right scan: whenever a value is below the prefix maximum it belongs in the unsorted interval, so the right end grows. A right-to-left scan uses the suffix minimum for the left end. Both ends start at -1; if the right end never moves, return 0. Two linear passes, constant space.

We can traverse the array from left to right and maintain a maximum value mx. If the current value is less than mx, it means that the current value is not in the correct position, and we update the right boundary r to the current position. Similarly, we can traverse the array from right to left and maintain a minimum value mi. If the current value is greater than mi, it means that the current value is not in the correct position, and we update the left boundary l to the current position. At initialization, we set l and r to -1. If l and r are not updated, it means that the array is already sorted, and we return 0. Otherwise, we return r - l + 1.

The time complexity is O(n), and the space complexity is O(1). Here, n is the length of the array.

Python 3

```python
class Solution:
    def findUnsortedSubarray(self, nums: List[int]) -> int:
        mi, mx = inf, -inf
        l = r = -1
        n = len(nums)
        for i, x in enumerate(nums):
            if mx > x:
                r = i
            else:
                mx = x
            if mi < nums[n - i - 1]:
                l = n - i - 1
            else:
                mi = nums[n - i - 1]
        return 0 if r == -1 else r - l + 1
```

PART 2 · MONOTONIC STACK · PROBLEM 3 OF 6

769. Max Chunks To Make Sorted

Medium · Stack, Greedy, Array, Sorting, Monotonic Stack

leetcode.com/problems/max-chunks-to-make-sorted

★ **TOP 10 PROBLEM** in Monotonic Stack: master this one first

PROBLEM

You are given an integer array `arr` of length `n` that represents a permutation of the integers in the range `[0, n - 1]`.

We split `arr` into some number of **chunks** (i.e., partitions), and individually sort each chunk. After concatenating them, the result should equal the sorted array.

Return *the largest number of chunks we can make to sort the array*.

Example 1:

```
Input: arr = [4,3,2,1,0]
Output: 1
Explanation:
Splitting into two or more chunks will not return the required result.
For example, splitting into [4, 3], [2, 1, 0] will result in [3, 4, 0, 1, 2], which isn't sorted.
```

Example 2:

```
Input: arr = [1,0,2,3,4]
Output: 4
Explanation:
We can split into two chunks, such as [1, 0], [2, 3, 4].
However, splitting into [1, 0], [2], [3], [4] is the highest number of chunks possible.
```

Constraints:

- `n == arr.length`
- `1 <= n <= 10`
- `0 <= arr[i] < n`
- All the elements of `arr` are **unique**.

SOLUTIONS (PYTHON 3)

Solution 1: Greedy + One Pass

How to think about it

The array is a permutation of 0..n-1. A cut after i is legal iff the prefix is exactly {0,…,i}. That is the prefix maximum equaling i. One pass counting those hits.

Since arr is a permutation of [0,..,n-1], if the maximum value mx among the numbers traversed so far is equal to the current index i, it means a split can be made, and the answer is incremented.

Time complexity is O(n), and space complexity is O(1). Where n is the length of the array arr.

Python 3

```python
class Solution:
    def maxChunksToSorted(self, arr: List[int]) -> int:
        mx = ans = 0
        for i, v in enumerate(arr):
            mx = max(mx, v)
            if i == mx:
                ans += 1
        return ans
```

Solution 2: Monotonic Stack

> **How to think about it**
>
> Solution 1 uses value=index, which fails with duplicates. The monotonic stack of chunk maxima is the same as problem 768. A smaller new value merges earlier chunks; the stack length is the answer.

The solution of method one has certain limitations. If there are duplicate elements in the array, the correct answer cannot be obtained.

According to the problem, we can find that from left to right, each chunk has a maximum value, and these maximum values are monotonically increasing. We can use a stack to store these maximum values of the chunks. The size of the final stack is the maximum number of chunks that can be sorted.

This solution can not only solve this problem but also solve the problem 768. Max Chunks To Make Sorted II. You can try it yourself.

Time complexity is O(n), and space complexity is O(n). Where n is the length of the array arr.

Python 3

```python
class Solution:
    def maxChunksToSorted(self, arr: List[int]) -> int:
        stk = []
        for v in arr:
            if not stk or v >= stk[-1]:
                stk.append(v)
            else:
                mx = stk.pop()
                while stk and stk[-1] > v:
                    stk.pop()
                stk.append(mx)
        return len(stk)
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

Built on the solutions above: helper functions, then the function for each follow-up. No tests and no restating of the question.

```python
# FOLLOW-UPS (answered below, in this order):
# 1. The array may contain duplicates (not a permutation
# of 0..n-1)
# 2. Return the chunks (as start and end indices)

# ============================================================
# FOLLOW-UP 1: The array may contain duplicates (not a
# permutation of 0..n-1)
# ============================================================

# ---- follow-up 1: function ----
# Answer: Stack of chunk maximums: a new number smaller
# than the top merges chunks.
# Time: O(n).  Space: O(n).
def max_chunks_with_duplicates(arr):
    stack = []
    for x in arr:
        biggest = x

1762. Buildings With an Ocean View

Medium · Stack, Array, Monotonic Stack

leetcode.com/problems/buildings-with-an-ocean-view

★ **TOP 10 PROBLEM** in Monotonic Stack: master this one first

PROBLEM

There are `n` buildings in a line. You are given an integer array `heights` of size `n` that represents the heights of the buildings in the line.

The ocean is to the right of the buildings. A building has an ocean view if the building can see the ocean without obstructions. Formally, a building has an ocean view if all the buildings to its right have a **smaller** height.

Return a list of indices **(0-indexed)** of buildings that have an ocean view, sorted in increasing order.

Example 1:

```
Input: heights = [4,2,3,1]
Output: [0,2,3]
Explanation: Building 1 (0-indexed) does not have an ocean view because building 2 is taller.
```

Example 2:

```
Input: heights = [4,3,2,1]
Output: [0,1,2,3]
Explanation: All the buildings have an ocean view.
```

Example 3:

```
Input: heights = [1,3,2,4]
Output: [3]
Explanation: Only building 3 has an ocean view.
```

Constraints:

- `1 <= heights.length <= 10^5`
- `1 <= heights[i] <= 10^9`

SOLUTION (PYTHON 3)

Solution 1: Reverse Traversal to Find the Maximum on the Right

How to think about it

A building sees the ocean iff nothing to its right is at least as tall. A right-to-left scan keeping the right-hand maximum decides this. If the height exceeds mx, record the index and update mx. Reverse the collected indices to left-to-right order.

We traverse the array height in reverse order for each element v, comparing v with the maximum element mx on the right. If mx < v, it means all elements to the right are smaller than the current element, so the current position can see the ocean and is added to the result array ans. Then we update mx to v.

After the traversal, return ans in reverse order.

The time complexity is O(n), where n is the length of the array. Ignoring the space consumption of the answer array, the space complexity is O(1).

Python 3

```python
class Solution:
    def findBuildings(self, heights: List[int]) -> List[int]:
        ans = []
        mx = 0
        for i in range(len(heights) - 1, -1, -1):
            if heights[i] > mx:
                ans.append(i)
                mx = heights[i]
        return ans[::-1]
```

```

PART 2 · MONOTONIC STACK · PROBLEM 5 OF 6

321. Create Maximum Number

Hard · Stack, Greedy, Array, Two Pointers, Monotonic Stack

leetcode.com/problems/create-maximum-number

★ **TOP 10 PROBLEM** in Monotonic Stack: master this one first

PROBLEM

You are given two integer arrays `nums1` and `nums2` of lengths `m` and `n` respectively. `nums1` and `nums2` represent the digits of two numbers. You are also given an integer `k`.

Create the maximum number of length `k <= m + n` from digits of the two numbers. The relative order of the digits from the same array must be preserved.

Return an array of the `k` digits representing the answer.

Example 1:

```
Input: nums1 = [3,4,6,5], nums2 = [9,1,2,5,8,3], k = 5
Output: [9,8,6,5,3]
```

Example 2:

```
Input: nums1 = [6,7], nums2 = [6,0,4], k = 5
Output: [6,7,6,0,4]
```

Example 3:

```
Input: nums1 = [3,9], nums2 = [8,9], k = 3
Output: [9,8,9]
```

Constraints:

- `m == nums1.length`
- `n == nums2.length`
- `1 <= m, n <= 500`
- `0 <= nums1[i], nums2[i] <= 9`
- `1 <= k <= m + n`
- `nums1` and `nums2` do not have leading zeros.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Pick a total of k digits from two arrays, preserving order in each. One monotone stack cannot split the quota across both. Enumerate taking x digits from nums1 (in the feasible range), extract the best subsequences of lengths x and k-x with monotone stacks, and merge by lexicographic compare. Keep the best merge. Equal prefixes must look ahead so the merge is not locally greedy.

Python 3

```python
class Solution:
    def maxNumber(self, nums1: List[int], nums2: List[int], k: int) -> List[int]:
        def f(nums: List[int], k: int) -> List[int]:
            n = len(nums)
            stk = [0] * k
            top = -1
            remain = n - k
            for x in nums:
                while top >= 0 and stk[top] < x and remain > 0:
                    top -= 1
                    remain -= 1
                if top + 1 < k:
                    top += 1
                    stk[top] = x
                else:
                    remain -= 1
            return stk

        def compare(nums1: List[int], nums2: List[int], i: int, j: int) -> bool:
            if i >= len(nums1):
                return False
            if j >= len(nums2):
                return True
            if nums1[i] > nums2[j]:
                return True
            if nums1[i] < nums2[j]:
                return False
            return compare(nums1, nums2, i + 1, j + 1)

        def merge(nums1: List[int], nums2: List[int]) -> List[int]:
            m, n = len(nums1), len(nums2)
            i = j = 0
            ans = [0] * (m + n)
            for k in range(m + n):
                if compare(nums1, nums2, i, j):
                    ans[k] = nums1[i]
                    i += 1
                else:
                    ans[k] = nums2[j]
                    j += 1
            return ans

        m, n = len(nums1), len(nums2)
        l, r = max(0, k - n), min(k, m)
        ans = [0] * k
        for x in range(l, r + 1):
            arr1 = f(nums1, x)
            arr2 = f(nums2, k - x)
            arr = merge(arr1, arr2)
            if ans < arr:
                ans = arr
        return ans
```

Complexity. Time: O(k * (m + n + k^2)). Space: O(k).

1944. Number of Visible People in a Queue

Hard · Stack, Array, Monotonic Stack

leetcode.com/problems/number-of-visible-people-in-a-queue

★ **TOP 10 PROBLEM** in Monotonic Stack: master this one first

PROBLEM

There are `n` people standing in a queue, and they numbered from `0` to `n - 1` in **left to right** order. You are given an array `heights` of **distinct** integers where `heights[i]` represents the height of the `i`th person.

A person can **see** another person to their right in the queue if everybody in between is **shorter** than both of them. More formally, the `i`th person can see the `j`th person if `i < j` and `min(heights[i], heights[j]) > max(heights[i+1], heights[i+2], ..., heights[j-1])`.

Return *an array* `answer` *of length* `n` *where* `answer[i]` *is the* ***number of people*** *the* `i`th *person can* ***see*** *to their right in the queue*.

Example 1:

```
Input: heights = [10,6,8,5,11,9]
Output: [3,1,2,1,1,0]
Explanation:
Person 0 can see person 1, 2, and 4.
Person 1 can see person 2.
Person 2 can see person 3 and 4.
Person 3 can see person 4.
Person 4 can see person 5.
Person 5 can see no one since nobody is to the right of them.
```

Example 2:

```
Input: heights = [5,1,2,3,10]
Output: [4,1,1,1,0]
```

Constraints:

- `n == heights.length`
- `1 <= n <= 10`^{5}
- `1 <= heights[i] <= 10`^{5}
- All the values of `heights` are **unique**.

SOLUTION (PYTHON 3)

Solution 1: Monotonic Stack

> **How to think about it**
>
> Person i sees j iff everyone in between is shorter. A rightward scan per i is $O(n^2)$. Visible heights to the right of i are strictly increasing. A stack increasing from top to bottom pops every shorter person (each counts) and, if someone remains, adds one more blocked by a taller person. Each height enters and leaves the stack once.

We observe that for the i-th person, the people he can see must be strictly increasing in height from left to right.

Therefore, we can traverse the array heights in reverse order, using a stack stk that is monotonically increasing from top to bottom to record the heights of the people we have traversed.

For the i-th person, if the stack is not empty and the top element of the stack is less than heights[i], we increment the count of people the i-th person can see, then pop the top element of the stack, until the stack is empty or the top element of the stack is greater than or equal to heights[i]. If the stack is not empty at this point, it means the top element of the stack is greater than or equal to heights[i], so we increment the count of people the i-th person can see by 1.

Next, we push heights[i] onto the stack and continue to the next person.

After traversing, we return the answer array ans.

The time complexity is O(n), and the space complexity is O(n). Here, n is the length of the array heights.

Python 3

```python
class Solution:
    def canSeePersonsCount(self, heights: List[int]) -> List[int]:
        n = len(heights)
        ans = [0] * n
        stk = []
        for i in range(n - 1, -1, -1):
            while stk and stk[-1] < heights[i]:
                ans[i] += 1
                stk.pop()
            if stk:
                ans[i] += 1
            stk.append(heights[i])
        return ans
```

346. Moving Average from Data Stream

Easy · Design, Queue, Array, Data Stream

leetcode.com/problems/moving-average-from-data-stream

★ **TOP 10 PROBLEM** in Queues: master this one first

PROBLEM

Given a stream of integers and a window size, calculate the moving average of all integers in the sliding window.

Implement the `MovingAverage` class:

- `MovingAverage(int size)` Initializes the object with the size of the window `size`.
- `double next(int val)` Returns the moving average of the last `size` values of the stream.

Example 1:

```
Input
["MovingAverage", "next", "next", "next", "next"]
[[3], [1], [10], [3], [5]]
Output
[null, 1.0, 5.5, 4.66667, 6.0]

Explanation
MovingAverage movingAverage = new MovingAverage(3);
movingAverage.next(1); // return 1.0 = 1 / 1
movingAverage.next(10); // return 5.5 = (1 + 10) / 2
movingAverage.next(3); // return 4.66667 = (1 + 10 + 3) / 3
movingAverage.next(5); // return 6.0 = (10 + 3 + 5) / 3
```

Constraints:

- $1 <= size <= 1000$
- $-10^5 <= val <= 10^5$
- At most 10^4 calls will be made to `next`.

SOLUTIONS (PYTHON 3)

Solution 1: Circular Array

How to think about it

A moving average over a fixed window. Resumming the window is O(size). Keep the running sum for O(1) updates. A circular buffer overwrites index cnt mod size: subtract the old value, add the new one. The average is s/min(cnt,size).

We define a variable s to calculate the sum of the last size elements, and a variable cnt to record the total number of current elements. Additionally, we use an array data of length size to record the value of each element at each position.

When calling the next function, we first calculate the index i where val should be stored, then update the sum s, set the value at index i to val, and increment the element count by one. Finally, we return the value of s/(min(cnt, size)).

The time complexity is O(1), and the space complexity is O(n), where n is the integer size given in the problem.

Python 3

```
class MovingAverage:

    def __init__(self, size: int):
        self.s = 0
        self.data = [0] * size
        self.cnt = 0

    def next(self, val: int) -> float:
        i = self.cnt % len(self.data)
        self.s += val - self.data[i]
        self.data[i] = val
        self.cnt += 1
        return self.s / min(self.cnt, len(self.data))

# Your MovingAverage object will be instantiated and called as such:
# obj = MovingAverage(size)
# param_1 = obj.next(val)
```

Solution 2: Queue

> **How to think about it**
>
> Modular indexing is easy to get wrong. A queue stores the window: when full, pop the front and subtract, then append. Same meaning, clearer code.

We can use a queue q to store the last size elements, and a variable s to record the sum of these size elements.

When calling the next function, we first check if the length of the queue q is equal to size. If it is, we dequeue the front element of the queue q and update the value of s. Then we enqueue val and update the value of s. Finally, we return the value of s/len(q).

The time complexity is O(1), and the space complexity is O(n), where n is the integer size given in the problem.

Python 3

```
class MovingAverage:
    def __init__(self, size: int):
        self.n = size
        self.s = 0
        self.q = deque()

    def next(self, val: int) -> float:
        if len(self.q) == self.n:
            self.s -= self.q.popleft()
        self.q.append(val)
        self.s += val
        return self.s / len(self.q)

# Your MovingAverage object will be instantiated and called as such:
# obj = MovingAverage(size)
# param_1 = obj.next(val)
```

PART 2 · QUEUES · PROBLEM 2 OF 2

2327. Number of People Aware of a Secret

Medium · Queue, Dynamic Programming, Simulation

leetcode.com/problems/number-of-people-aware-of-a-secret

★ **TOP 10 PROBLEM** in Queues: master this one first

PROBLEM

On day `1`, one person discovers a secret.

You are given an integer `delay`, which means that each person will **share** the secret with a new person **every day**, starting from `delay` days after discovering the secret. You are also given an integer `forget`, which means that each person will **forget** the secret `forget` days after discovering it. A person **cannot** share the secret on the same day they forgot it, or on any day afterwards.

Given an integer `n`, return *the number of people who know the secret at the end of day* `n`. Since the answer may be very large, return it **modulo** $10^9 + 7$.

Example 1:

```
Input: n = 6, delay = 2, forget = 4
Output: 5
Explanation:
Day 1: Suppose the first person is named A. (1 person)
Day 2: A is the only person who knows the secret. (1 person)
Day 3: A shares the secret with a new person, B. (2 people)
Day 4: A shares the secret with a new person, C. (3 people)
Day 5: A forgets the secret, and B shares the secret with a new person, D. (3 people)
Day 6: B shares the secret with E, and C shares the secret with F. (5 people)
```

Example 2:

```
Input: n = 4, delay = 1, forget = 3
Output: 6
Explanation:
Day 1: The first person is named A. (1 person)
Day 2: A shares the secret with B. (2 people)
Day 3: A and B share the secret with 2 new people, C and D. (4 people)
Day 4: A forgets the secret. B, C, and D share the secret with 3 new people. (6 people)
```

Constraints:

- `2 <= n <= 1000`
- `1 <= delay < forget <= n`

SOLUTION (PYTHON 3)

Solution 1: Difference Array

How to think about it

A person shares once per day on [delay, forget) after learning, then forgets. n ≤ 1000, so a day-by-day simulation is fine. Let cnt[i] be new learners on day i; they copy themselves on each later share day. A difference array d tracks who still remembers; the prefix through day n is the answer.

We use a difference array d[i] to record the change in the number of people who know the secret on day i, and an array cnt[i] to record the number of people who newly learn the secret on day i.

For the cnt[i] people who newly learn the secret on day i, they can share the secret with another cnt[i] people each day during the interval [i+delay, i+forget).

The answer is $\sum_{i=1}^{n} d[i]$.

The time complexity is $O(n^2)$, and the space complexity is $O(n)$, where n is the given integer.

Python 3

```
class Solution:
    def peopleAwareOfSecret(self, n: int, delay: int, forget: int) -> int:
        m = (n << 1) + 10
        d = [0] * m
        cnt = [0] * m
        cnt[1] = 1
        for i in range(1, n + 1):
            if cnt[i]:
                d[i] += cnt[i]
                d[i + forget] -= cnt[i]
                nxt = i + delay
                while nxt < i + forget:
                    cnt[nxt] += cnt[i]
                    nxt += 1
        mod = 10**9 + 7
        return sum(d[: n + 1]) % mod
```

2762. Continuous Subarrays

Medium · Queue, Array, Ordered Set, Sliding Window, Monotonic Queue, Heap (Priority Queue)

leetcode.com/problems/continuous-subarrays

★ **TOP 10 PROBLEM** in Monotonic Queue: master this one first

PROBLEM

You are given a **0-indexed** integer array `nums`. A subarray of `nums` is called **continuous** if:

- Let `i, i + 1, ..., j` be the indices in the subarray. Then, for each pair of indices `i <= i1, i2 <= j, 0 <= |nums[i1] - nums[i2]| <= 2`.

Return *the total number of **continuous** subarrays.*

A subarray is a contiguous **non-empty** sequence of elements within an array.

Example 1:

```
Input: nums = [5,4,2,4]
Output: 8
Explanation:
Continuous subarray of size 1: [5], [4], [2], [4].
Continuous subarray of size 2: [5,4], [4,2], [2,4].
Continuous subarray of size 3: [4,2,4].
There are no subarrys of size 4.
Total continuous subarrays = 4 + 3 + 1 = 8.
It can be shown that there are no more continuous subarrays.
```

Example 2:

```
Input: nums = [1,2,3]
Output: 6
Explanation:
Continuous subarray of size 1: [1], [2], [3].
Continuous subarray of size 2: [1,2], [2,3].
Continuous subarray of size 3: [1,2,3].
Total continuous subarrays = 3 + 2 + 1 = 6.
```

Constraints:

- `1 <= nums.length <= 10^5`
- `1 <= nums[i] <= 10^9`

SOLUTIONS (PYTHON 3)

Solution 1: Ordered List + Two Pointers

How to think about it

A subarray is continuous iff its maximum and minimum differ by at most 2. Checking every pair of ends is quadratic and too slow at length 10^5. After the right end inserts a value, drop left-end elements from a sorted list until the max–min gap is at most 2. The number of legal subarrays that end here equals the list size.

We can use two pointers, i and j, to maintain the left and right endpoints of the current subarray, and use an ordered list to maintain all elements in the current subarray.

Iterate through the array nums. For the current number nums[i] we're iterating over, we add it to the ordered list. If the difference between the maximum and minimum values in the ordered list is greater than 2, we then loop to move the pointer i to the right, continuously removing nums[i] from the ordered list, until the list is empty or the maximum difference between elements in the ordered list is not greater than 2. At this point, the number of uninterrupted subarrays is j - i + 1, which we

add to the answer.

After the iteration, return the answer.

The time complexity is O(n × log n) and the space complexity is O(n), where n is the length of the array nums.

Python 3

```python
class Solution:
    def continuousSubarrays(self, nums: List[int]) -> int:
        ans = i = 0
        sl = SortedList()
        for x in nums:
            sl.add(x)
            while sl[-1] - sl[0] > 2:
                sl.remove(nums[i])
                i += 1
            ans += len(sl)
        return ans
```

Solution 2: Monotonic queue + Two Pointers

> **How to think about it**
>
> A sorted list pays a logarithm per update. Only the extrema matter, so two monotonic deques of indices suffice. When the gap exceeds 2, pop the older extremum and advance the left end. The counting is unchanged, and each index enters and leaves a deque once.

Python 3 (written for this guide: the doocs page has no Python 3 version of this solution)

```python
class Solution:
    def continuousSubarrays(self, nums: List[int]) -> int:
        min_q, max_q = deque(), deque()
        total = 0
        left = 0
        for right, x in enumerate(nums):
            while min_q and nums[min_q[-1]] > x:
                min_q.pop()
            while max_q and nums[max_q[-1]] < x:
                max_q.pop()
            min_q.append(right)
            max_q.append(right)
            while min_q and max_q and nums[max_q[0]] - nums[min_q[0]] > 2:
                if max_q[0] < min_q[0]:
                    left = max_q[0] + 1
                    max_q.popleft()
                else:
                    left = min_q[0] + 1
                    min_q.popleft()
            total += right - left + 1
        return total
```

Complexity. Time: O(n). Space: O(n).

```

3578. Count Partitions With Max-Min Difference at Most K

Medium · Queue, Array, Dynamic Programming, Prefix Sum, Sliding Window, Monotonic Queue

leetcode.com/problems/count-partitions-with-max-min-difference-at-most-k

★ **TOP 10 PROBLEM** in Monotonic Queue: master this one first

PROBLEM

You are given an integer array `nums` and an integer `k`. Your task is to partition `nums` into one or more **non-empty** contiguous segments such that in each segment, the difference between its **maximum** and **minimum** elements is **at most** `k`.

Return the total number of ways to partition `nums` under this condition.

Since the answer may be too large, return it **modulo** $10^9 + 7$.

Example 1:

Input: nums = [9,4,1,3,7], k = 4

Output: 6

Explanation:

There are 6 valid partitions where the difference between the maximum and minimum elements in each segment is at most `k = 4`:

- `[[9], [4], [1], [3], [7]]`
- `[[9], [4], [1], [3, 7]]`
- `[[9], [4], [1, 3], [7]]`
- `[[9], [4, 1], [3], [7]]`
- `[[9], [4, 1], [3, 7]]`
- `[[9], [4, 1, 3], [7]]`

Example 2:

Input: nums = [3,3,4], k = 0

Output: 2

Explanation:

There are 2 valid partitions that satisfy the given conditions:

- `[[3], [3], [4]]`
- `[[3, 3], [4]]`

Constraints:

- $2 \le \text{nums.length} \le 5 * 10^4$
- $1 \le \text{nums}[i] \le 10^9$
- $0 \le k \le 10^9$

SOLUTION (PYTHON 3)

Solution 1: Dynamic Programming + Two Pointers + Ordered Set

How to think about it

Every part of a partition must have max-min ≤ k. f[r] is the number of ways to partition the prefix of length r; the last part is some [l,r], so f[r] sums f[j] over legal last parts. The legal left end only moves right: an ordered set stores the window extrema and advances l when the gap exceeds k. A prefix sum g evaluates the range sum in O(1).

We define f[i] as the number of ways to partition the first i elements. If an array satisfies that the difference between its maximum and minimum values does not exceed k, then any of its subarrays also satisfies this condition. Therefore, we can use two pointers to maintain a sliding window representing the current subarray.

When we reach the r-th element, we need to find the left pointer l such that the subarray from l to r satisfies that the difference between the maximum and minimum values does not exceed k. We can use an ordered set to maintain the elements in the current window, so that we can quickly get the maximum and minimum values.

Each time we add a new element, we insert it into the ordered set and check the difference between the maximum and minimum values in the current window. If it exceeds k, we move the left pointer l until the condition is satisfied. The number of partition ways ending at the r-th element is f[l - 1] + f[l] + … + f[r - 1]. We can use a prefix sum array to quickly calculate this value.

The answer is f[n], where n is the length of the array.

The time complexity is O(n × log n) and the space complexity is O(n), where n is the length of the array nums.

Python 3

```python
class Solution:
    def countPartitions(self, nums: List[int], k: int) -> int:
        mod = 10**9 + 7
        sl = SortedList()
        n = len(nums)
        f = [1] + [0] * n
        g = [1] + [0] * n
        l = 1
        for r, x in enumerate(nums, 1):
            sl.add(x)
            while sl[-1] - sl[0] > k:
                sl.remove(nums[l - 1])
                l += 1
            f[r] = (g[r - 1] - (g[l - 2] if l >= 2 else 0) + mod) % mod
            g[r] = (g[r - 1] + f[r]) % mod
        return f[n]
```

        else:
            parts[-1].append(x)
            low, high = low2, high2
    return parts
```

PART 2 · MONOTONIC QUEUE · PROBLEM 3 OF 3

1499. Max Value of Equation

Hard · Queue, Array, Sliding Window, Monotonic Queue, Heap (Priority Queue)

leetcode.com/problems/max-value-of-equation

★ **TOP 10 PROBLEM** in Monotonic Queue: master this one first

PROBLEM

You are given an array `points` containing the coordinates of points on a 2D plane, sorted by the x-values, where `points[i] = [x_i, y_i]` such that `x_i < x_j` for all `1 <= i < j <= points.length`. You are also given an integer `k`.

Return *the maximum value of the equation* `y_i + y_j + |x_i - x_j|` where `|x_i - x_j| <= k` and `1 <= i < j <= points.length`.

It is guaranteed that there exists at least one pair of points that satisfy the constraint `|x_i - x_j| <= k`.

Example 1:

```
Input: points = [[1,3],[2,0],[5,10],[6,-10]], k = 1
Output: 4
Explanation: The first two points satisfy the condition |xi - xj| <= 1 and if we calculate the equation
we get 3 + 0 + |1 - 2| = 4. Third and fourth points also satisfy the condition and give a value of 10 +
-10 + |5 - 6| = 1.
No other pairs satisfy the condition, so we return the max of 4 and 1.
```

Example 2:

```
Input: points = [[0,0],[3,0],[9,2]], k = 3
Output: 3
Explanation: Only the first two points have an absolute difference of 3 or less in the x-values, and
give the value of 0 + 0 + |0 - 3| = 3.
```

Constraints:

- `2 <= points.length <= 10^5`
- `points[i].length == 2`
- `-10^8 <= x_i, y_i <= 10^8`
- `0 <= k <= 2 * 10^8`
- `x_i < x_j` for all `1 <= i < j <= points.length`
- `x_i` form a strictly increasing sequence.

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

x is strictly increasing and n≤ 10^5. Rewrite $y_i+y_j+|x_i-x_j|=(y_i-x_i)+(x_j+y_j)$. For each j we need the max y_i-x_i among $x_j-x_i\le k$. A heap of (x_i-y_i,x_i) pops expired points (min-heap on x-y is max y-x) and adds the current x+y.

Python 3

```python
class Solution:
    def findMaxValueOfEquation(self, points: List[List[int]], k: int) -> int:
        ans = -inf
        pq = []
        for x, y in points:
            while pq and x - pq[0][1] > k:
                heappop(pq)
            if pq:
                ans = max(ans, x + y - pq[0][0])
            heappush(pq, (x - y, x))
        return ans
```

Complexity. Time: O(n log n). Space: O(n).

Solution 2

> **How to think about it**
>
> Method 1 is O(log n) per point. A decreasing deque maintains the window max of y-x in amortized O(1): drop expired heads and dominated tails before pushing.

Python 3

```python
class Solution:
    def findMaxValueOfEquation(self, points: List[List[int]], k: int) -> int:
        ans = -inf
        q = deque()
        for x, y in points:
            while q and x - q[0][0] > k:
                q.popleft()
            if q:
                ans = max(ans, x + y + q[0][1] - q[0][0])
            while q and y - x >= q[-1][1] - q[-1][0]:
                q.pop()
            q.append((x, y))
        return ans
```

220. Contains Duplicate III

Hard · Array, Bucket Sort, Ordered Set, Sorting, Sliding Window

leetcode.com/problems/contains-duplicate-iii

★ **TOP 10 PROBLEM** in Bucket Sort: master this one first

PROBLEM

You are given an integer array `nums` and two integers `indexDiff` and `valueDiff`.

Find a pair of indices `(i, j)` such that:

- `i != j`,
- `abs(i - j) <= indexDiff`.
- `abs(nums[i] - nums[j]) <= valueDiff`, and

Return `true` *if such pair exists or* `false` *otherwise*.

Example 1:

```
Input: nums = [1,2,3,1], indexDiff = 3, valueDiff = 0
Output: true
Explanation: We can choose (i, j) = (0, 3).
We satisfy the three conditions:
i != j --> 0 != 3
abs(i - j) <= indexDiff --> abs(0 - 3) <= 3
abs(nums[i] - nums[j]) <= valueDiff --> abs(1 - 1) <= 0
```

Example 2:

```
Input: nums = [1,5,9,1,5,9], indexDiff = 2, valueDiff = 3
Output: false
Explanation: After trying all the possible pairs (i, j), we cannot satisfy the three conditions, so we
return false.
```

Constraints:

- $2 \le nums.length \le 10^5$
- $-10^9 \le nums[i] \le 10^9$
- $1 \le indexDiff \le nums.length$
- $0 \le valueDiff \le 10^9$

SOLUTION (PYTHON 3)

Solution 1: Sliding Window + Ordered Set

How to think about it

We need a pair whose indices differ by at most indexDiff and values by at most valueDiff. A hash set only tests equality, not nearest neighbors. Keep an ordered set of the last indexDiff values. For v, look up the least element ≥ v-valueDiff; if it is also ≤ v+valueDiff, we are done. Then insert v and drop the value that leaves the window.

We maintain a sliding window of size k, and the elements in the window are kept in order.

We traverse the array `nums`. For each element nums[i], we look for the first element in the ordered set that is greater than or equal to nums[i] - t. If the element exists, and this element is less than or equal to nums[i] + t, it means we have found a pair of elements that meet the conditions, and we return `true`. Otherwise, we insert nums[i] into the ordered set, and if the size of the ordered set exceeds k, we need to remove the earliest added element from the ordered set.

The time complexity is O(n × log k), where n is the length of the array `nums`. For each element, we need O(log k) time to find the element in the ordered set, and there are n elements in total, so the total time complexity is O(n × log k).

Python 3

```
class Solution:
    def containsNearbyAlmostDuplicate(
        self, nums: List[int], indexDiff: int, valueDiff: int
    ) -> bool:
        s = SortedSet()
        for i, v in enumerate(nums):
            j = s.bisect_left(v - valueDiff)
            if j < len(s) and s[j] <= v + valueDiff:
                return True
            s.add(v)
            if i >= indexDiff:
                s.remove(nums[i - indexDiff])
        return False
```

leetcode.com/problems/integer-to-english-words

★ **TOP 10 PROBLEM** in Recursion: master this one first

PROBLEM

Convert a non-negative integer `num` to its English words representation.

Example 1:

```
Input: num = 123
Output: "One Hundred Twenty Three"
```

Example 2:

```
Input: num = 12345
Output: "Twelve Thousand Three Hundred Forty Five"
```

Example 3:

```
Input: num = 1234567
Output: "One Million Two Hundred Thirty Four Thousand Five Hundred Sixty Seven"
```

Constraints:

- $0 <= num <= 2^{31} - 1$

SOLUTION (PYTHON 3)

Solution 1

How to think about it

English names group by thousands: Billion, Million, Thousand. Each block has at most three digits and is built from the teens table, the tens table, and Hundred. 0 is Zero. From high to low, convert each nonempty block with transfer and append the scale word.

Python 3

```
class Solution:
    def numberToWords(self, num: int) -> str:
        if num == 0:
            return 'Zero'

        lt20 = [
            '',
            'One',
            'Two',
            'Three',
            'Four',
            'Five',
            'Six',
            'Seven',
            'Eight',
            'Nine',
            'Ten',
            'Eleven',
            'Twelve',
            'Thirteen',
            'Fourteen',
            'Fifteen',
            'Sixteen',
            'Seventeen',
            'Eighteen',
            'Nineteen',
        ]
        tens = [
            '',
            'Ten',
            'Twenty',
            'Thirty',
            'Forty',
            'Fifty',
            'Sixty',
            'Seventy',
            'Eighty',
            'Ninety',
        ]
        thousands = ['Billion', 'Million', 'Thousand', '']

        def transfer(num):
            if num == 0:
                return ''
            if num < 20:
                return lt20[num] + ' '
            if num < 100:
                return tens[num // 10] + ' ' + transfer(num % 10)
            return lt20[num // 100] + ' Hundred ' + transfer(num % 100)

        res = []
        i, j = 1000000000, 0
        while i > 0:
            if num // i != 0:
                res.append(transfer(num // i))
                res.append(thousands[j])
                res.append(' ')
                num %= i
            j += 1
            i //= 1000

        return ''.join(res).strip()
```

Complexity. Time: O(1) (at most 10 digits). Space: O(1).

761. Special Binary String

Hard · String, Divide and Conquer, Sorting

leetcode.com/problems/special-binary-string

★ **TOP 10 PROBLEM** in Recursion: master this one first

PROBLEM

Special binary strings are binary strings with the following two properties:

- The number of `0`'s is equal to the number of `1`'s.
- Every prefix of the binary string has at least as many `1`'s as `0`'s.

You are given a **special binary** string `s`.

A move consists of choosing two consecutive, non-empty, special substrings of `s`, and swapping them. Two strings are consecutive if the last character of the first string is exactly one index before the first character of the second string.

Return *the lexicographically largest resulting string possible after applying the mentioned operations on the string*.

Example 1:

```
Input: s = "11011000"
Output: "11100100"
Explanation: The strings "10" [occuring at s[1]] and "1100" [at s[3]] are swapped.
This is the lexicographically largest string possible after some number of swaps.
```

Example 2:

```
Input: s = "10"
Output: "10"
```

Constraints:

- `1 <= s.length <= 50`
- `s[i]` is either `'0'` or `'1'`.
- `s` is a special binary string.

SOLUTION (PYTHON 3)

Solution 1: Recursion + Sorting

How to think about it

A special binary string is a valid parentheses string with 1/0. Swapping adjacent special pieces increases the lexicographic order. n≤ 50, but the recursive shape is the real lever. The string is a concatenation of 1+special+0 blocks. Maximize each interior, then sort those blocks descending. A balance counter isolates blocks; recurse on the inside, sort, and join.

We can treat the special binary sequence as "valid parentheses", where 1 represents an opening parenthesis and 0 represents a closing parenthesis. For example, "11011000" can be viewed as "((()(()))".

Swapping two consecutive non-empty special substrings is equivalent to swapping two adjacent valid parentheses. We can use recursion to solve this problem.

We treat each "valid parenthesis" in string s as a part, process it recursively, and finally sort them to get the final answer.

The time complexity is $O(n^2)$, and the space complexity is $O(n)$, where n is the length of string s.

Python 3

```
class Solution:
    def makeLargestSpecial(self, s: str) -> str:
        if s == '':
            return ''
        ans = []
        cnt = 0
        i = j = 0
        while i < len(s):
            cnt += 1 if s[i] == '1' else -1
            if cnt == 0:
                ans.append('1' + self.makeLargestSpecial(s[j + 1 : i]) + '0')
                j = i + 1
            i += 1
        ans.sort(reverse=True)
        return ''.join(ans)
```

Convert Sorted List to Binary Search Tree (Part 1, pattern 24, page 1311)

PART 2 · DIVIDE AND CONQUER · PROBLEM 1 OF 3

1763. Longest Nice Substring

Easy · Bit Manipulation, Hash Table, String, Divide and Conquer, Sliding Window

leetcode.com/problems/longest-nice-substring

★ **TOP 10 PROBLEM** in Divide and Conquer: master this one first

PROBLEM

A string `s` is **nice** if, for every letter of the alphabet that `s` contains, it appears **both** in uppercase and lowercase. For example, `"abABB"` is nice because `'A'` and `'a'` appear, and `'B'` and `'b'` appear. However, `"abA"` is not because `'b'` appears, but `'B'` does not.

Given a string `s`, return *the longest **substring** of `s` that is **nice**. If there are multiple, return the substring of the **earliest** occurrence. If there are none, return an empty string*.

Example 1:

```
Input: s = "YazaAay"
Output: "aAa"
Explanation: "aAa" is a nice string because 'A/a' is the only letter of the alphabet in s, and both 'A'
and 'a' appear.
"aAa" is the longest nice substring.
```

Example 2:

```
Input: s = "Bb"
Output: "Bb"
Explanation: "Bb" is a nice string because both 'B' and 'b' appear. The whole string is a substring.
```

Example 3:

```
Input: s = "c"
Output: ""
Explanation: There are no nice substrings.
```

Constraints:

- `1 <= s.length <= 100`
- `s` consists of uppercase and lowercase English letters.

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

A nice substring contains both cases of every letter that appears. n is small enough to try all substrings. Fix the left end i, extend rightward, and store characters in a set. When every letter has both cases and the window is longer, record it. Ties keep the earlier substring.

Python 3

```python
class Solution:
    def longestNiceSubstring(self, s: str) -> str:
        n = len(s)
        ans = ''
        for i in range(n):
            ss = set()
            for j in range(i, n):
                ss.add(s[j])
                if (
                    all(c.lower() in ss and c.upper() in ss for c in ss)
                    and len(ans) < j - i + 1
                ):
                    ans = s[i : j + 1]
        return ans
```

Complexity. Time: O(n^2 * C), C = 52 letters. Space: O(C).

Solution 2

> **How to think about it**
>
> Solution 1 scans the set for each window, paying an extra C factor. With 26 letters, two bitmasks for lower and upper case suffice; the window is nice iff the masks are equal.

Python 3

```python
class Solution:
    def longestNiceSubstring(self, s: str) -> str:
        n = len(s)
        ans = ''
        for i in range(n):
            lower = upper = 0
            for j in range(i, n):
                if s[j].islower():
                    lower |= 1 << (ord(s[j]) - ord('a'))
                else:
                    upper |= 1 << (ord(s[j]) - ord('A'))
                if lower == upper and len(ans) < j - i + 1:
                    ans = s[i : j + 1]
        return ans
```

Complexity. Time: O(n^2). Space: O(1).

427. Construct Quad Tree

Medium · Tree, Array, Divide and Conquer, Matrix

leetcode.com/problems/construct-quad-tree

★ **TOP 10 PROBLEM** in Divide and Conquer: master this one first

PROBLEM

Given a `n * n` matrix `grid` of `0's` and `1's` only. We want to represent `grid` with a Quad-Tree.

Return *the root of the Quad-Tree representing* `grid`.

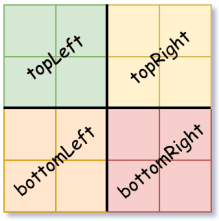
A Quad-Tree is a tree data structure in which each internal node has exactly four children. Besides, each node has two attributes:

- `val`: True if the node represents a grid of 1's or False if the node represents a grid of 0's. Notice that you can assign the `val` to True or False when `isLeaf` is False, and both are accepted in the answer.
- `isLeaf`: True if the node is a leaf node on the tree or False if the node has four children.

```
class Node {
    public boolean val;
    public boolean isLeaf;
    public Node topLeft;
    public Node topRight;
    public Node bottomLeft;
    public Node bottomRight;
}
```

We can construct a Quad-Tree from a two-dimensional area using the following steps:

1. If the current grid has the same value (i.e all `1's` or all `0's`) set `isLeaf` True and set `val` to the value of the grid and set the four children to Null and stop.
2. If the current grid has different values, set `isLeaf` to False and set `val` to any value and divide the current grid into four sub-grids as shown in the photo.
3. Recurse for each of the children with the proper sub-grid.



If you want to know more about the Quad-Tree, you can refer to the wiki.

Quad-Tree format:

You don't need to read this section for solving the problem. This is only if you want to understand the output format here. The output represents the serialized format of a Quad-Tree using level order traversal, where `null` signifies a path terminator where no node exists below.

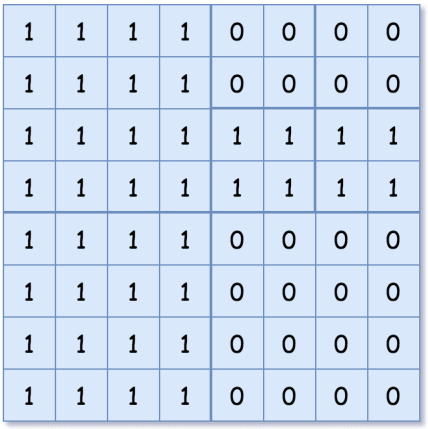
It is very similar to the serialization of the binary tree. The only difference is that the node is represented as a list `[isLeaf, val]`.

If the value of `isLeaf` or `val` is True we represent it as **1** in the list `[isLeaf, val]` and if the value of `isLeaf` or `val` is False we represent it as **0**.

Example 1:

```
Input: grid = [[0,1],[1,0]]
Output: [[0,1],[1,0],[1,1],[1,1],[1,0]]
Explanation: The explanation of this example is shown below:
Notice that 0 represents False and 1 represents True in the photo representing the Quad-Tree.
```

Example 2:



```
Input: grid = [[1,1,1,1,0,0,0,0],[1,1,1,1,0,0,0,0],[1,1,1,1,1,1,1,1],[1,1,1,1,1,1,1,1],[1,1,1,1,0,0,0,
0],[1,1,1,1,0,0,0,0],[1,1,1,1,0,0,0,0],[1,1,1,1,0,0,0,0]]
Output: [[0,1],[1,1],[0,1],[1,1],[1,0],null,null,null,null,[1,0],[1,0],[1,1],[1,1]]
Explanation: All values in the grid are not the same. We divide the grid into four sub-grids.
The topLeft, bottomLeft and bottomRight each has the same value.
The topRight have different values so we divide it into 4 sub-grids where each has the same value.
Explanation is shown in the photo below:
```

Constraints:

- `n == grid.length == grid[i].length`
- `n == 2^x` where `0 <= x <= 6`

SOLUTION (PYTHON 3)

Solution 1

How to think about it

A quad tree stores a uniform block as a leaf and otherwise splits into four. Rescanning every sub-rectangle repeats work, yet n≤ 64 and a four-way split keep the total scan acceptable. DFS inspects whether the current rectangle contains both 0 and 1. One value yields a leaf; otherwise recurse on the four quadrants. A leaf's val is that block's color. Testing uniformity before splitting avoids cutting a solid region.

Python 3

```
"""
# Definition for a QuadTree node.
class Node:
    def __init__(self, val, isLeaf, topLeft, topRight, bottomLeft, bottomRight):
        self.val = val
        self.isLeaf = isLeaf
        self.topLeft = topLeft
        self.topRight = topRight
        self.bottomLeft = bottomLeft
        self.bottomRight = bottomRight
"""

class Solution:
    def construct(self, grid: List[List[int]]) -> 'Node':
        def dfs(a, b, c, d):
            zero = one = 0
            for i in range(a, c + 1):
                for j in range(b, d + 1):
                    if grid[i][j] == 0:
                        zero = 1
                    else:
                        one = 1
            isLeaf = zero + one == 1
            val = isLeaf and one
            if isLeaf:
                return Node(grid[a][b], True)
            topLeft = dfs(a, b, (a + c) // 2, (b + d) // 2)
            topRight = dfs(a, (b + d) // 2 + 1, (a + c) // 2, d)
            bottomLeft = dfs((a + c) // 2 + 1, b, c, (b + d) // 2)
            bottomRight = dfs((a + c) // 2 + 1, (b + d) // 2 + 1, c, d)
            return Node(val, isLeaf, topLeft, topRight, bottomLeft, bottomRight)

        return dfs(0, 0, len(grid) - 1, len(grid[0]) - 1)
```

Complexity. Time: O(n^2 log n) for an n by n grid (every level scans the whole grid). Space: O(log n) recursion (plus the O(n^2) tree).

654. Maximum Binary Tree

Medium · Stack, Tree, Array, Divide and Conquer, Binary Tree, Cartesian Tree, Monotonic Stack

leetcode.com/problems/maximum-binary-tree

★ **TOP 10 PROBLEM** in Divide and Conquer: master this one first

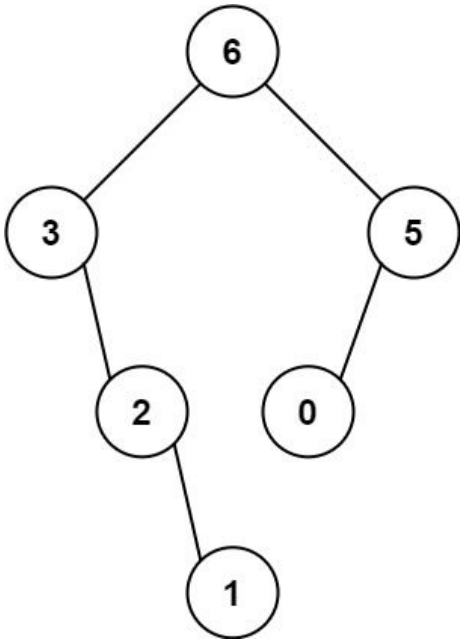
PROBLEM

You are given an integer array `nums` with no duplicates. A **maximum binary tree** can be built recursively from `nums` using the following algorithm:

1. Create a root node whose value is the maximum value in `nums`.
2. Recursively build the left subtree on the **subarray prefix** to the **left** of the maximum value.
3. Recursively build the right subtree on the **subarray suffix** to the **right** of the maximum value.

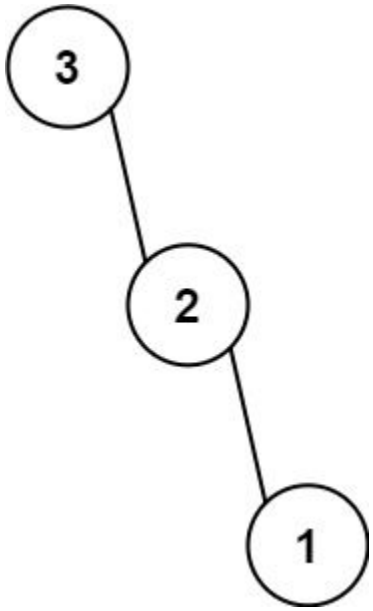
Return *the **maximum binary tree** built from* `nums`.

Example 1:



```
Input: nums = [3,2,1,6,0,5]
Output: [6,3,5,null,2,0,null,null,1]
Explanation: The recursive calls are as follow:
- The largest value in [3,2,1,6,0,5] is 6. Left prefix is [3,2,1] and right suffix is [0,5].
    - The largest value in [3,2,1] is 3. Left prefix is [] and right suffix is [2,1].
        - Empty array, so no child.
        - The largest value in [2,1] is 2. Left prefix is [] and right suffix is [1].
            - Empty array, so no child.
            - Only one element, so child is a node with value 1.
    - The largest value in [0,5] is 5. Left prefix is [0] and right suffix is [].
        - Only one element, so child is a node with value 0.
        - Empty array, so no child.
```

Example 2:



```
Input: nums = [3,2,1]
Output: [3,null,2,null,1]
```

Constraints:

- `1 <= nums.length <= 1000`
- `0 <= nums[i] <= 1000`
- All integers in `nums` are **unique**.

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

The root is the interval maximum; children follow the same rule. A linear scan for the max is $O(n^2)$ worst-case, acceptable for $n \le 10^3$. Take `max` and its index, then recurse on the two sides.

Python 3

```python
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def constructMaximumBinaryTree(self, nums: List[int]) -> Optional[TreeNode]:
        def dfs(nums):
            if not nums:
                return None
            val = max(nums)
            i = nums.index(val)
            root = TreeNode(val)
            root.left = dfs(nums[:i])
            root.right = dfs(nums[i + 1 :])
            return root

        return dfs(nums)
```

Solution 2

> **How to think about it**
>
> Each max query in method 1 is linear. A segment tree answers range maxima in O(log n), so the same recursion becomes O(nlog n).

Python 3

```python
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def constructMaximumBinaryTree(self, nums: List[int]) -> Optional[TreeNode]:
        def dfs(l, r):
            if l > r:
                return None
            val = tree.query(1, l, r)
            root = TreeNode(val)
            root.left = dfs(l, d[val] - 1)
            root.right = dfs(d[val] + 1, r)
            return root

        d = {v: i for i, v in enumerate(nums, 1)}
        tree = SegmentTree(nums)
        return dfs(1, len(nums))

class Node:
    def __init__(self):
        self.l = 0
        self.r = 0
        self.v = 0

class SegmentTree:
    def __init__(self, nums):
        self.nums = nums
        n = len(nums)
        self.tr = [Node() for _ in range(n << 2)]
        self.build(1, 1, n)

    def build(self, u, l, r):
        self.tr[u].l, self.tr[u].r = l, r
        if l == r:
            self.tr[u].v = self.nums[l - 1]
            return
        mid = (l + r) >> 1
        self.build(u << 1, l, mid)
        self.build(u << 1 | 1, mid + 1, r)
        self.pushup(u)

    def query(self, u, l, r):
        if self.tr[u].l >= l and self.tr[u].r <= r:
            return self.tr[u].v
        mid = (self.tr[u].l + self.tr[u].r) >> 1
        v = 0
        if l <= mid:
            v = max(v, self.query(u << 1, l, r))
        if r > mid:
            v = max(v, self.query(u << 1 | 1, l, r))
        return v

    def pushup(self, u):
        self.tr[u].v = max(self.tr[u << 1].v, self.tr[u << 1 | 1].v)
```

Solution 3

How to think about it

The segment tree is extra structure. A decreasing stack finds the nearest greater neighbor on the left: the last popped node becomes the left child, and the new top takes the current node as its right child. One pass builds the tree.

Python 3

```python
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def constructMaximumBinaryTree(self, nums: List[int]) -> Optional[TreeNode]:
        stk = []
        for v in nums:
            node = TreeNode(v)
            last = None
            while stk and stk[-1].val < v:
                last = stk.pop()
            node.left = last
            if stk:
                stk[-1].right = node
            stk.append(node)
        return stk[0]
```

Complexity. Time: O(n). Space: O(n).

Solution 4: Explicit Stack

How to think about it

The root is the maximum of an interval, and both children follow the same rule. n ≤ 1000, so a linear scan for each maximum is acceptable in time. On an increasing array the maximum is always at the right end, so the first call always handles the remaining n-1 elements on the left and the depth is n, past the default recursion limit. The root of a segment depends only on its two endpoints, so the subarray does not need to be copied. Store pending half-open intervals [l, r) on an explicit stack, together with which side of the parent they hang from. Pop an interval, scan for its maximum, create the node, then push the right interval and the left interval. An empty interval is skipped.

Scan the half-open interval [l, r) for the index i of the maximum, and make nums[i] the root. The left child is the interval [l, i) and the right child is [i + 1, r). Pending intervals live on an explicit stack: after a root is created, push the right interval and then the left interval. Empty intervals are skipped. The first interval is [0, n).

The time complexity is $O(n^2)$, and the space complexity is O(n), where n is the length of the array.

Python 3

```python
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def constructMaximumBinaryTree(self, nums: List[int]) -> Optional[TreeNode]:
        n = len(nums)
        root = None
        stk = [(0, n, None, 0)]
        while stk:
            l, r, parent, side = stk.pop()
            if l >= r:
                continue
            i = l
            for j in range(l + 1, r):
                if nums[j] > nums[i]:
                    i = j
            node = TreeNode(nums[i])
            if parent is None:
                root = node
            elif side == 0:
                parent.left = node
            else:
                parent.right = node
            stk.append((i + 1, r, node, 1))
            stk.append((l, i, node, 0))
        return root
```

Solution 5: Segment Tree + Explicit Stack

How to think about it

Solution 1 already builds the tree with an explicit stack, but each maximum is still a linear scan. A segment tree answers a range maximum in O(log n). The left interval can still form a chain of length n, so those two child intervals go on the same explicit stack. The total time is O(n log n).

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def constructMaximumBinaryTree(self, nums: List[int]) -> Optional[TreeNode]:
        d = {v: i for i, v in enumerate(nums, 1)}
        tree = SegmentTree(nums)
        root = None
        stk = [(1, len(nums), None, 0)]
        while stk:
            l, r, parent, side = stk.pop()
            if l > r:
                continue
            val = tree.query(1, l, r)
            node = TreeNode(val)
            i = d[val]
            if parent is None:
                root = node
            elif side == 0:
                parent.left = node
            else:
                parent.right = node
            stk.append((i + 1, r, node, 1))
            stk.append((l, i - 1, node, 0))
        return root

class Node:
    def __init__(self):
        self.l = 0
        self.r = 0
        self.v = 0

class SegmentTree:
    def __init__(self, nums):
        self.nums = nums
        n = len(nums)
        self.tr = [Node() for _ in range(n << 2)]
        self.build(1, 1, n)

    def build(self, u, l, r):
        self.tr[u].l, self.tr[u].r = l, r
        if l == r:
            self.tr[u].v = self.nums[l - 1]

PART 2 · BINARY SEARCH · PROBLEM 1 OF 9

278. First Bad Version

Easy · Binary Search, Interactive

leetcode.com/problems/first-bad-version

★ **TOP 10 PROBLEM** in Binary Search: master this one first

PROBLEM

You are a product manager and currently leading a team to develop a new product. Unfortunately, the latest version of your product fails the quality check. Since each version is developed based on the previous version, all the versions after a bad version are also bad.

Suppose you have `n` versions `[1, 2, ..., n]` and you want to find out the first bad one, which causes all the following ones to be bad.

You are given an API `bool isBadVersion(version)` which returns whether `version` is bad. Implement a function to find the first bad version. You should minimize the number of calls to the API.

Example 1:

```
Input: n = 5, bad = 4
Output: 4
Explanation:
call isBadVersion(3) -> false
call isBadVersion(5) -> true
call isBadVersion(4) -> true
Then 4 is the first bad version.
```

Example 2:

```
Input: n = 1, bad = 1
Output: 1
```

Constraints:

- `1 <= bad <= n <= 2^31 - 1`

SOLUTION (PYTHON 3)

Solution 1: Binary Search

How to think about it

Once a version is bad, every later one is bad. If isBadVersion(mid) then the first bad version lies in the left half including mid; otherwise it lies to the right. The search stops at l=r, the first bad version.

We define the left boundary of the binary search as l = 1 and the right boundary as r = n.

While l < r, we calculate the middle position mid = floor((l + r)/2), then call the `isBadVersion(mid)` API. If it returns true, it means the first bad version is between [l, mid], so we set r = mid; otherwise, the first bad version is between [mid + 1, r], so we set l = mid + 1.

Finally, we return l.

The time complexity is O(log n), and the space complexity is O(1).

Python 3

```
# The isBadVersion API is already defined for you.
# def isBadVersion(version: int) -> bool:

class Solution:
    def firstBadVersion(self, n: int) -> int:
        l, r = 1, n
        while l < r:
            mid = (l + r) >> 1
            if isBadVersion(mid):
                r = mid
            else:
                l = mid + 1
        return l
```

```

367. Valid Perfect Square

Easy · Math, Binary Search

leetcode.com/problems/valid-perfect-square

★ **TOP 10 PROBLEM** in Binary Search: master this one first

PROBLEM

Given a positive integer num, return `true` *if* `num` *is a perfect square or* `false` *otherwise*.

A **perfect square** is an integer that is the square of an integer. In other words, it is the product of some integer with itself.

You must not use any built-in library function, such as `sqrt`.

Example 1:

```
Input: num = 16
Output: true
Explanation: We return true because 4 * 4 = 16 and 4 is an integer.
```

Example 2:

```
Input: num = 14
Output: false
Explanation: We return false because 3.742 * 3.742 = 14 and 3.742 is not an integer.
```

Constraints:

- `1 <= num <= 2^31 - 1`

SOLUTIONS (PYTHON 3)

Solution 1: Binary Search

How to think about it

Is num a perfect square? Scanning to √num is O(√n). Binary search on x^2 is enough. Find the least x in [1,num] with $x^2 \geq$ num, then test equality. The code uses `bisect_left` with $x \mapsto x^2$.

We can use binary search to solve this problem. Define the left boundary l = 1 and the right boundary r = num of the binary search, then find the smallest integer x that satisfies $x^2 \geq$ num in the range [l, r]. Finally, if x^2 = num, then num is a perfect square.

The time complexity is O(log n), where n is the given number. The space complexity is O(1).

Python 3

```python
class Solution:
    def isPerfectSquare(self, num: int) -> bool:
        l = bisect_left(range(1, num + 1), num, key=lambda x: x * x) + 1
        return l * l == num
```

Solution 2: Mathematics

How to think about it

Binary search needs the monotone squares. The odd sum 1+3+…+(2n-1)=n^2, so subtract increasing odds until num hits 0. Shorter code in O(√n).

Since 1 + 3 + 5 + … + (2n - 1) = n^2, we can gradually subtract 1, 3, 5, … from num. If num finally equals 0, then num is a perfect square.

The time complexity is O(√n), and the space complexity is O(1).

Python 3

```
class Solution:
    def isPerfectSquare(self, num: int) -> bool:
        i = 1
        while num > 0:
            num -= i
            i += 2
        return num == 0
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

374. Guess Number Higher or Lower

Easy · Binary Search, Interactive

leetcode.com/problems/guess-number-higher-or-lower

★ **TOP 10 PROBLEM** in Binary Search: master this one first

PROBLEM

We are playing the Guess Game. The game is as follows:

I pick a number from `1` to `n`. You have to guess which number I picked (the number I picked stays the same throughout the game).

Every time you guess wrong, I will tell you whether the number I picked is higher or lower than your guess.

You call a pre-defined API `int guess(int num)`, which returns three possible results:

- `-1`: Your guess is higher than the number I picked (i.e. `num > pick`).
- `1`: Your guess is lower than the number I picked (i.e. `num < pick`).
- `0`: your guess is equal to the number I picked (i.e. `num == pick`).

Return *the number that I picked*.

Example 1:

```
Input: n = 10, pick = 6
Output: 6
```

Example 2:

```
Input: n = 1, pick = 1
Output: 1
```

Example 3:

```
Input: n = 2, pick = 1
Output: 1
```

Constraints:

- `1 <= n <= 2^31 - 1`
- `1 <= pick <= n`

SOLUTION (PYTHON 3)

Solution 1: Binary Search

How to think about it

Guess a number in [1,n]; `guess` says higher or lower. Linear probes take n tries. The range is sorted, so binary search. Find the first x with `guess(x)\le 0`. The code uses key -guess(x) and a single `bisect`.

We perform a binary search in the interval [1,..n], and find the first number that satisfies `guess(x) <= 0`, which is the answer.

The time complexity is O(log n), where n is the upper limit given in the problem. The space complexity is O(1).

Python 3

```
# The guess API is already defined for you.
# @param num, your guess
# @return -1 if num is higher than the picked number
#          1 if num is lower than the picked number
#          otherwise return 0
# def guess(num: int) -> int:

class Solution:
    def guessNumber(self, n: int) -> int:
        return bisect.bisect(range(1, n + 1), 0, key=lambda x: -guess(x))
```

        else:
            low = middle + 1
    return None, count
```

744. Find Smallest Letter Greater Than Target

Easy · Array, Binary Search

leetcode.com/problems/find-smallest-letter-greater-than-target

★ **TOP 10 PROBLEM** in Binary Search: master this one first

PROBLEM

You are given an array of characters `letters` that is sorted in **non-decreasing order**, and a character `target`. There are **at least two different** characters in `letters`.

Return *the smallest character in* `letters` *that is lexicographically greater than* `target`. If such a character does not exist, return the first character in `letters`.

Example 1:

```
Input: letters = ["c","f","j"], target = "a"
Output: "c"
Explanation: The smallest character that is lexicographically greater than 'a' in letters is 'c'.
```

Example 2:

```
Input: letters = ["c","f","j"], target = "c"
Output: "f"
Explanation: The smallest character that is lexicographically greater than 'c' in letters is 'f'.
```

Example 3:

```
Input: letters = ["x","x","y","y"], target = "z"
Output: "x"
Explanation: There are no characters in letters that is lexicographically greater than 'z' so we
return letters[0].
```

Constraints:

- `2 <= letters.length <= 10^4`
- `letters[i]` is a lowercase English letter.
- `letters` is sorted in **non-decreasing** order.
- `letters` contains at least two different characters.
- `target` is a lowercase English letter.

SOLUTION (PYTHON 3)

Solution 1: Binary Search

How to think about it

Among non-decreasing letters, find the smallest one strictly greater than target, wrapping to the front. The array is sorted, so we binary-search. That is an upper bound. If it falls at n, the answer is letters[0]—index modulo n. bisect_right on the code points, then letters[i mod n]. O(log n).

Since `letters` is sorted in non-decreasing order, we can use binary search to find the smallest character that is larger than `target`.

We define the left boundary of the binary search as l = 0, and the right boundary as r = n. For each binary search, we calculate the middle position mid = (l + r) / 2. If letters[mid] > target, it means we need to continue searching in the left half, so we set r = mid. Otherwise, we need to continue searching in the right half, so we set l = mid + 1.

Finally, we return letters[l mod n].

The time complexity is O(log n), where n is the length of `letters`. The space complexity is O(1).

Python 3

```
class Solution:
    def nextGreatestLetter(self, letters: List[str], target: str) -> str:
        i = bisect_right(letters, ord(target), key=lambda c: ord(c))
        return letters[i % len(letters)]
```

```

240. Search a 2D Matrix II

Medium · Array, Binary Search, Divide and Conquer, Matrix

leetcode.com/problems/search-a-2d-matrix-ii

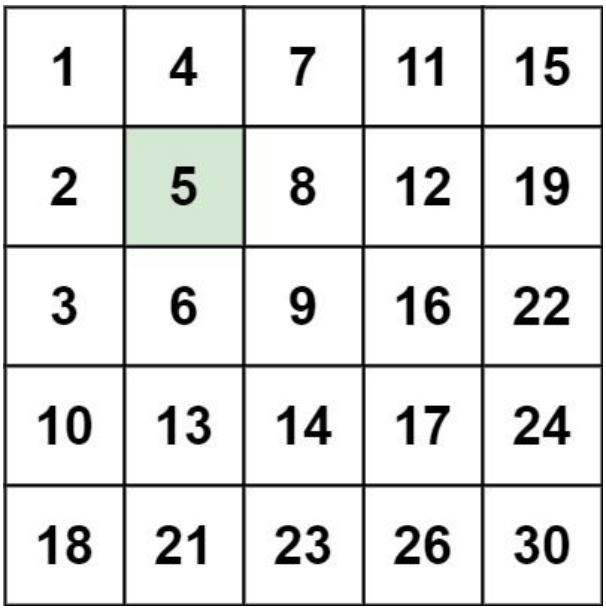
★ **TOP 10 PROBLEM** in Binary Search: master this one first

PROBLEM

Write an efficient algorithm that searches for a value `target` in an `m x n` integer matrix `matrix`. This matrix has the following properties:

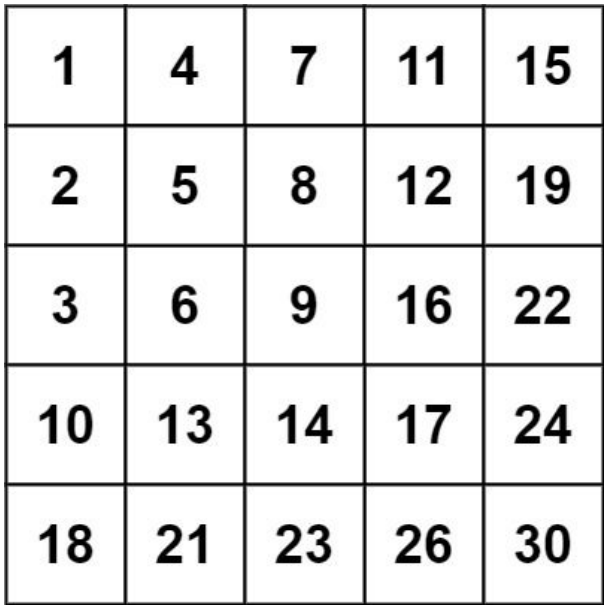
- Integers in each row are sorted in ascending from left to right.
- Integers in each column are sorted in ascending from top to bottom.

Example 1:



```
Input: matrix = [[1,4,7,11,15],[2,5,8,12,19],[3,6,9,16,22],[10,13,14,17,24],[18,21,23,26,30]], target = 5
Output: true
```

Example 2:



1	4	7	11	15
2	5	8	12	19
3	6	9	16	22
10	13	14	17	24
18	21	23	26	30

```
Input: matrix = [[1,4,7,11,15],[2,5,8,12,19],[3,6,9,16,22],[10,13,14,17,24],[18,21,23,26,30]], target
= 20
Output: false
```

Constraints:

- `m == matrix.length`
- `n == matrix[i].length`
- `1 <= n, m <= 300`
- -10^9 `<= matrix[i][j] <=` 10^9
- All the integers in each row are **sorted** in ascending order.
- All the integers in each column are **sorted** in ascending order.
- -10^9 `<= target <=` 10^9

SOLUTIONS (PYTHON 3)

Solution 1: Binary Search

> **How to think about it**
> Each row (and column) is sorted, so we can binary-search target in every row. That is O(mlog n) with no extra memory.

Since all elements in each row are sorted in ascending order, for each row, we can use binary search to find the first element greater than or equal to target, and then check if that element is equal to target. If it is equal to target, it means the target value is found, and we return true. If it is not equal to target, it means all elements in this row are less than target, and we should continue searching the next row.

If all rows have been searched and the target value is not found, it means the target value does not exist, and we return false.

The time complexity is O(m × log n), where m and n are the number of rows and columns of the matrix, respectively. The space complexity is O(1).

Python 3

```python
class Solution:
    def searchMatrix(self, matrix: List[List[int]], target: int) -> bool:
        for row in matrix:
            j = bisect_left(row, target)
            if j < len(matrix[0]) and row[j] == target:
                return True
        return False
```

Solution 2: Search from Bottom-Left or Top-Right

> **How to think about it**
>
> Per-row binary search ignores column order. From the bottom-left, a too-large value moves up (dropping that column above) and a too-small value moves right (dropping that row to the right). Each step discards a row or a column, in O(m+n) time.

We start the search from the bottom-left or top-right corner and move towards the top-right or bottom-left direction. Compare the current element matrix[i][j] with target:

- If matrix[i][j] = target, it means the target value is found, and we return true.
- If matrix[i][j] > target, it means all elements in this column from the current position upwards are greater than target, so we move the i pointer upwards, i.e., i ← i - 1.
- If matrix[i][j] < target, it means all elements in this row from the current position to the right are less than target, so we move the j pointer to the right, i.e., j ← j + 1.

If the search ends and the target is not found, return false.

The time complexity is O(m + n), where m and n are the number of rows and columns of the matrix, respectively. The space complexity is O(1).

Python 3

```python
class Solution:
    def searchMatrix(self, matrix: List[List[int]], target: int) -> bool:
        m, n = len(matrix), len(matrix[0])
        i, j = m - 1, 0
        while i >= 0 and j < n:
            if matrix[i][j] == target:
                return True
            if matrix[i][j] > target:
                i -= 1
            else:
                j += 1
        return False
```

PART 2 · BINARY SEARCH · PROBLEM 6 OF 9

475. Heaters

Medium · Array, Two Pointers, Binary Search, Sorting

leetcode.com/problems/heaters

★ **TOP 10 PROBLEM** in Binary Search: master this one first

PROBLEM

Winter is coming! During the contest, your first job is to design a standard heater with a fixed warm radius to warm all the houses.

Every house can be warmed, as long as the house is within the heater's warm radius range.

Given the positions of `houses` and `heaters` on a horizontal line, return *the minimum radius standard of heaters so that those heaters could cover all houses.*

Notice that all the `heaters` follow your radius standard, and the warm radius will be the same.

Example 1:

```
Input: houses = [1,2,3], heaters = [2]
Output: 1
Explanation: The only heater was placed in the position 2, and if we use the radius 1 standard, then all the houses can be warmed.
```

Example 2:

```
Input: houses = [1,2,3,4], heaters = [1,4]
Output: 1
Explanation: The two heaters were placed at positions 1 and 4. We need to use a radius 1 standard, then all the houses can be warmed.
```

Example 3:

```
Input: houses = [1,5], heaters = [2]
Output: 3
```

Constraints:

- `1 <= houses.length, heaters.length <= 3 * 10^4`
- `1 <= houses[i], heaters[i] <= 10^9`

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Heaters must cover every house; we want the smallest common radius. Trying every radius is huge, yet feasibility grows with the radius. Sort both arrays and binary-search r. A two-pointer check lets each heater cover [h-r,h+r]: a house to the left fails, a house to the right needs the next heater. Both sequences are sorted, so the pointers only move forward and one check is linear.

Python 3

```python
class Solution:
    def findRadius(self, houses: List[int], heaters: List[int]) -> int:
        houses.sort()
        heaters.sort()

        def check(r):
            m, n = len(houses), len(heaters)
            i = j = 0
            while i < m:
                if j >= n:
                    return False
                mi = heaters[j] - r
                mx = heaters[j] + r
                if houses[i] < mi:
                    return False
                if houses[i] > mx:
                    j += 1
                else:
                    i += 1
            return True

        left, right = 0, int(1e9)
        while left < right:
            mid = (left + right) >> 1
            if check(mid):
                right = mid
            else:
                left = mid + 1
        return left
```

Complexity. Time: O(m log m + n log n + (m + n) log R), R = largest radius searched. Space: O(log n) for the sorts.

528. Random Pick with Weight

Medium · Array, Math, Binary Search, Prefix Sum, Randomized

leetcode.com/problems/random-pick-with-weight

★ **TOP 10 PROBLEM** in Binary Search: master this one first

PROBLEM

You are given a **0-indexed** array of positive integers `w` where `w[i]` describes the **weight** of the i^{th} index.

You need to implement the function `pickIndex()`, which **randomly** picks an index in the range `[0, w.length - 1]` (**inclusive**) and returns it. The **probability** of picking an index `i` is `w[i] / sum(w)`.

- For example, if `w = [1, 3]`, the probability of picking index `0` is `1 / (1 + 3) = 0.25` (i.e., `25%`), and the probability of picking index `1` is `3 / (1 + 3) = 0.75` (i.e., `75%`).

Example 1:

```
Input
["Solution","pickIndex"]
[[[1]],[]]
Output
[null,0]

Explanation
Solution solution = new Solution([1]);
solution.pickIndex(); // return 0. The only option is to return 0 since there is only one element in w.
```

Example 2:

```
Input
["Solution","pickIndex","pickIndex","pickIndex","pickIndex","pickIndex"]
[[[1,3]],[],[],[],[],[]]
Output
[null,1,1,1,1,0]

Explanation
Solution solution = new Solution([1, 3]);
solution.pickIndex(); // return 1. It is returning the second element (index = 1) that has a
probability of 3/4.
solution.pickIndex(); // return 1
solution.pickIndex(); // return 1
solution.pickIndex(); // return 1
solution.pickIndex(); // return 0. It is returning the first element (index = 0) that has a
probability of 1/4.

Since this is a randomization problem, multiple answers are allowed.
All of the following outputs can be considered correct:
[null,1,1,1,1,0]
[null,1,1,1,1,1]
[null,1,1,1,0,0]
[null,1,1,1,0,1]
[null,1,0,1,0,0]
......
and so on.
```

Constraints:

- `1 <= w.length <= 10^4`
- `1 <= w[i] <= 10^5`
- `pickIndex` will be called at most `10^4` times.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

We must sample index i with probability proportional to w[i], many times, so a linear scan per call is wasteful. Prefix sums turn weights into intervals on [1, S]. Draw a uniform integer and binary-search the interval. Build is O(n) and each pick is O(log n). Subtract one because the prefix array is padded with a leading 0.

Python 3

```
class Solution:
    def __init__(self, w: List[int]):
        self.s = [0]
        for c in w:
            self.s.append(self.s[-1] + c)

    def pickIndex(self) -> int:
        x = random.randint(1, self.s[-1])
        left, right = 1, len(self.s) - 1
        while left < right:
            mid = (left + right) >> 1
            if self.s[mid] >= x:
                right = mid
            else:
                left = mid + 1
        return left - 1

# Your Solution object will be instantiated and called as such:
# obj = Solution(w)
# param_1 = obj.pickIndex()
```

1552. Magnetic Force Between Two Balls

Medium · Array, Binary Search, Sorting

leetcode.com/problems/magnetic-force-between-two-balls

★ **TOP 10 PROBLEM** in Binary Search: master this one first

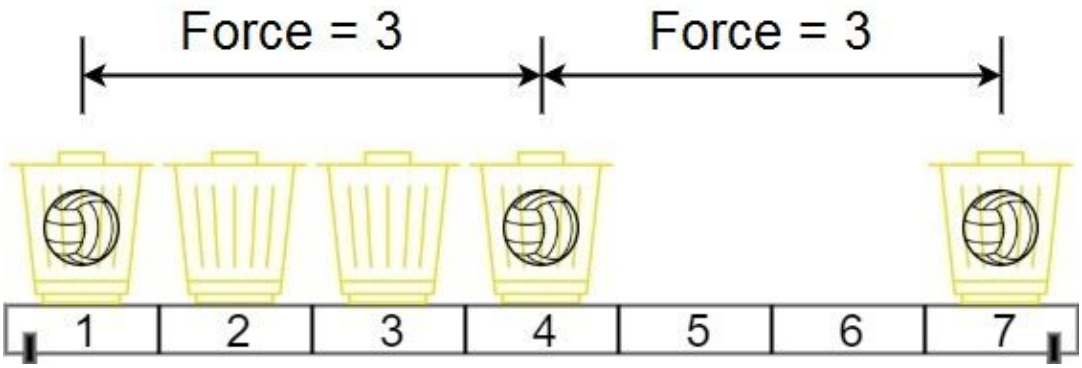
PROBLEM

In the universe Earth C-137, Rick discovered a special form of magnetic force between two balls if they are put in his new invented basket. Rick has `n` empty baskets, the `i`th basket is at `position[i]`, Morty has `m` balls and needs to distribute the balls into the baskets such that the **minimum magnetic force** between any two balls is **maximum**.

Rick stated that magnetic force between two different balls at positions `x` and `y` is `|x - y|`.

Given the integer array `position` and the integer `m`. Return *the required force*.

Example 1:



```
Input: position = [1,2,3,4,7], m = 3
Output: 3
Explanation: Distributing the 3 balls into baskets 1, 4 and 7 will make the magnetic force between ball pairs [3, 3, 6]. The minimum magnetic force is 3. We cannot achieve a larger minimum magnetic force than 3.
```

Example 2:

```
Input: position = [5,4,3,2,1,1000000000], m = 2
Output: 999999999
Explanation: We can use baskets 1 and 1000000000.
```

Constraints:

- `n == position.length`
- `2 <= n <= 10`^{5}
- `1 <= position[i] <= 10`^{9}
- All integers in `position` are **distinct**.
- `2 <= m <= position.length`

SOLUTION (PYTHON 3)

Solution 1: Binary Search

How to think about it

Place m balls to maximize the minimum gap. Positions reach 10^9, so we cannot enumerate layouts by gap; n≤ 10^5 still allows a fast feasibility test. Larger gaps admit fewer balls, which is monotone. After sorting, binary-search a gap f and scan left to right, placing a ball only when it is at least f from the previous one. Treat “cannot place m balls” as the search key; the predecessor of the first failing f is the largest feasible gap.

We notice that the greater the minimum magnetic force between any two balls, the fewer balls can be placed, which exhibits monotonicity. We can use binary search to find the maximum minimum magnetic force that allows the number of balls not less than m to be placed.

First, we sort the positions of the baskets, and then use binary search with the left boundary l = 1 and the right boundary r = position[n - 1], where n is the number of baskets. In each binary search iteration, we calculate the midpoint m = (l + r + 1) / 2, and then determine if there is a way to place the balls such that the number of balls placed is not less than m.

The problem is transformed into determining whether a given minimum magnetic force f can place m balls. We can traverse the positions of the baskets from left to right, and if the distance between the position of the last ball and the current basket's position is greater than or equal to f, it indicates that a ball can be placed in the current basket. Finally, we check if the number of balls placed is not less than m.

The time complexity is O(n × log n + n × log M), and the space complexity is O(log n). Here, n and M respectively represent the number of baskets and the maximum value of the basket positions.

Python 3

```python
class Solution:
    def maxDistance(self, position: List[int], m: int) -> int:
        def check(f: int) -> bool:
            prev = -inf
            cnt = 0
            for curr in position:
                if curr - prev >= f:
                    prev = curr
                    cnt += 1
            return cnt < m

        position.sort()
        l, r = 1, position[-1]
        return bisect_left(range(l, r + 1), True, key=check)
```

    return count
```

PART 2 · BINARY SEARCH · PROBLEM 9 OF 9

1095. Find in Mountain Array

Hard · Array, Binary Search, Interactive, Ternary Search

leetcode.com/problems/find-in-mountain-array

★ **TOP 10 PROBLEM** in Binary Search: master this one first

PROBLEM

*(This problem is an **interactive problem**.)*

You may recall that an array `arr` is a **mountain array** if and only if:

- `arr.length >= 3`
- There exists some `i` with `0 < i < arr.length - 1` such that:
  - `arr[0] < arr[1] < ... < arr[i - 1] < arr[i]`
  - `arr[i] > arr[i + 1] > ... > arr[arr.length - 1]`

Given a mountain array `mountainArr`, return the **minimum** `index` such that `mountainArr.get(index) == target`. If such an `index` does not exist, return `-1`.

You cannot access the mountain array directly. You may only access the array using a `MountainArray` interface:

- `MountainArray.get(k)` returns the element of the array at index `k` (0-indexed).
- `MountainArray.length()` returns the length of the array.

Submissions making more than `100` calls to `MountainArray.get` will be judged *Wrong Answer*. Also, any solutions that attempt to circumvent the judge will result in disqualification.

Example 1:

```
Input: mountainArr = [1,2,3,4,5,3,1], target = 3
Output: 2
Explanation: 3 exists in the array, at index=2 and index=5. Return the minimum index, which is 2.
```

Example 2:

```
Input: mountainArr = [0,1,2,4,2,1], target = 3
Output: -1
Explanation: 3 does not exist in the array, so we return -1.
```

Constraints:

- `3 <= mountainArr.length() <=` 10^4
- `0 <= target <=` 10^9
- `0 <= mountainArr.get(index) <=` 10^9

SOLUTION (PYTHON 3)

Solution 1

How to think about it

The mountain is available only through `get`, and n≤ 10^4 requires logarithmic queries. Find the peak, then binary-search the increasing left and the decreasing right. Comparing get(mid) with get(mid+1) locates the peak. `search` uses k=± 1 so the same lower-bound loop works on both sides. The left half is tried first so the smallest index is returned.

Python 3

```
# """
# This is MountainArray's API interface.
# You should not implement it, or speculate about its implementation
# """
# class MountainArray:
#    def get(self, index: int) -> int:
#    def length(self) -> int:

class Solution:
    def findInMountainArray(self, target: int, mountain_arr: 'MountainArray') -> int:
        def search(l: int, r: int, k: int) -> int:
            while l < r:
                mid = (l + r) >> 1
                if k * mountain_arr.get(mid) >= k * target:
                    r = mid
                else:
                    l = mid + 1
            return -1 if mountain_arr.get(l) != target else l

        n = mountain_arr.length()
        l, r = 0, n - 1
        while l < r:
            mid = (l + r) >> 1
            if mountain_arr.get(mid) > mountain_arr.get(mid + 1):
                r = mid
            else:
                l = mid + 1
        ans = search(0, l, 1)
        return search(l + 1, n - 1, -1) if ans == -1 else ans
```

Complexity. Time: O(log n) calls to get. Space: O(1).

301. Remove Invalid Parentheses

Hard · Breadth-First Search, String, Backtracking

leetcode.com/problems/remove-invalid-parentheses

★ **TOP 10 PROBLEM** in Backtracking: master this one first

PROBLEM

Given a string `s` that contains parentheses and letters, remove the minimum number of invalid parentheses to make the input string valid.

Return *a list of **unique strings** that are valid with the minimum number of removals*. You may return the answer in **any order**.

Example 1:

```
Input: s = "()())()"
Output: ["(())()","()()()"]
```

Example 2:

```
Input: s = "(a)())()"
Output: ["(a())()","(a)()()"]
```

Example 3:

```
Input: s = ")("
Output: [""]
```

Constraints:

- `1 <= s.length <= 25`
- `s` consists of lowercase English letters and parentheses `'('` and `')'`.
- There will be at most `20` parentheses in `s`.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

We must delete as few parentheses as possible and list every optimal string. Choosing delete-or-keep at each parenthesis branches too widely, and most paths are not minimal. A scan first yields lower bounds l and r on deletions. The search tracks remaining quotas and the current left/right counts; prune when leftover characters cannot finish the deletions or a prefix has more right parentheses than left. Try deleting (if quota remains) then keeping, and deduplicate with a set. Only paths that delete exactly the minimum survive.

Python 3

```python
class Solution:
    def removeInvalidParentheses(self, s: str) -> List[str]:
        def dfs(i, l, r, lcnt, rcnt, t):
            if i == n:
                if l == 0 and r == 0:
                    ans.add(t)
                return
            if n - i < l + r or lcnt < rcnt:
                return
            if s[i] == '(' and l:
                dfs(i + 1, l - 1, r, lcnt, rcnt, t)
            elif s[i] == ')' and r:
                dfs(i + 1, l, r - 1, lcnt, rcnt, t)
            dfs(i + 1, l, r, lcnt + (s[i] == '('), rcnt + (s[i] == ')'), t + s[i])

        l = r = 0
        for c in s:
            if c == '(':
                l += 1
            elif c == ')':
                if l:
                    l -= 1
                else:
                    r += 1
        ans = set()
        n = len(s)
        dfs(0, l, r, 0, 0, '')
        return list(ans)
```

Complexity. Time: O(2^n) in the worst case (heavily pruned in practice). Space: O(n) recursion (plus the answers).

Medium · Tree, Depth-First Search, Breadth-First Search, Hash Table, Binary Tree, Sorting

leetcode.com/problems/binary-tree-vertical-order-traversal

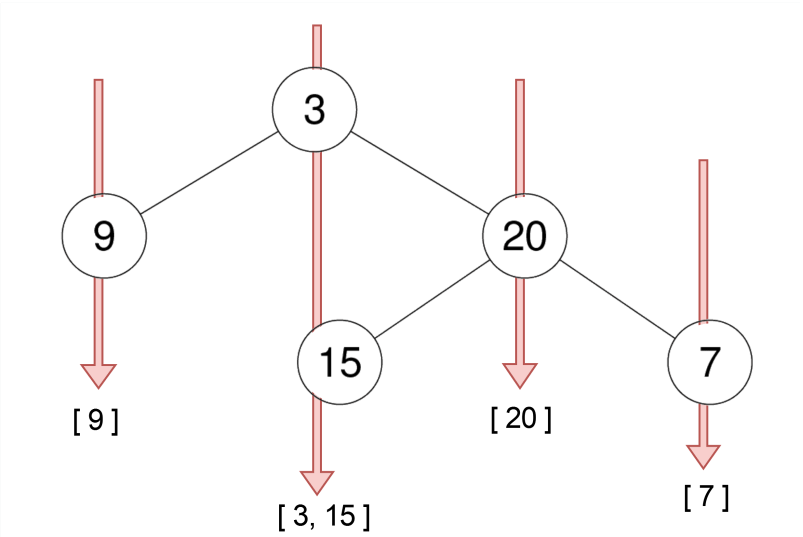
★ **TOP 10 PROBLEM** in Tree Traversal - Level Order: master this one first

PROBLEM

Given the `root` of a binary tree, return ***the vertical order traversal*** *of its nodes' values*. (i.e., from top to bottom, column by column).

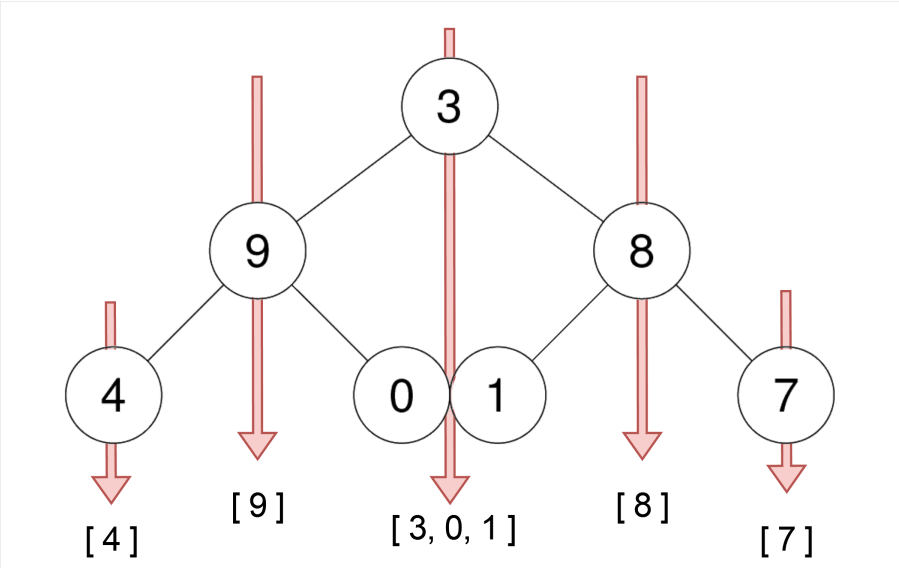
If two nodes are in the same row and column, the order should be from **left to right**.

Example 1:



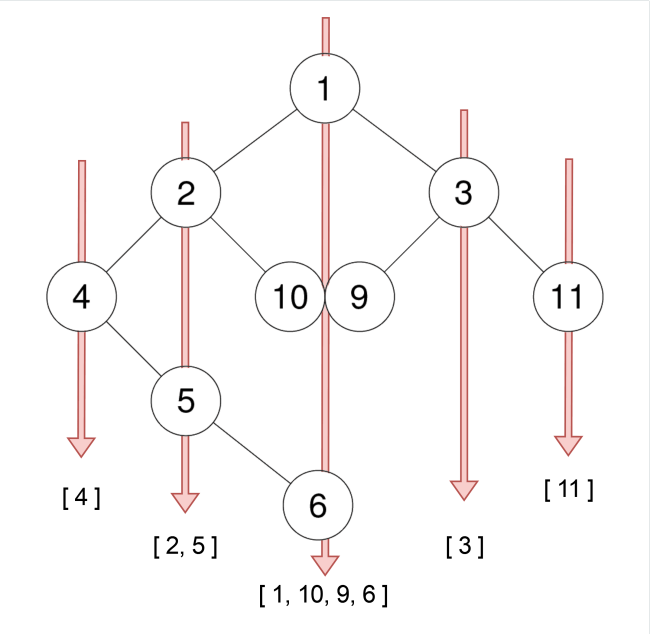
```
Input: root = [3,9,20,null,null,15,7]
Output: [[9],[3,15],[20],[7]]
```

Example 2:



```
Input: root = [3,9,8,4,0,1,7]
Output: [[4],[9],[3,0,1],[8],[7]]
```

Example 3:



```
Input: root = [1,2,3,4,10,9,11,null,5,null,null,null,null,null,null,null,6]
Output: [[4],[2,5],[1,10,9,6],[3],[11]]
```

Constraints:

- The number of nodes in the tree is in the range `[0, 100]`.
- `-100 <= Node.val <= 100`

SOLUTIONS (PYTHON 3)

Solution 1: DFS

> **How to think about it**
>
> Vertical order lists columns left to right and, within a column, top to bottom. DFS is not level order, so a column may see a deep node first. Record depth and horizontal offset, bucket by column, then sort each bucket by depth. Sorting column keys yields left-to-right order.

DFS traverses the binary tree, recording the value, depth, and horizontal offset of each node. Then sort all nodes by horizontal offset from small to large, then by depth from small to large, and finally group by horizontal offset.

The time complexity is O(nlog log n), and the space complexity is O(n). Where n is the number of nodes in the binary tree.

Python 3

```python
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def verticalOrder(self, root: Optional[TreeNode]) -> List[List[int]]:
        def dfs(root, depth, offset):
            if root is None:
                return
            d[offset].append((depth, root.val))
            dfs(root.left, depth + 1, offset - 1)
            dfs(root.right, depth + 1, offset + 1)

        d = defaultdict(list)
        dfs(root, 0, 0)
        ans = []
        for _, v in sorted(d.items()):
            v.sort(key=lambda x: x[0])
            ans.append([x[1] for x in v])
        return ans
```

Solution 2: BFS

> **How to think about it**
>
> Method 1 still sorts each column by depth. BFS visits shallower nodes first, so a column is already top-down; only column keys need sorting. Enqueue left/right with offsets -1 and +1.

A better approach to this problem should be BFS, traversing from top to bottom level by level.

The time complexity is O(nlog n), and the space complexity is O(n). Where n is the number of nodes in the binary tree.

Python 3

```python
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def verticalOrder(self, root: Optional[TreeNode]) -> List[List[int]]:
        if root is None:
            return []
        q = deque([(root, 0)])
        d = defaultdict(list)
        while q:
            for _ in range(len(q)):
                root, offset = q.popleft()
                d[offset].append(root.val)
                if root.left:
                    q.append((root.left, offset - 1))
                if root.right:
                    q.append((root.right, offset + 1))
        return [v for _, v in sorted(d.items())]
```

leetcode.com/problems/binary-tree-paths

★ **TOP 10 PROBLEM** in Tree Traversal - Pre Order: master this one first

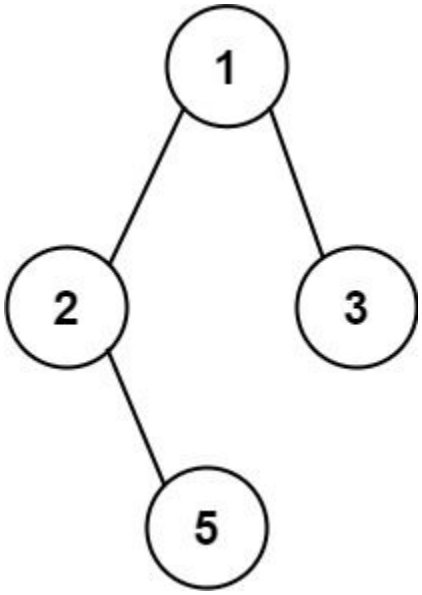
PROBLEM

You are given the `root` of a binary tree.

Return all **root-to-leaf** paths in **any order**.

A **leaf** is a node with no children.

Example 1:



```
Input: root = [1,2,3,null,5]
Output: ["1->2->5","1->3"]
```

Example 2:

```
Input: root = [1]
Output: ["1"]
```

Constraints:

- The number of nodes in the tree is in the range `[1, 100]`.
- `-100 <= Node.val <= 100`

SOLUTION (PYTHON 3)

Solution 1: DFS

How to think about it

Root-to-leaf paths are recorded while we walk. DFS appends the current value, joins the path at a leaf, and pops on the way back.

We can use depth-first search to traverse the entire binary tree. Each time, we add the current node to the path. If the current node is a leaf node, we add the entire path to the answer. Otherwise, we continue to recursively traverse the child nodes of the node. Finally, when the recursion ends and returns to the current node, we need to remove the current node

from the path.

The time complexity is $O(n^2)$, and the space complexity is O(n). Where n is the number of nodes in the binary tree.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def binaryTreePaths(self, root: Optional[TreeNode]) -> List[str]:
        def dfs(root: Optional[TreeNode]):
            if root is None:
                return
            t.append(str(root.val))
            if root.left is None and root.right is None:
                ans.append("->".join(t))
            else:
                dfs(root.left)
                dfs(root.right)
            t.pop()

        ans = []
        t = []
        dfs(root)
        return ans
```

PART 2 · TREE TRAVERSAL - PRE ORDER · PROBLEM 2 OF 7

404. Sum of Left Leaves

Easy · Tree, Depth-First Search, Breadth-First Search, Binary Tree

leetcode.com/problems/sum-of-left-leaves

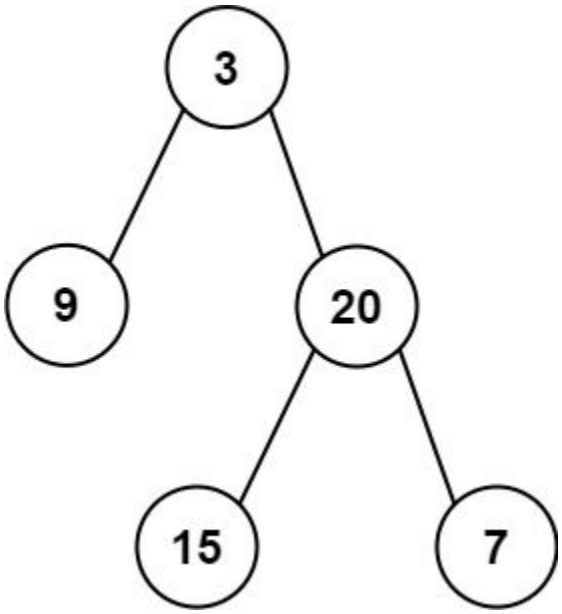
★ **TOP 10 PROBLEM** in Tree Traversal - Pre Order: master this one first

PROBLEM

Given the `root` of a binary tree, return *the sum of all left leaves.*

A **leaf** is a node with no children. A **left leaf** is a leaf that is the left child of another node.

Example 1:



```
Input: root = [3,9,20,null,null,15,7]
Output: 24
Explanation: There are two left leaves in the binary tree, with values 9 and 15 respectively.
```

Example 2:

```
Input: root = [1]
Output: 0
```

Constraints:

- The number of nodes in the tree is in the range `[1, 1000]`.
- `-1000 <= Node.val <= 1000`

SOLUTIONS (PYTHON 3)

Solution 1: Recursion

How to think about it

A left leaf is a left child with no children, not an arbitrary left subtree. Scanning a subtree from every node would revisit nodes. One recursion suffices: always walk the right child; if the left child is a leaf, add its value, otherwise recurse. An empty tree contributes 0. Treating a leaf as both children being null avoids an extra walk.

First, we check if `root` is null. If it is, we return 0.

Otherwise, we recursively call the `sumOfLeftLeaves` function to calculate the sum of all left leaves in `root`'s right subtree, and assign the result to the answer variable ans. Then we check if `root`'s left child exists. If it does, we check if it is a leaf node. If it is a leaf node, we add its value to the answer variable ans. Otherwise, we recursively call the `sumOfLeftLeaves` function to calculate the sum of all left leaves in `root`'s left subtree, and add the result to the answer variable ans.

Finally, we return the answer.

The time complexity is O(n), and the space complexity is O(n), where n is the number of nodes in the binary tree.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def sumOfLeftLeaves(self, root: Optional[TreeNode]) -> int:
        if root is None:
            return 0
        ans = self.sumOfLeftLeaves(root.right)
        if root.left:
            if root.left.left == root.left.right:
                ans += root.left.val
            else:
                ans += self.sumOfLeftLeaves(root.left)
        return ans
```

Solution 2: Stack

> **How to think about it**
>
> The same classification, implemented with an explicit stack: pop a node, add a left leaf or push the left child, and push a right child when it exists. Asymptotics are unchanged; the call stack is no longer implicit.

We can also convert the recursion in Solution 1 to iteration, using a stack to simulate the recursion process.

Similar to Solution 1, we first check if `root` is null. If it is, we return 0.

Otherwise, we initialize the answer variable ans to 0, and then initialize a stack stk and add `root` to the stack.

While the stack is not empty, we pop the top element `root` from the stack. If `root`'s left child exists, we check if it is a leaf node. If it is a leaf node, we add its value to the answer variable ans. Otherwise, we add its left child to the stack. Then we check if `root`'s right child exists. If it does, we add it to the stack.

Finally, we return the answer.

The time complexity is O(n), and the space complexity is O(n), where n is the number of nodes in the binary tree.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def sumOfLeftLeaves(self, root: Optional[TreeNode]) -> int:
        if root is None:
            return 0
        ans = 0
        stk = [root]
        while stk:
            root = stk.pop()
            if root.left:
                if root.left.left == root.left.right:
                    ans += root.left.val
                else:
                    stk.append(root.left)
            if root.right:
                stk.append(root.right)
        return ans
```

572. Subtree of Another Tree

Easy · Tree, Depth-First Search, Binary Tree, String Matching, Hash Function

leetcode.com/problems/subtree-of-another-tree

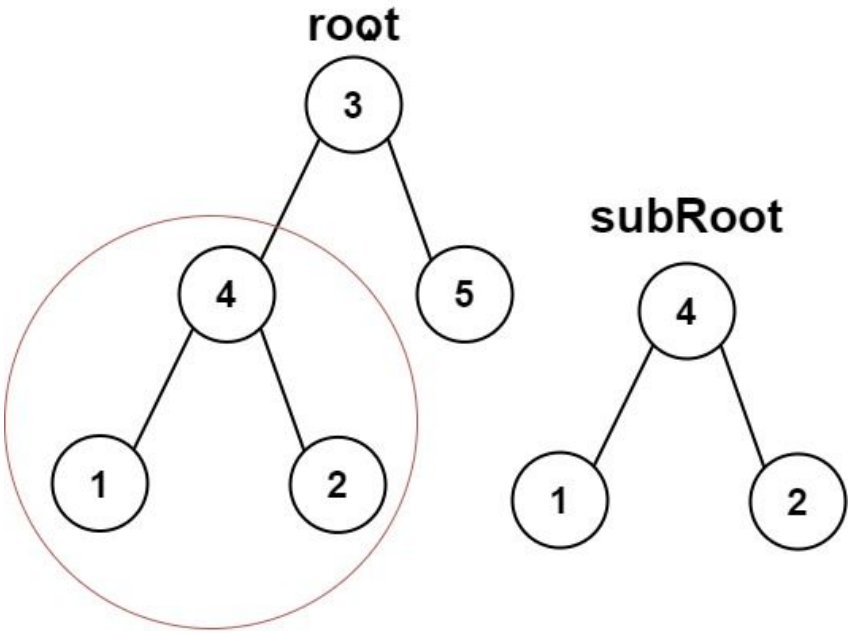
★ **TOP 10 PROBLEM** in Tree Traversal - Pre Order: master this one first

PROBLEM

Given the roots of two binary trees `root` and `subRoot`, return `true` if there is a subtree of `root` with the same structure and node values of `subRoot` and `false` otherwise.

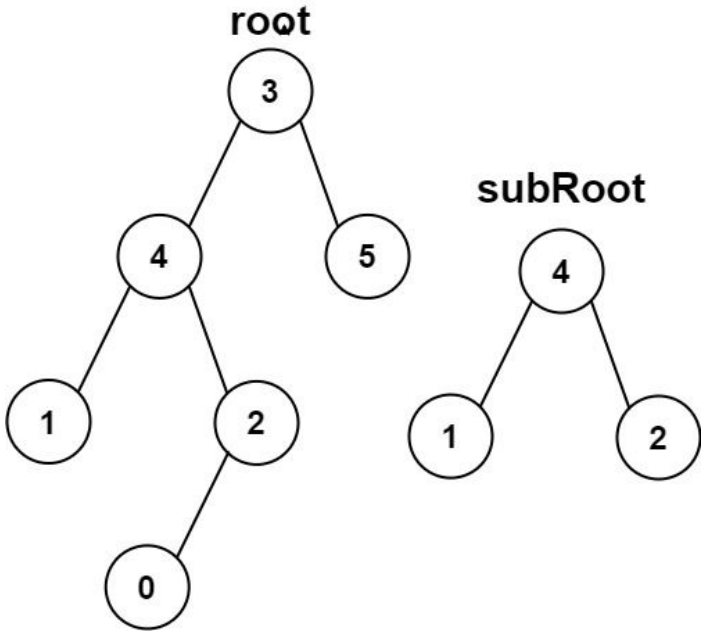
A subtree of a binary tree `tree` is a tree that consists of a node in `tree` and all of this node's descendants. The tree `tree` could also be considered as a subtree of itself.

Example 1:



```
Input: root = [3,4,5,1,2], subRoot = [4,1,2]
Output: true
```

Example 2:



```
Input: root = [3,4,5,1,2,null,null,null,null,0], subRoot = [4,1,2]
Output: false
```

Constraints:

- The number of nodes in the `root` tree is in the range `[1, 2000]`.
- The number of nodes in the `subRoot` tree is in the range `[1, 1000]`.
- -10^4 <= root.val <= 10^4
- -10^4 <= subRoot.val <= 10^4

SOLUTION (PYTHON 3)

Solution 1: DFS

> **How to think about it**
>
> Ask whether subRoot equals some subtree of root. Comparing at every node is O(mn) in the worst case and fits the limits. `same` walks two trees together. The outer DFS invokes `same` at each node and returns on the first hit. Compare the root first so mismatches exit early.

We define a helper function same(p, q) to determine whether the tree rooted at p and the tree rooted at q are identical. If the root values of the two trees are equal, and their left and right subtrees are also respectively equal, then the two trees are identical.

In the isSubtree(root, subRoot) function, we first check if root is null. If it is, we return false. Otherwise, we check if root and subRoot are identical. If they are, we return true. Otherwise, we recursively check if the left or right subtree of root contains subRoot.

The time complexity is O(n × m), and the space complexity is O(n). Here, n and m are the number of nodes in the trees root and subRoot, respectively.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def isSubtree(self, root: Optional[TreeNode], subRoot: Optional[TreeNode]) -> bool:
        def same(p: Optional[TreeNode], q: Optional[TreeNode]) -> bool:
            if p is None or q is None:
                return p is q
            return p.val == q.val and same(p.left, q.left) and same(p.right, q.right)

        if root is None:
            return False
        return (
            same(root, subRoot)
            or self.isSubtree(root.left, subRoot)
            or self.isSubtree(root.right, subRoot)
        )
```

106. Construct Binary Tree from Inorder and Postorder Traversal

Medium · Tree, Array, Hash Table, Divide and Conquer, Binary Tree

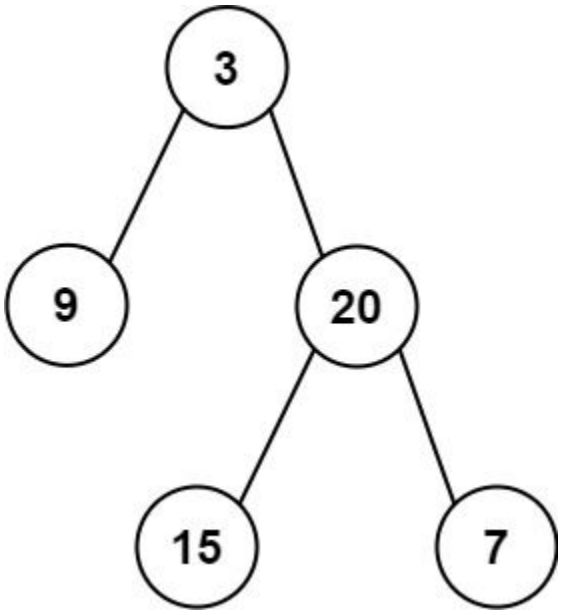
leetcode.com/problems/construct-binary-tree-from-inorder-and-postorder-traversal

★ **TOP 10 PROBLEM** in Tree Traversal - Pre Order: master this one first

PROBLEM

Given two integer arrays `inorder` and `postorder` where `inorder` is the inorder traversal of a binary tree and `postorder` is the postorder traversal of the same tree, construct and return *the binary tree*.

Example 1:



```
Input: inorder = [9,3,15,20,7], postorder = [9,15,7,20,3]
Output: [3,9,20,null,null,15,7]
```

Example 2:

```
Input: inorder = [-1], postorder = [-1]
Output: [-1]
```

Constraints:

- `1 <= inorder.length <= 3000`
- `postorder.length == inorder.length`
- `-3000 <= inorder[i], postorder[i] <= 3000`
- `inorder` and `postorder` consist of **unique** values.
- Each value of `postorder` also appears in `inorder`.
- `inorder` is **guaranteed** to be the inorder traversal of the tree.
- `postorder` is **guaranteed** to be the postorder traversal of the tree.

SOLUTION (PYTHON 3)

Solution 1: Hash Table + Recursion

How to think about it

The last postorder value is the root; inorder again splits left and right. Linear search for the root each time can be $O(n^2)$. Values are unique, so we index inorder first. The last value of the current postorder slice is the root; the count of inorder values to its left is the left-subtree size, which splits the remaining postorder into two recursive ranges.

The last node in the post-order traversal is the root node. We can find the position of the root node in the in-order traversal, and then recursively construct the left and right subtrees.

Specifically, we first use a hash table d to store the position of each node in the in-order traversal. Then we design a recursive function dfs(i, j, n), where i and j represent the starting positions of the in-order and post-order traversals, respectively, and n represents the number of nodes in the subtree. The function logic is as follows:

- If n ≤ 0, it means the subtree is empty, return a null node.
- Otherwise, take out the last node v of the post-order traversal, and then find the position k of v in the in-order traversal using the hash table d. Then the number of nodes in the left subtree is k - i, and the number of nodes in the right subtree is n - k + i - 1.
- Recursively construct the left subtree dfs(i, j, k - i) and the right subtree dfs(k + 1, j + k - i, n - k + i - 1), connect them to the root node, and finally return the root node.

The time complexity is O(n), and the space complexity is O(n). Here, n is the number of nodes in the binary tree.

Python 3

```python
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def buildTree(self, inorder: List[int], postorder: List[int]) -> Optional[TreeNode]:
        def dfs(i: int, j: int, n: int) -> Optional[TreeNode]:
            if n <= 0:
                return None
            v = postorder[j + n - 1]
            k = d[v]
            l = dfs(i, j, k - i)
            r = dfs(k + 1, j + k - i, n - k + i - 1)
            return TreeNode(v, l, r)

        d = {v: i for i, v in enumerate(inorder)}
        return dfs(0, 0, len(inorder))
```

222. Count Complete Tree Nodes

Medium · Bit Manipulation, Tree, Binary Search, Binary Tree

leetcode.com/problems/count-complete-tree-nodes

★ **TOP 10 PROBLEM** in Tree Traversal - Pre Order: master this one first

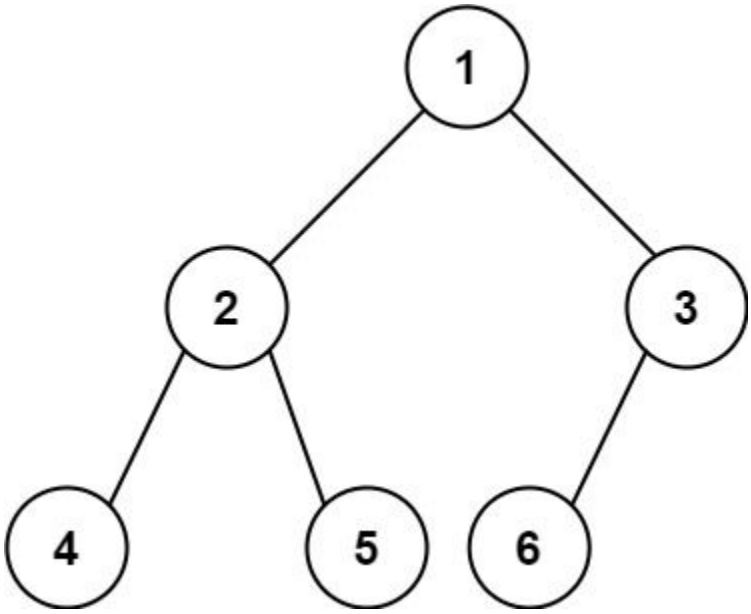
PROBLEM

Given the `root` of a **complete** binary tree, return the number of the nodes in the tree.

According to **Wikipedia**, every level, except possibly the last, is completely filled in a complete binary tree, and all nodes in the last level are as far left as possible. It can have between `1` and 2^h nodes inclusive at the last level `h`.

Design an algorithm that runs in less than `O(n)` time complexity.

Example 1:



```
Input: root = [1,2,3,4,5,6]
Output: 6
```

Example 2:

```
Input: root = []
Output: 0
```

Example 3:

```
Input: root = [1]
Output: 1
```

Constraints:

- The number of nodes in the tree is in the range `[0, 5 * 10^4]`.
- `0 <= Node.val <= 5 * 10^4`
- The tree is guaranteed to be **complete**.

SOLUTIONS (PYTHON 3)

Solution 1: Recursion

> **How to think about it**
>
> A complete tree can still be counted by ordinary recursion: the size is 1 plus the sizes of the two subtrees, visiting every node once.

We recursively traverse the entire tree and count the number of nodes.

The time complexity is O(n), and the space complexity is O(n), where n is the number of nodes in the tree.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def countNodes(self, root: Optional[TreeNode]) -> int:
        if root is None:
            return 0
        return 1 + self.countNodes(root.left) + self.countNodes(root.right)
```

Solution 2: Binary Search

> **How to think about it**
>
> The linear walk ignores that the last level is packed left. If the left and right heights match, the left subtree is perfect and contributes 2^{left} nodes (including the root), so we recurse only on the right; otherwise the right subtree is perfect and we recurse on the left. Each height walk is O(log n) and the recursion depth is O(log n), for $O(\log^2 n)$ time.

For this problem, we can also take advantage of the characteristics of a complete binary tree to design a faster algorithm.

Characteristics of a complete binary tree: leaf nodes can only appear on the bottom and second-to-bottom layers, and the leaf nodes on the bottom layer are concentrated on the left side of the tree. It should be noted that a full binary tree is definitely a complete binary tree, but a complete binary tree is not necessarily a full binary tree.

If the number of layers in a full binary tree is h, then the total number of nodes is $2^h - 1$.

We first count the heights of the left and right subtrees of root, denoted as left and right.

1. If left = right, it means that the left subtree is a full binary tree, so the total number of nodes in the left subtree is $2^{left} - 1$. Plus the root node, it is 2^{left}. Then we recursively count the right subtree.
1. If left > right, it means that the right subtree is a full binary tree, so the total number of nodes in the right subtree is $2^{right} - 1$. Plus the root node, it is 2^{right}. Then we recursively count the left subtree.

The time complexity is $O(\log^2 n)$.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def countNodes(self, root: Optional[TreeNode]) -> int:
        def depth(root):
            d = 0
            while root:
                d += 1
                root = root.left
            return d

        if root is None:
            return 0
        left, right = depth(root.left), depth(root.right)
        if left == right:
            return (1 << left) + self.countNodes(root.right)
        return (1 << right) + self.countNodes(root.left)
```

687. Longest Univalue Path

Medium · Tree, Depth-First Search, Binary Tree, Tree DP

leetcode.com/problems/longest-univalue-path

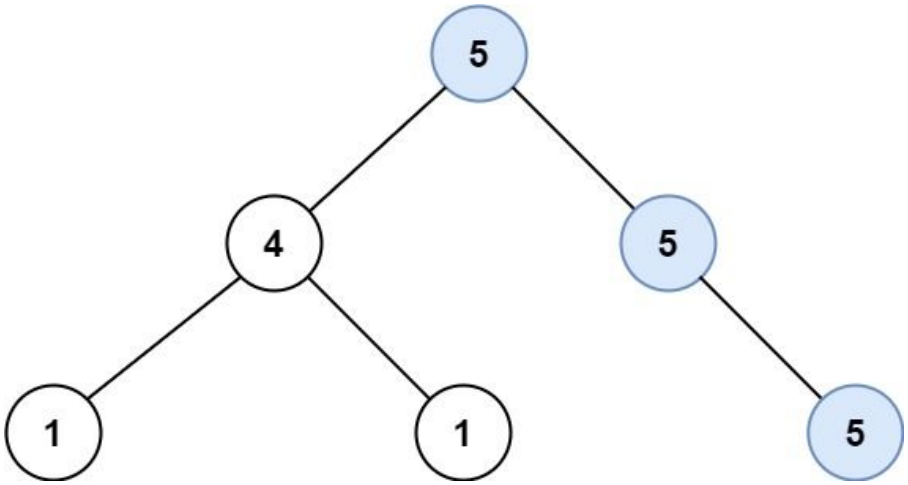
★ **TOP 10 PROBLEM** in Tree Traversal - Pre Order: master this one first

PROBLEM

Given the `root` of a binary tree, return *the length of the longest path, where each node in the path has the same value*. This path may or may not pass through the root.

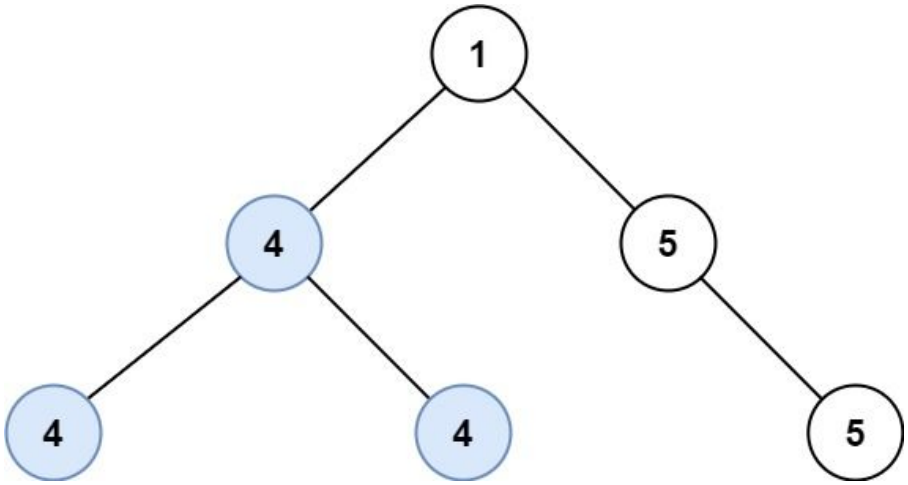
The length of the path between two nodes is represented by the number of edges between them.

Example 1:



```
Input: root = [5,4,5,1,1,null,5]
Output: 2
Explanation: The shown image shows that the longest path of the same value (i.e. 5).
```

Example 2:



```
Input: root = [1,4,5,4,4,null,5]
Output: 2
Explanation: The shown image shows that the longest path of the same value (i.e. 4).
```

Constraints:

- The number of nodes in the tree is in the range `[0, 10^4]`.

- `-1000 <= Node.val <= 1000`
- The depth of the tree will not exceed `1000`.

SOLUTION (PYTHON 3)

Solution 1: DFS

> **How to think about it**
>
> A univalue path may bend at a node and is counted in edges. Root-to-leaf walks miss a left-plus-right combination. DFS returns the longest same-value downward run: increment only if the child matches. Update the answer with l+r and return max(l,r).

We design a function dfs(root), which represents the longest univalue path length extending downward with the root node as one endpoint of the path.

In dfs(root), we first recursively call dfs(root.left) and dfs(root.right) to get two return values l and r. These two return values represent the longest univalue path lengths extending downward with the left and right children of the root node as one endpoint of the path, respectively.

If the root has a left child and root.val = root.left.val, then the longest univalue path length extending downward with the left child of the root as one endpoint of the path should be l + 1; otherwise, this length is 0. If the root has a right child and root.val = root.right.val, then the longest univalue path length extending downward with the right child of the root as one endpoint of the path should be r + 1; otherwise, this length is 0.

After recursively calling the left and right children, we update the answer to max(ans, l + r), which is the longest univalue path length passing through the root with the root as one endpoint of the path.

Finally, the dfs(root) function returns the longest univalue path length extending downward with the root as one endpoint of the path, which is max(l, r).

In the main function, we call dfs(root) to get the answer.

The time complexity is O(n), and the space complexity is O(n). Here, n is the number of nodes in the binary tree.

Python 3

```python
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def longestUnivaluePath(self, root: Optional[TreeNode]) -> int:
        def dfs(root: Optional[TreeNode]) -> int:
            if root is None:
                return 0
            l, r = dfs(root.left), dfs(root.right)
            l = l + 1 if root.left and root.left.val == root.val else 0
            r = r + 1 if root.right and root.right.val == root.val else 0
            nonlocal ans
            ans = max(ans, l + r)
            return max(l, r)

        ans = 0
        dfs(root)
        return ans
```

1026. Maximum Difference Between Node and Ancestor

Medium · Tree, Depth-First Search, Binary Tree

leetcode.com/problems/maximum-difference-between-node-and-ancestor

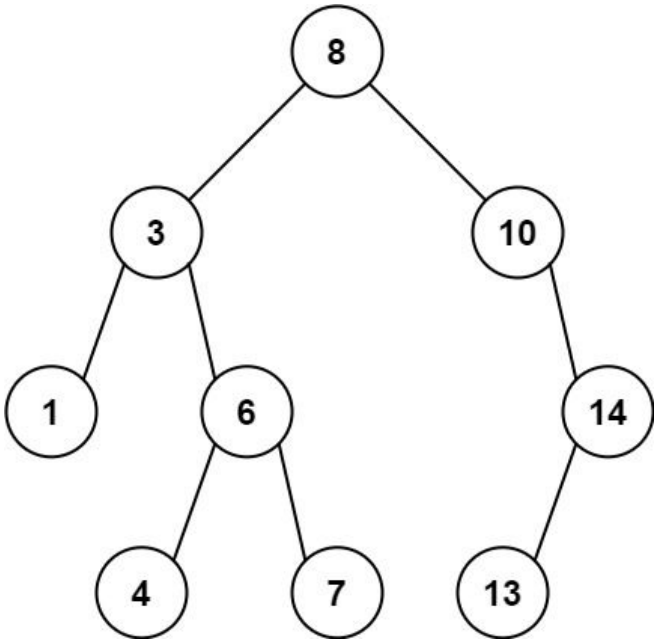
★ **TOP 10 PROBLEM** in Tree Traversal - Pre Order: master this one first

PROBLEM

Given the `root` of a binary tree, find the maximum value `v` for which there exist **different** nodes `a` and `b` where `v = |a.val - b.val|` and `a` is an ancestor of `b`.

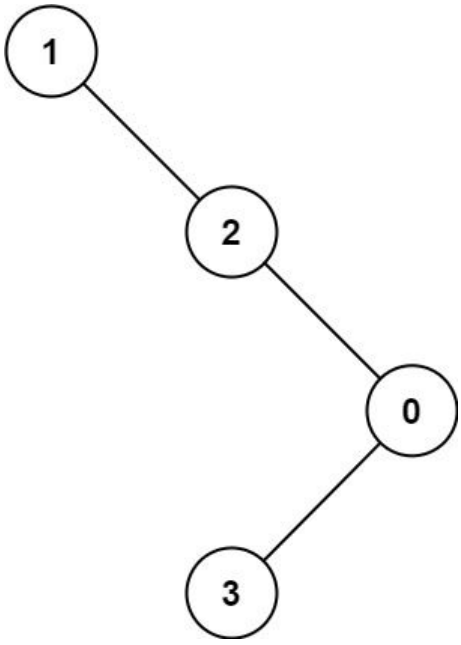
A node `a` is an ancestor of `b` if either: any child of `a` is equal to `b` or any child of `a` is an ancestor of `b`.

Example 1:



```
Input: root = [8,3,10,1,6,null,14,null,null,4,7,13]
Output: 7
Explanation: We have various ancestor-node differences, some of which are given below :
|8 - 3| = 5
|3 - 7| = 4
|8 - 1| = 7
|10 - 13| = 3
Among all possible differences, the maximum value of 7 is obtained by |8 - 1| = 7.
```

Example 2:



```
Input: root = [1,null,2,null,0,3]
Output: 3
```

Constraints:

- The number of nodes in the tree is in the range `[2, 5000]`.
- `0 <= Node.val <= 10^5`

SOLUTION (PYTHON 3)

Solution 1: DFS

> **How to think about it**
>
> Collecting every ancestor at each node repeats paths and is heavy for n≤ 5000. Only the minimum and maximum on the path matter. DFS carries (mi,mx) downward, updates the answer with |val-mi| and |val-mx|, then includes the current value in the range. One traversal of the tree is enough.

For each node, to find the maximum difference with its ancestor nodes, we only need to find the difference between the maximum and minimum values of the ancestor nodes. The maximum difference among all nodes and their ancestor nodes is the answer.

Therefore, we design a function dfs(root, mi, mx), where the current node being searched is root, the maximum value of its ancestor nodes is mx, and the minimum value is mi. The function updates the maximum difference ans.

The logic of the function dfs(root, mi, mx) is as follows:

- If root is null, return directly.
- Otherwise, we update ans = max(ans, |mi - root.val|, |mx - root.val|).
- Then update mi = min(mi, root.val), mx = max(mx, root.val), and recursively search the left and right subtrees.

In the main function, we call dfs(root, root.val, root.val), and finally return ans.

The time complexity is O(n), and the space complexity is O(n). Where n is the number of nodes in the binary tree.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def maxAncestorDiff(self, root: Optional[TreeNode]) -> int:
        def dfs(root: Optional[TreeNode], mi: int, mx: int):
            if root is None:
                return
            nonlocal ans
            ans = max(ans, abs(mi - root.val), abs(mx - root.val))
            mi = min(mi, root.val)
            mx = max(mx, root.val)
            dfs(root.left, mi, mx)
            dfs(root.right, mi, mx)

        ans = 0
        dfs(root, root.val, root.val)
        return ans
```

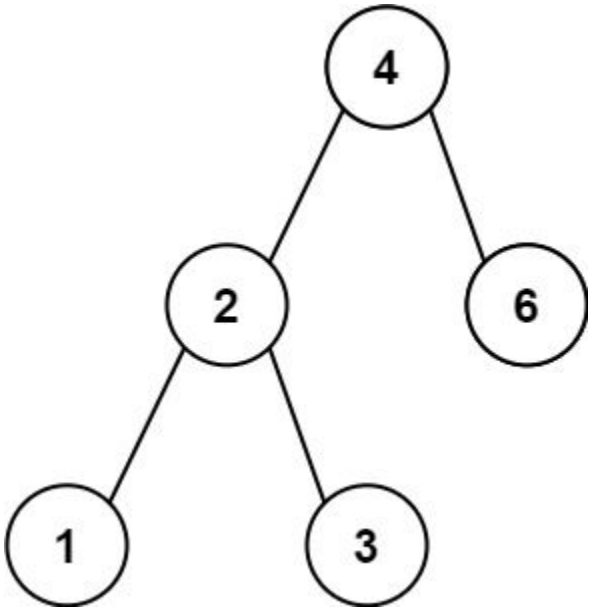
leetcode.com/problems/minimum-distance-between-bst-nodes

★ **TOP 10 PROBLEM** in Tree Traversal - In Order: master this one first

PROBLEM

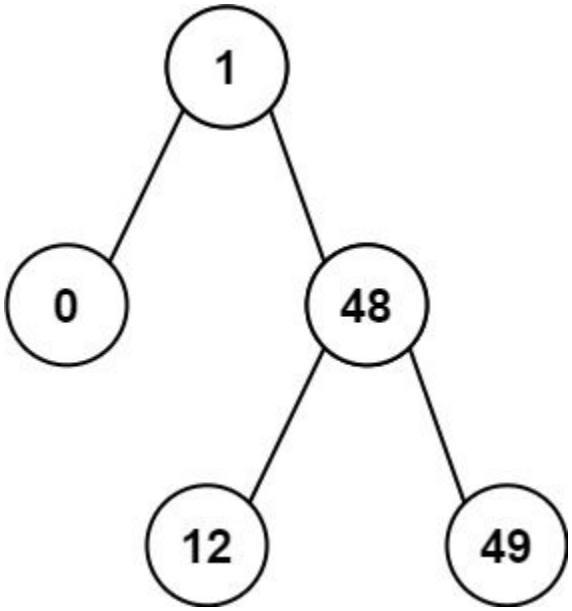
Given the `root` of a Binary Search Tree (BST), return *the minimum difference between the values of any two different nodes in the tree*.

Example 1:



```
Input: root = [4,2,6,1,3]
Output: 1
```

Example 2:



```
Input: root = [1,0,48,null,null,12,49]
Output: 1
```

Constraints:

- The number of nodes in the tree is in the range `[2, 100]`.
- `0 <= Node.val <= 10^5`

Note: This question is the same as 530: https://leetcode.com/problems/minimum-absolute-difference-in-bst/

SOLUTION (PYTHON 3)

Solution 1: Inorder Traversal

> **How to think about it**
>
> Minimum difference between any two BST values. Inorder is sorted, so the minimum lies between consecutive inorder values. Walk inorder, keep pre, and update ans by root.val-pre.

The problem requires us to find the minimum difference between the values of any two nodes. Since the inorder traversal of a binary search tree is an increasing sequence, we only need to find the minimum difference between the values of two adjacent nodes in the inorder traversal.

We can use a recursive method to implement the inorder traversal. During the process, we use a variable pre to save the value of the previous node. This way, we can calculate the minimum difference between the values of two adjacent nodes during the traversal.

The time complexity is O(n), and the space complexity is O(n). Here, n is the number of nodes in the binary search tree.

Python 3

```python
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def minDiffInBST(self, root: Optional[TreeNode]) -> int:
        def dfs(root: Optional[TreeNode]):
            if root is None:
                return
            dfs(root.left)
            nonlocal pre, ans
            ans = min(ans, root.val - pre)
            pre = root.val
            dfs(root.right)

        pre = -inf
        ans = inf
        dfs(root)
        return ans
```

leetcode.com/problems/boundary-of-binary-tree

★ **TOP 10 PROBLEM** in Tree Traversal - Post-Order: master this one first

PROBLEM

The **boundary** of a binary tree is the concatenation of the **root**, the **left boundary**, the **leaves** ordered from left-to-right, and the **reverse order** of the **right boundary**.

The **left boundary** is the set of nodes defined by the following:

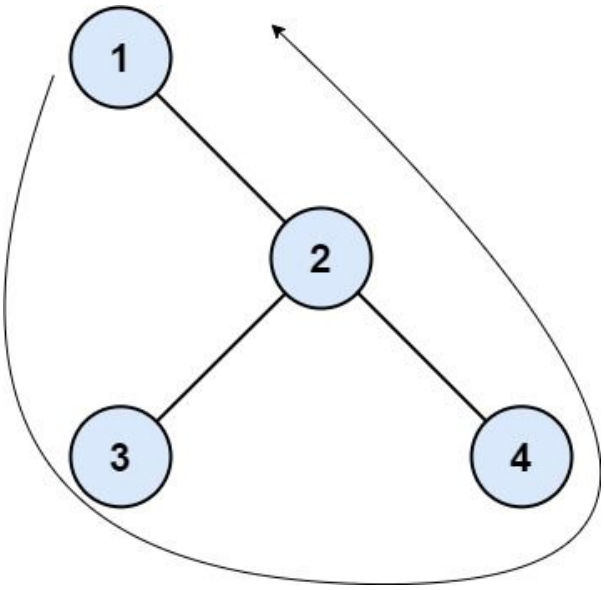
- The root node's left child is in the left boundary. If the root does not have a left child, then the left boundary is **empty**.
- If a node is in the left boundary and has a left child, then the left child is in the left boundary.
- If a node is in the left boundary, has **no** left child, but has a right child, then the right child is in the left boundary.
- The leftmost leaf is **not** in the left boundary.

The **right boundary** is similar to the **left boundary**, except it is the right side of the root's right subtree. Again, the leaf is **not** part of the **right boundary**, and the **right boundary** is empty if the root does not have a right child.

The **leaves** are nodes that do not have any children. For this problem, the root is **not** a leaf.

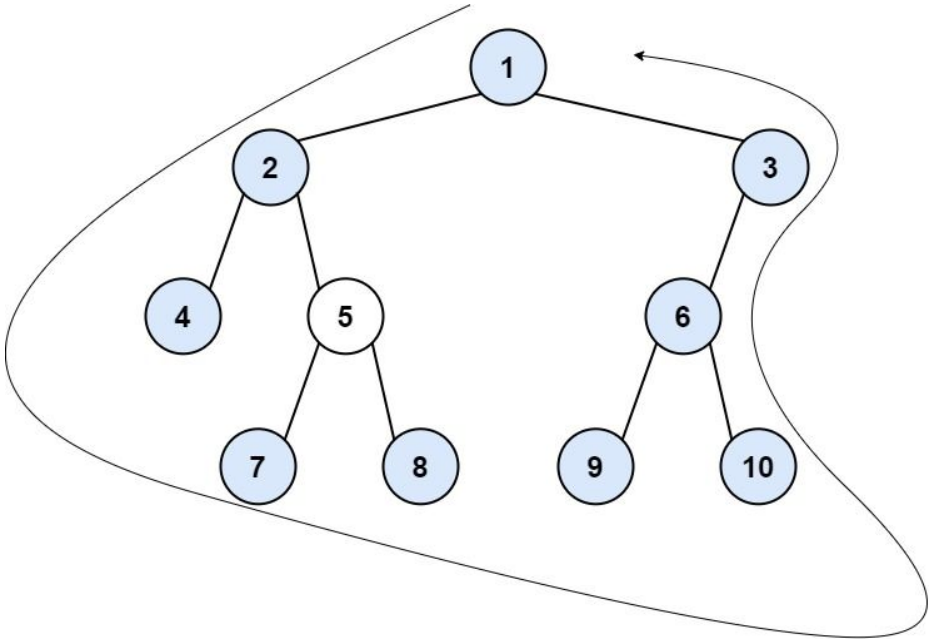
Given the `root` of a binary tree, return *the values of its **boundary***.

Example 1:



```
Input: root = [1,null,2,3,4]
Output: [1,3,4,2]
Explanation:
- The left boundary is empty because the root does not have a left child.
- The right boundary follows the path starting from the root's right child 2 -> 4.
  4 is a leaf, so the right boundary is [2].
- The leaves from left to right are [3,4].
Concatenating everything results in [1] + [] + [3,4] + [2] = [1,3,4,2].
```

Example 2:



```
Input: root = [1,2,3,4,5,6,null,null,null,7,8,9,10]
Output: [1,2,4,7,8,9,10,6,3]
Explanation:
- The left boundary follows the path starting from the root's left child 2 -> 4.
  4 is a leaf, so the left boundary is [2].
- The right boundary follows the path starting from the root's right child 3 -> 6 -> 10.
  10 is a leaf, so the right boundary is [3,6], and in reverse order is [6,3].
- The leaves from left to right are [4,7,8,9,10].
Concatenating everything results in [1] + [2] + [4,7,8,9,10] + [6,3] = [1,2,4,7,8,9,10,6,3].
```

Constraints:

- The number of nodes in the tree is in the range $[1, 10^4]$.
- $-1000 <= Node.val <= 1000$

SOLUTION (PYTHON 3)

Solution 1: DFS

> **How to think about it**
>
> The boundary is the left side, the leaves, and the right side in counterclockwise order. The root is listed once and leaves must not repeat. One mixed walk struggles with direction and deduplication. Three DFS passes: left edge prefers left (else right) and skips leaves; a second pass collects leaves; the right edge prefers right and is reversed. The root is emitted first if it is not a leaf. A flag i selects the role.

First, if the tree has only one node, we directly return a list with the value of that node.

Otherwise, we can use depth-first search (DFS) to find the left boundary, leaf nodes, and right boundary of the binary tree.

Specifically, we can use a recursive function dfs to find these three parts. In the dfs function, we need to pass in a list nums, a node root, and an integer i, where nums is used to store the current part's node values, and root and i represent the current node and the type of the current part (left boundary, leaf nodes, or right boundary), respectively.

The function implementation is as follows:

- If root is null, then directly return.
- If i = 0, we need to find the left boundary. If root is not a leaf node, we add the value of root to nums. If root has a left child, we recursively call the dfs function, passing in nums, the left child of root, and i. Otherwise, we recursively call the dfs function, passing in nums, the right child of root, and i.

- If i = 1, we need to find the leaf nodes. If root is a leaf node, we add the value of root to nums. Otherwise, we recursively call the dfs function, passing in nums, the left child of root and i, as well as nums, the right child of root and i.
- If i = 2, we need to find the right boundary. If root is not a leaf node, we add the value of root to nums. If root has a right child, we recursively call the dfs function, passing in nums, the right child of root, and i. Otherwise, we recursively call the dfs function, passing in nums, the left child of root, and i.

We call the dfs function separately to find the left boundary, leaf nodes, and right boundary, and then concatenate these three parts to get the answer.

The time complexity is O(n) and the space complexity is O(n), where n is the number of nodes in the binary tree.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def boundaryOfBinaryTree(self, root: Optional[TreeNode]) -> List[int]:
        def dfs(nums: List[int], root: Optional[TreeNode], i: int):
            if root is None:
                return
            if i == 0:
                if root.left != root.right:
                    nums.append(root.val)
                    if root.left:
                        dfs(nums, root.left, i)
                    else:
                        dfs(nums, root.right, i)
            elif i == 1:
                if root.left == root.right:
                    nums.append(root.val)
                else:
                    dfs(nums, root.left, i)
                    dfs(nums, root.right, i)
            else:
                if root.left != root.right:
                    nums.append(root.val)
                    if root.right:
                        dfs(nums, root.right, i)
                    else:
                        dfs(nums, root.left, i)

        ans = [root.val]
        if root.left == root.right:

652. Find Duplicate Subtrees

Medium · Tree, Depth-First Search, Hash Table, Binary Tree

leetcode.com/problems/find-duplicate-subtrees

★ **TOP 10 PROBLEM** in Tree Traversal - Post-Order: master this one first

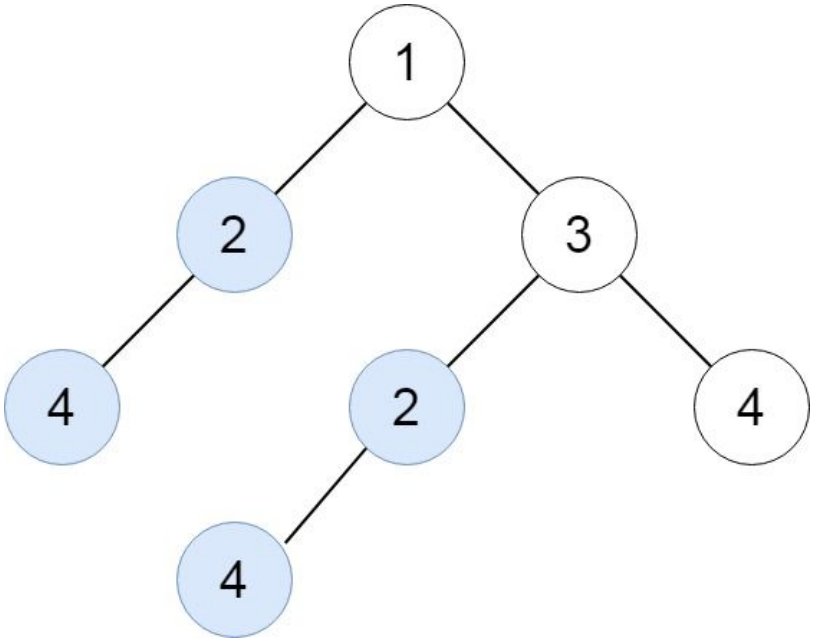
PROBLEM

Given the `root` of a binary tree, return all **duplicate subtrees**.

For each kind of duplicate subtrees, you only need to return the root node of any **one** of them.

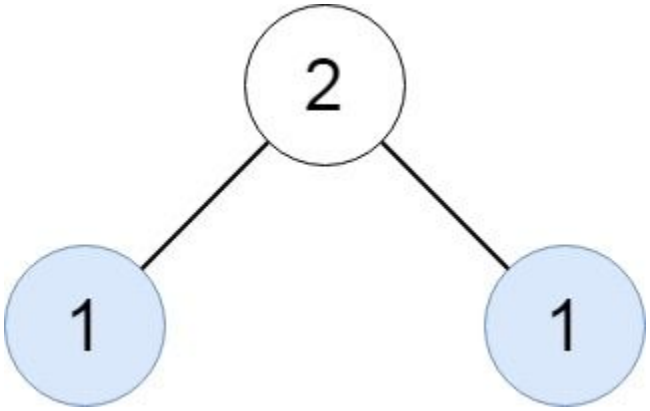
Two trees are **duplicate** if they have the **same structure** with the **same node values**.

Example 1:



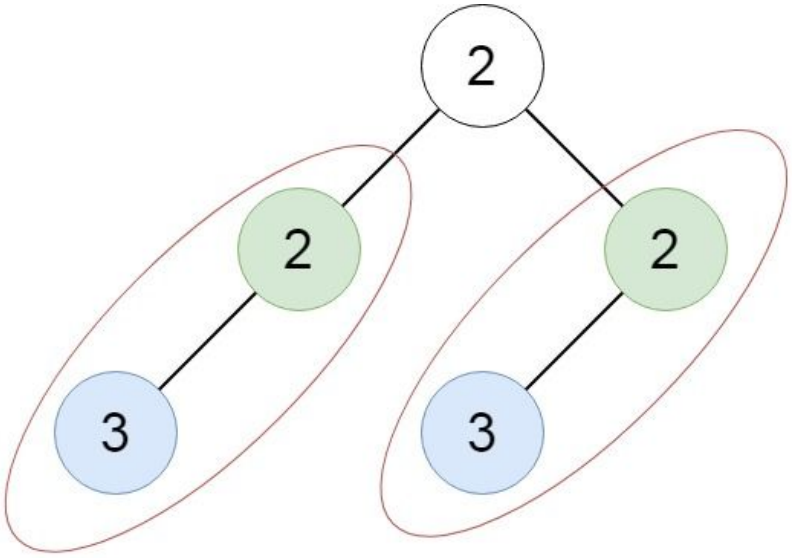
```
Input: root = [1,2,3,4,null,2,4,null,null,4]
Output: [[2,4],[4]]
```

Example 2:



```
Input: root = [2,1,1]
Output: [[1]]
```

Example 3:



```
Input: root = [2,2,2,3,null,3,null]
Output: [[2,3],[3]]
```

Constraints:

- The number of the nodes in the tree will be in the range `[1, 5000]`
- `-200 <= Node.val <= 200`

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Duplicate subtrees share structure and values. Pairwise comparison is quadratic. Serialize each subtree in postorder and count the strings. When a serialization first reaches 2, record that root so each shape is reported once.

Python 3

```python
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def findDuplicateSubtrees(
        self, root: Optional[TreeNode]
    ) -> List[Optional[TreeNode]]:
        def dfs(root):
            if root is None:
                return '#'
            v = f'{root.val},{dfs(root.left)},{dfs(root.right)}'
            counter[v] += 1
            if counter[v] == 2:
                ans.append(root)
            return v

        ans = []
        counter = Counter()
        dfs(root)
        return ans
```

979. Distribute Coins in Binary Tree

Medium · Tree, Depth-First Search, Binary Tree, Tree DP

leetcode.com/problems/distribute-coins-in-binary-tree

★ **TOP 10 PROBLEM** in Tree Traversal - Post-Order: master this one first

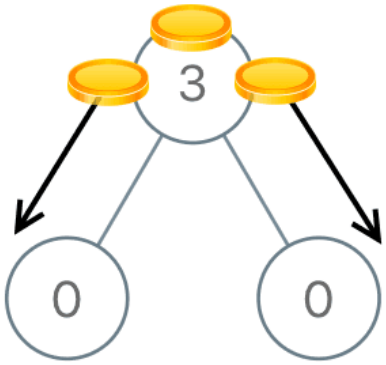
PROBLEM

You are given the `root` of a binary tree with `n` nodes where each `node` in the tree has `node.val` coins. There are `n` coins in total throughout the whole tree.

In one move, we may choose two adjacent nodes and move one coin from one node to another. A move may be from parent to child, or from child to parent.

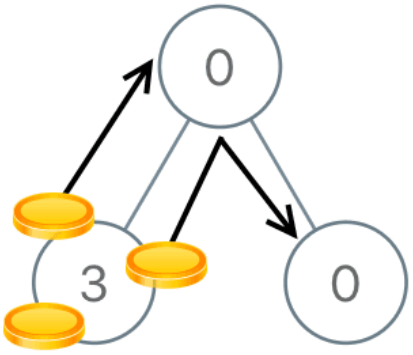
Return *the **minimum** number of moves required to make every node have **exactly** one coin*.

Example 1:



```
Input: root = [3,0,0]
Output: 2
Explanation: From the root of the tree, we move one coin to its left child, and one coin to its right child.
```

Example 2:



```
Input: root = [0,3,0]
Output: 3
Explanation: From the left child of the root, we move two coins to the root [taking two moves]. Then,
we move one coin from the root of the tree to the right child.
```

Constraints:

- The number of nodes in the tree is `n`.
- `1 <= n <= 100`
- `0 <= Node.val <= n`
- The sum of all `Node.val` is `n`.

SOLUTION (PYTHON 3)

Solution 1: DFS

> **How to think about it**
>
> Moving one coin across an edge counts as one step, until every node has exactly one coin. Routing globally is messy, yet a subtree's surplus must cross the edge to its parent: surplus =coins-nodes, and its absolute value is the traffic on that edge. DFS adds the absolute left and right surpluses and returns the combined surplus.

We define a function dfs(node), which represents the coin overload in the subtree rooted at node, i.e., the number of coins minus the number of nodes. If dfs(node) is positive, it means the subtree has more coins than nodes, and the excess coins need to be moved out of the subtree; if dfs(node) is negative, it means the subtree has fewer coins than nodes, and the shortfall needs to be moved into the subtree.

In the function dfs(node), we first traverse the left and right subtrees to obtain the coin overload left and right of the left and right subtrees, respectively. Then, the current number of moves needs to be increased by |left| + |right|, which means moving the coins from the left and right subtrees to the current node. After that, we return the coin overload of the entire subtree, which is left + right + node.val - 1.

Finally, we return the number of moves.

The time complexity is O(n), and the space complexity is O(h). Here, n and h respectively represent the number of nodes and the height of the binary tree.

Python 3

```python
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def distributeCoins(self, root: Optional[TreeNode]) -> int:
        def dfs(root):
            if root is None:
                return 0
            left, right = dfs(root.left), dfs(root.right)
            nonlocal ans
            ans += abs(left) + abs(right)
            return left + right + root.val - 1

        ans = 0
        dfs(root)
        return ans
```

1110. Delete Nodes And Return Forest

Medium · Tree, Depth-First Search, Array, Hash Table, Binary Tree

leetcode.com/problems/delete-nodes-and-return-forest

★ **TOP 10 PROBLEM** in Tree Traversal - Post-Order: master this one first

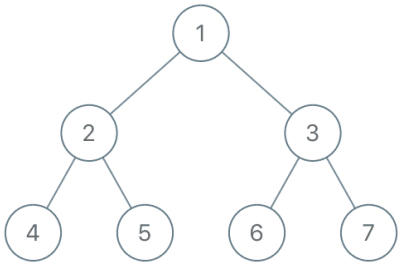
PROBLEM

Given the `root` of a binary tree, each node in the tree has a distinct value.

After deleting all nodes with a value in `to_delete`, we are left with a forest (a disjoint union of trees).

Return the roots of the trees in the remaining forest. You may return the result in any order.

Example 1:



```
Input: root = [1,2,3,4,5,6,7], to_delete = [3,5]
Output: [[1,2,null,4],[6],[7]]
```

Example 2:

```
Input: root = [1,2,4,null,3], to_delete = [3]
Output: [[1,2,4]]
```

Constraints:

- The number of nodes in the given tree is at most `1000`.
- Each node has a distinct value between `1` and `1000`.
- `to_delete.length <= 1000`
- `to_delete` contains distinct values between `1` and `1000`.

SOLUTIONS (PYTHON 3)

Solution 1: DFS

How to think about it

Deleting nodes splits the tree into a forest. A new root is a surviving node whose parent was deleted (or the original root if it survives). A post-order DFS processes both children first, then deletes the current node if required, promoting any surviving children to new roots. A hash set makes the delete-test expected constant time. If the original root survives, it is appended last.

First, we use a hash table or an array of length 1001, `s`, to record all nodes that need to be deleted.

Next, we design a function `dfs(root)` that returns the root of the subtree with `root` as the root after deleting all nodes that need to be deleted. The execution logic of the function `dfs(root)` is as follows:

- If `root` is null, we return null;
- Otherwise, we recursively execute `dfs(root.left)` and `dfs(root.right)`, and assign the return values to `root.left` and `root.right` respectively. If `root` does not need to be deleted, we return `root`; if `root` needs to be

deleted, we check whether `root.left` and `root.right` are null. If they are not null, we add them to the answer array; finally, we return null.

In the main function, we call `dfs(root)`. If the result is not null, it means that the root node does not need to be deleted, and we add the root node to the answer array. Finally, we return the answer array.

The time complexity is O(n), and the space complexity is O(n). Here, n is the number of nodes in the tree.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def delNodes(
        self, root: Optional[TreeNode], to_delete: List[int]
    ) -> List[TreeNode]:
        def dfs(root: Optional[TreeNode]) -> Optional[TreeNode]:
            if root is None:
                return None
            root.left, root.right = dfs(root.left), dfs(root.right)
            if root.val not in s:
                return root
            if root.left:
                ans.append(root.left)
            if root.right:
                ans.append(root.right)
            return None

        s = set(to_delete)
        ans = []
        if dfs(root):
            ans.append(root)
        return ans
```

Solution 2: BFS

> **How to think about it**
>
> Method 1 relies on the recursion stack for post-order deletion. BFS walks top-down: sever a child that must be deleted, and if the current node is deleted, record its still-linked children as new roots. Level order finishes the cuts without a return value; the original root is appended if it survives.

Python 3 (written for this guide: the doocs page has no Python 3 version of this solution)

```python
class Solution:
    def delNodes(self, root: Optional[TreeNode], to_delete: List[int]) -> List[TreeNode]:
        if not root:
            return []
        gone = set(to_delete)
        forest = []
        level = [root]
        while level:
            next_level = []
            for node in level:
                if node.left:
                    next_level.append(node.left)
                    if node.left.val in gone:
                        node.left = None
                if node.right:
                    next_level.append(node.right)
                    if node.right.val in gone:
                        node.right = None
                if node.val in gone:                  # the children of a deleted node become roots
                    if node.left:
                        forest.append(node.left)
                    if node.right:
                        forest.append(node.right)
            level = next_level
        if root.val not in gone:
            forest.append(root)
        return forest
```

Complexity. Time: O(n). Space: O(w), w = widest level.

leetcode.com/problems/inorder-successor-in-bst

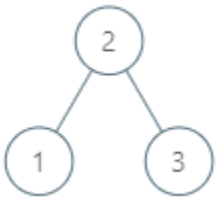
★ **TOP 10 PROBLEM** in BST / Ordered Set: master this one first

PROBLEM

Given the `root` of a binary search tree and a node `p` in it, return *the in-order successor of that node in the BST*. If the given node has no in-order successor in the tree, return `null`.

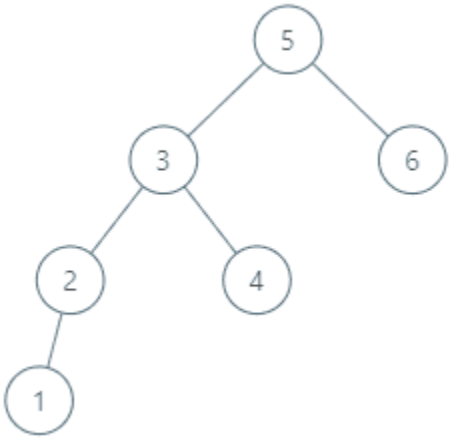
The successor of a node `p` is the node with the smallest key greater than `p.val`.

Example 1:



```
Input: root = [2,1,3], p = 1
Output: 2
Explanation: 1's in-order successor node is 2. Note that both p and the return value is of TreeNode type.
```

Example 2:



```
Input: root = [5,3,6,2,4,null,null,1], p = 6
Output: null
Explanation: There is no in-order successor of the current node, so the answer is null.
```

Constraints:

- The number of nodes in the tree is in the range `[1, 10^4]`.
- `-10^5 <= Node.val <= 10^5`
- All Nodes will have unique values.

SOLUTION (PYTHON 3)

Solution 1: Binary Search

> **How to think about it**
>
> The inorder successor is the smallest key greater than p. On a BST we walk as in binary search: if the current key is larger it is a candidate and we go left; otherwise we go right. The last candidate on that path is the successor, in time proportional to the height.

The in-order traversal of a binary search tree is an ascending sequence, so we can use the binary search method.

The in-order successor node of a binary search tree node p satisfies:

1. The value of the in-order successor node is greater than the value of node p.
2. The in-order successor is the node with the smallest value among all nodes greater than p.

Therefore, for the current node root, if root.val > p.val, then root could be the in-order successor of p. We record root as ans and then search the left subtree, i.e., root = root.left. If root.val ≤ p.val, then root cannot be the in-order successor of p, and we search the right subtree, i.e., root = root.right.

The time complexity is O(h), where h is the height of the binary search tree. The space complexity is O(1).

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, x):
#         self.val = x
#         self.left = None
#         self.right = None

class Solution:
    def inorderSuccessor(self, root: TreeNode, p: TreeNode) -> Optional[TreeNode]:
        ans = None
        while root:
            if root.val > p.val:
                ans = root
                root = root.left
            else:
                root = root.right
        return ans
```

333. Largest BST Subtree

Medium · Tree, Depth-First Search, Binary Search Tree, Dynamic Programming, Binary Tree, Tree DP

leetcode.com/problems/largest-bst-subtree

★ **TOP 10 PROBLEM** in BST / Ordered Set: master this one first

PROBLEM

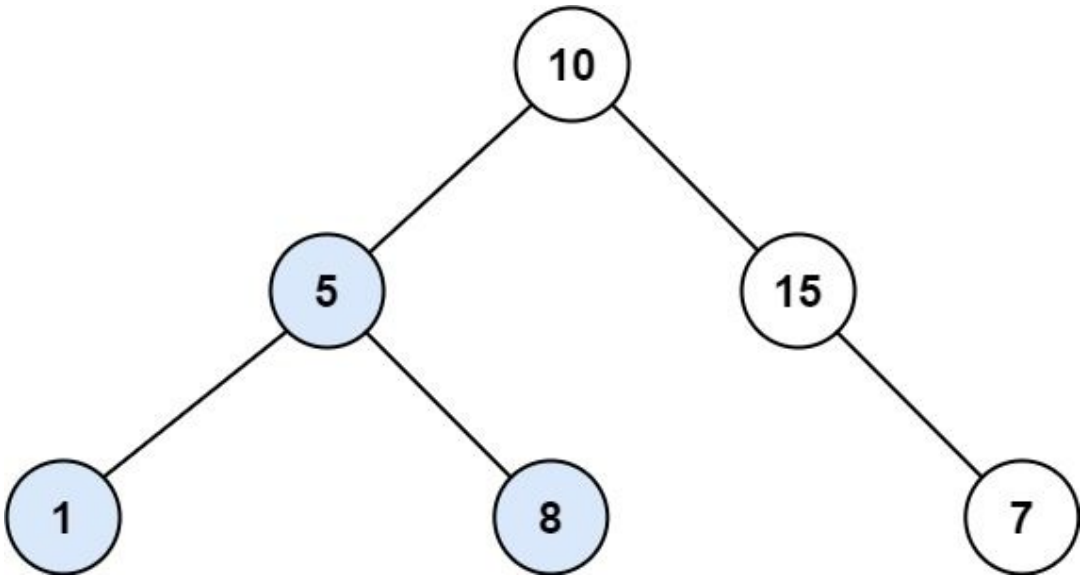
Given the root of a binary tree, find the largest subtree, which is also a Binary Search Tree (BST), where the largest means subtree has the largest number of nodes.

A **Binary Search Tree (BST)** is a tree in which all the nodes follow the below-mentioned properties:

- The left subtree values are less than the value of their parent (root) node's value.
- The right subtree values are greater than the value of their parent (root) node's value.

Note: A subtree must include all of its descendants.

Example 1:



```
Input: root = [10,5,15,1,8,null,7]
Output: 3
Explanation: The Largest BST Subtree in this case is the highlighted one. The return value is the
subtree's size, which is 3.
```

Example 2:

```
Input: root = [4,2,7,2,3,5,null,2,null,null,null,null,null,1]
Output: 2
```

Constraints:

- The number of nodes in the tree is in the range `[0, 10^4]`.
- `-10^4 <= Node.val <= 10^4`

Follow up: Can you figure out ways to solve it with `O(n)` time complexity?

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Find the size of the largest BST subtree. Validating a BST at every node repeats work. A subtree is a BST iff both sides are BSTs and the root sits between their extrema. Postorder returns (min,max,size). If left-max < root < right-min, merge sizes and update the answer; otherwise return sentinels (-∞,∞,0) so ancestors cannot absorb it. An empty tree returns (∞,-∞,0) so a leaf succeeds.

Python 3

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def largestBSTSubtree(self, root: Optional[TreeNode]) -> int:
        def dfs(root):
            if root is None:
                return inf, -inf, 0
            lmi, lmx, ln = dfs(root.left)
            rmi, rmx, rn = dfs(root.right)

426. Convert Binary Search Tree to Sorted Doubly Linked List

Medium · Stack, Tree, Depth-First Search, Binary Search Tree, Linked List, Binary Tree, Doubly-Linked List

leetcode.com/problems/convert-binary-search-tree-to-sorted-doubly-linked-list

★ **TOP 10 PROBLEM** in BST / Ordered Set: master this one first

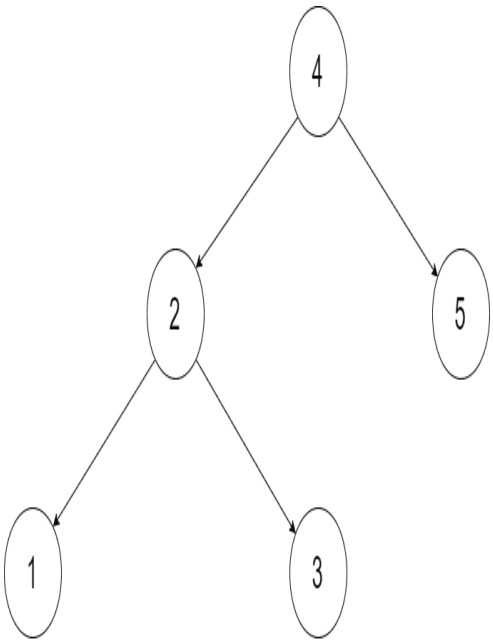
PROBLEM

Convert a **Binary Search Tree** to a sorted **Circular Doubly-Linked List** in place.

You can think of the left and right pointers as synonymous to the predecessor and successor pointers in a doubly-linked list. For a circular doubly linked list, the predecessor of the first element is the last element, and the successor of the last element is the first element.

We want to do the transformation **in place**. After the transformation, the left pointer of the tree node should point to its predecessor, and the right pointer should point to its successor. You should return the pointer to the smallest element of the linked list.

Example 1:



```
Input: root = [4,2,5,1,3]

Output: [1,2,3,4,5]

Explanation: The figure below shows the transformed BST. The solid line indicates the successor
relationship, while the dashed line means the predecessor relationship.
```

Example 2:

```
Input: root = [2,1,3]
Output: [1,2,3]
```

Constraints:

- The number of nodes in the tree is in the range `[0, 2000]`.
- `-1000 <= Node.val <= 1000`
- All the values of the tree are **unique**.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

In-order traversal of a BST is sorted. Collecting nodes into an array then wiring them uses extra memory. The problem asks for an in-place circular list, reusing left/right as pred/succ. During in-order, link prev with the current node and remember the first node as head. Afterwards connect head with the last node to close the circle. Left–root–right makes the link order match the sorted sequence; a null prev identifies the head.

Python 3

```
"""
# Definition for a Node.
class Node:
    def __init__(self, val, left=None, right=None):
        self.val = val
        self.left = left
        self.right = right
"""

class Solution:
    def treeToDoublyList(self, root: 'Optional[Node]') -> 'Optional[Node]':
        def dfs(root):
            if root is None:
                return
            nonlocal prev, head
            dfs(root.left)
            if prev:
                prev.right = root
                root.left = prev
            else:
                head = root
            prev = root
            dfs(root.right)

        if root is None:
            return None
        head = prev = None
        dfs(root)
        prev.right = head
        head.left = prev
        return head
```

Complexity. Time: O(n). Space: O(h).

510. Inorder Successor in BST II

Medium · Tree, Binary Search Tree, Binary Tree

leetcode.com/problems/inorder-successor-in-bst-ii

★ **TOP 10 PROBLEM** in BST / Ordered Set: master this one first

PROBLEM

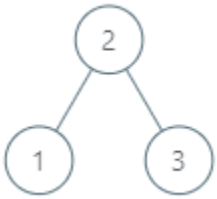
Given a `node` in a binary search tree, return *the in-order successor of that node in the BST*. If that node has no in-order successor, return `null`.

The successor of a `node` is the node with the smallest key greater than `node.val`.

You will have direct access to the node but not to the root of the tree. Each node will have a reference to its parent node. Below is the definition for `Node`:

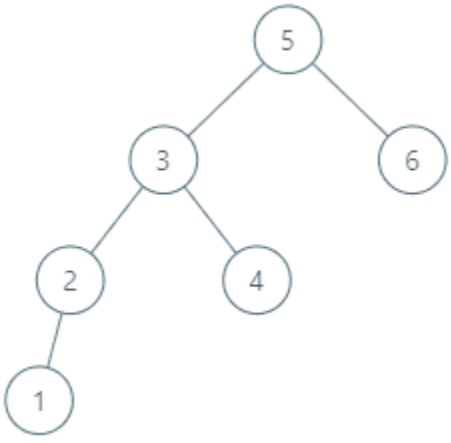
```
class Node {
    public int val;
    public Node left;
    public Node right;
    public Node parent;
}
```

Example 1:



```
Input: tree = [2,1,3], node = 1
Output: 2
Explanation: 1's in-order successor node is 2. Note that both the node and the return value is of Node type.
```

Example 2:



```
Input: tree = [5,3,6,2,4,null,null,1], node = 6
Output: null
Explanation: There is no in-order successor of the current node, so the answer is null.
```

Constraints:

- The number of nodes in the tree is in the range `[1, 10^4]`.
- `-10^5 <= Node.val <= 10^5`
- All Nodes will have unique values.

Follow up: Could you solve it without looking up any of the node's values?

SOLUTION (PYTHON 3)

Solution 1: Case Discussion

> **How to think about it**
>
> The usual inorder successor walks from the root. Here we only have a parent pointer, not the tree root. There are two cases: if a right child exists, the successor is the leftmost node of that subtree; otherwise climb parents until the node is a left child, and that parent is the successor. Both walks follow a single chain.

If the `node` has a right subtree, then the in-order successor of `node` is the leftmost node in the right subtree.

If the `node` does not have a right subtree, then if `node` is the right child of its parent, we continue to search upwards until the parent of the node is null, or the node is the left child of its parent. In this case, the parent node is the in-order successor.

The time complexity is O(h), where h is the height of the binary tree. The space complexity is O(1).

Python 3

```
"""
# Definition for a Node.
class Node:
    def __init__(self, val):
        self.val = val
        self.left = None
        self.right = None
        self.parent = None
"""

class Solution:
    def inorderSuccessor(self, node: 'Node') -> 'Optional[Node]':
        if node.right:
            node = node.right
            while node.left:
                node = node.left
            return node
        while node.parent and node.parent.right is node:
            node = node.parent
        return node.parent
```

1233. Remove Sub-Folders from the Filesystem

Medium · Depth-First Search, Trie, Array, String

leetcode.com/problems/remove-sub-folders-from-the-filesystem

★ **TOP 10 PROBLEM** in Tries: master this one first

PROBLEM

Given a list of folders `folder`, return *the folders after removing all **sub-folders** in those folders*. You may return the answer in **any order**.

If a `folder[i]` is located within another `folder[j]`, it is called a **sub-folder** of it. A sub-folder of `folder[j]` must start with `folder[j]`, followed by a `"/"`. For example, `"/a/b"` is a sub-folder of `"/a"`, but `"/b"` is not a sub-folder of `"/a/b/c"`.

The format of a path is one or more concatenated strings of the form: `'/'` followed by one or more lowercase English letters.

- For example, `"/leetcode"` and `"/leetcode/problems"` are valid paths while an empty string and `"/"` are not.

Example 1:

```
Input: folder = ["/a","/a/b","/c/d","/c/d/e","/c/f"]
Output: ["/a","/c/d","/c/f"]
Explanation: Folders "/a/b" is a subfolder of "/a" and "/c/d/e" is inside of folder "/c/d" in our
filesystem.
```

Example 2:

```
Input: folder = ["/a","/a/b/c","/a/b/d"]
Output: ["/a"]
Explanation: Folders "/a/b/c" and "/a/b/d" will be removed because they are subfolders of "/a".
```

Example 3:

```
Input: folder = ["/a/b/c","/a/b/ca","/a/b/d"]
Output: ["/a/b/c","/a/b/ca","/a/b/d"]
```

Constraints:

- `1 <= folder.length <= 4 * 10^4`
- `2 <= folder[i].length <= 100`
- `folder[i]` contains only lowercase letters and `'/'`.
- `folder[i]` always starts with the character `'/'`.
- Each folder name is **unique**.

SOLUTIONS (PYTHON 3)

Solution 1: Sorting

How to think about it

A subfolder is lexicographically after its parent and starts with the parent path plus /. n reaches 4× 10^4, so pairwise prefix tests are too slow. After sorting we only compare with the last kept folder: a descendant is dropped, otherwise the path is a new root. Sorting turns parent-child into an adjacent-prefix relation, so one scan suffices.

First, we sort the array `folder` in lexicographical order, then traverse the array. For the current folder f we are traversing, if its length is greater than or equal to the length of the last folder in the answer array, and its prefix includes the last folder in the answer array plus a `/`, then f is a subfolder of the last folder in the answer array, and we don't need to add it to the

answer array. Otherwise, we add f to the answer array.

After the traversal ends, the folders in the answer array are the answer required by the problem.

The time complexity is O(n × log n × m), and the space complexity is O(m). Where n and m are the length of the array `folder` and the maximum length of the strings in the array `folder`, respectively.

Python 3

```python
class Solution:
    def removeSubfolders(self, folder: List[str]) -> List[str]:
        folder.sort()
        ans = [folder[0]]
        for f in folder[1:]:
            m, n = len(ans[-1]), len(f)
            if m >= n or not (ans[-1] == f[:m] and f[m] == '/'):
                ans.append(f)
        return ans
```

Solution 2: Trie

> **How to think about it**
>
> Sorting relies on global lexicographic order and pays string-prefix comparisons. A trie inserts path segments and marks folder ends; a search that hits an end can skip the whole subtree as nested folders. Time follows total path length and avoids sorting.

We can use a trie to store all the folders in the array `folder`. Each node of the trie contains a `children` field, used to store the child nodes of the current node, and a `fid` field, used to store the index of the folder corresponding to the current node in the array `folder`.

For each folder f in the array `folder`, we first split f into several substrings according to `/`, then start from the root node and add the substrings to the trie in turn. Next, we start from the root node to search the trie. If the `fid` field of the current node is not `-1`, it means that the folder corresponding to the current node is a folder in the answer array. We add it to the answer array and return. Otherwise, we recursively search all child nodes of the current node and finally return the answer array.

The time complexity is O(n × m), and the space complexity is O(n × m). Where n and m are the length of the array `folder` and the maximum length of the strings in the array `folder`, respectively.

Python 3

```python
class Trie:
    def __init__(self):
        self.children = {}
        self.fid = -1

    def insert(self, i, f):
        node = self
        ps = f.split('/')
        for p in ps[1:]:
            if p not in node.children:
                node.children[p] = Trie()
            node = node.children[p]
        node.fid = i

    def search(self):
        def dfs(root):
            if root.fid != -1:
                ans.append(root.fid)
                return
            for child in root.children.values():
                dfs(child)

        ans = []
        dfs(self)
        return ans

class Solution:
    def removeSubfolders(self, folder: List[str]) -> List[str]:
        trie = Trie()
        for i, f in enumerate(folder):
            trie.insert(i, f)
        return [folder[i] for i in trie.search()]
```

```

PART 2 · TRIES · PROBLEM 2 OF 4

2452. Words Within Two Edits of Dictionary

Medium · Trie, Array, String

leetcode.com/problems/words-within-two-edits-of-dictionary

★ **TOP 10 PROBLEM** in Tries: master this one first

PROBLEM

You are given two string arrays, `queries` and `dictionary`. All words in each array comprise of lowercase English letters and have the same length.

In one **edit** you can take a word from `queries`, and change any letter in it to any other letter. Find all words from `queries` that, after a **maximum** of two edits, equal some word from `dictionary`.

Return *a list of all words from* `queries`*, that match with some word from* `dictionary` *after a maximum of* ***two edits***. Return the words in the **same order** they appear in `queries`.

Example 1:

```
Input: queries = ["word","note","ants","wood"], dictionary = ["wood","joke","moat"]
Output: ["word","note","wood"]
Explanation:
- Changing the 'r' in "word" to 'o' allows it to equal the dictionary word "wood".
- Changing the 'n' to 'j' and the 't' to 'k' in "note" changes it to "joke".
- It would take more than 2 edits for "ants" to equal a dictionary word.
- "wood" can remain unchanged (0 edits) and match the corresponding dictionary word.
Thus, we return ["word","note","wood"].
```

Example 2:

```
Input: queries = ["yes"], dictionary = ["not"]
Output: []
Explanation:
Applying any two edits to "yes" cannot make it equal to "not". Thus, we return an empty array.
```

Constraints:

- `1 <= queries.length, dictionary.length <= 100`
- `n == queries[i].length == dictionary[j].length`
- `1 <= n <= 100`
- All `queries[i]` and `dictionary[j]` are composed of lowercase English letters.

SOLUTION (PYTHON 3)

Solution 1: Brute Force Enumeration

How to think about it

At most 100 queries and dictionary words of length ≤ 100. For each query, count mismatches against each dictionary word; fewer than three is allowed. Accept the query on the first hit.

We directly traverse each word s in the array queries, and then traverse each word t in the array dictionary. If there exists a word t whose edit distance from s is less than 3, we add s to the answer array and then exit the inner loop. If there is no such word t, we continue to traverse the next word s.

The time complexity is O(m × n × l), where m and n are the lengths of the arrays queries and dictionary respectively, and l is the length of the word.

Python 3

```
class Solution:
    def twoEditWords(self, queries: List[str], dictionary: List[str]) -> List[str]:
        ans = []
        for s in queries:
            for t in dictionary:

3043. Find the Length of the Longest Common Prefix

Medium · Trie, Array, Hash Table, String

leetcode.com/problems/find-the-length-of-the-longest-common-prefix

★ **TOP 10 PROBLEM** in Tries: master this one first

PROBLEM

You are given two arrays with **positive** integers `arr1` and `arr2`.

A **prefix** of a positive integer is an integer formed by one or more of its digits, starting from its **leftmost** digit. For example, `123` is a prefix of the integer `12345`, while `234` is **not**.

A **common prefix** of two integers `a` and `b` is an integer `c`, such that `c` is a prefix of both `a` and `b`. For example, `5655359` and `56554` have common prefixes `565` and `5655` while `1223` and `43456` **do not** have a common prefix.

You need to find the length of the **longest common prefix** between all pairs of integers `(x, y)` such that `x` belongs to `arr1` and `y` belongs to `arr2`.

Return *the length of the **longest** common prefix among all pairs. If no common prefix exists among them*, *return* `0`.

Example 1:

```
Input: arr1 = [1,10,100], arr2 = [1000]
Output: 3
Explanation: There are 3 pairs (arr1[i], arr2[j]):
- The longest common prefix of (1, 1000) is 1.
- The longest common prefix of (10, 1000) is 10.
- The longest common prefix of (100, 1000) is 100.
The longest common prefix is 100 with a length of 3.
```

Example 2:

```
Input: arr1 = [1,2,3], arr2 = [4,4,4]
Output: 0
Explanation: There exists no common prefix for any pair (arr1[i], arr2[j]), hence we return 0.
Note that common prefixes between elements of the same array do not count.
```

Constraints:

- `1 <= arr1.length, arr2.length <= 5 * 10^4`
- `1 <= arr1[i], arr2[i] <= 10^8`

SOLUTION (PYTHON 3)

Solution 1: Hash Table

How to think about it

Integers are read as decimal strings; we want the longest common prefix between the two arrays. $n \le 5 \times 10^4$ forbids comparing every pair. All prefixes of a number are the values obtained by repeated division by 10. After storing arr_1 prefixes in a hash set, each value in arr_2 searches from itself toward shorter prefixes. The largest hit is the integer that encodes the longest prefix; its number of digits is the answer.

We can use a hash table to store all the prefixes of the numbers in `arr1`. Then, we traverse all the numbers x in `arr2`. For each number x, we start from the highest bit and gradually decrease, checking whether it exists in the hash table. If it does, we have found a common prefix, and we can update the answer accordingly.

The time complexity is $O(m \times \log M + n \times \log N)$, and the space complexity is $O(m \times \log M)$. Here, m and n are the lengths of `arr1` and `arr2` respectively, and M and N are the maximum values in `arr1` and `arr2` respectively.

Python 3

```
class Solution:
    def longestCommonPrefix(self, arr1: List[int], arr2: List[int]) -> int:
        s = set()
        for x in arr1:
            while x:
                s.add(x)
                x //= 10
        mx = 0
        for x in arr2:
            while x:
                if x in s:
                    mx = max(mx, x)
                    break
                x //= 10
        return len(str(mx)) if mx else 0
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

```

PART 2 · TRIES · PROBLEM 4 OF 4

425. Word Squares

Hard · Trie, Array, String, Backtracking

leetcode.com/problems/word-squares

★ **TOP 10 PROBLEM** in Tries: master this one first

PROBLEM

Given an array of **unique** strings `words`, return *all the* **word squares** *you can build from* `words`. The same word from `words` can be used **multiple times**. You can return the answer in **any order**.

A sequence of strings forms a valid **word square** if the k^{th} row and column read the same string, where `0 <= k < max(numRows, numColumns)`.

- For example, the word sequence `["ball","area","lead","lady"]` forms a word square because each word reads the same both horizontally and vertically.

Example 1:

```
Input: words = ["area","lead","wall","lady","ball"]
Output: [["ball","area","lead","lady"],["wall","area","lead","lady"]]
Explanation:
The output consists of two word squares. The order of output does not matter (just the order of words
in each word square matters).
```

Example 2:

```
Input: words = ["abat","baba","atan","atal"]
Output: [["baba","abat","baba","atal"],["baba","abat","baba","atan"]]
Explanation:
The output consists of two word squares. The order of output does not matter (just the order of words
in each word square matters).
```

Constraints:

- `1 <= words.length <= 1000`
- `1 <= words[i].length <= 4`
- All `words[i]` have the same length.
- `words[i]` consists of only lowercase English letters.
- All `words[i]` are **unique**.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Row k of a word square is forced to start with the k-th letters of the rows already chosen. Scanning the whole list for that prefix repeats the same comparisons. Insert every word into a trie and store indices on the path. DFS fills rows: the prefix is those k-th letters, and a trie walk returns every candidate at once. A square is complete when the number of rows equals the word length. Building the trie first turns prefix search into a descent.

Python 3

```
class Trie:
    def __init__(self):
        self.children = [None] * 26
        self.v = []

    def insert(self, w, i):
        node = self
        for c in w:
            idx = ord(c) - ord('a')
            if node.children[idx] is None:
                node.children[idx] = Trie()
            node = node.children[idx]
            node.v.append(i)

    def search(self, w):
        node = self
        for c in w:
            idx = ord(c) - ord('a')
            if node.children[idx] is None:
                return []
            node = node.children[idx]
        return node.v

class Solution:
    def wordSquares(self, words: List[str]) -> List[List[str]]:
        def dfs(t):
            if len(t) == len(words[0]):
                ans.append(t[:])
                return
            idx = len(t)
            pref = [v[idx] for v in t]
            indexes = trie.search(''.join(pref))
            for i in indexes:
                t.append(words[i])
                dfs(t)
                t.pop()

        trie = Trie()
        ans = []
        for i, w in enumerate(words):
            trie.insert(w, i)
        for w in words:
            dfs([w])
        return ans
```

Complexity. Time: exponential in the word length L: about O(N * 26^L) in the worst case. Space: O(N * L).

1405. Longest Happy String

Medium · Greedy, String, Heap (Priority Queue)

leetcode.com/problems/longest-happy-string

★ **TOP 10 PROBLEM** in Heaps: master this one first

PROBLEM

A string `s` is called **happy** if it satisfies the following conditions:

- `s` only contains the letters `'a'`, `'b'`, and `'c'`.
- `s` does not contain any of `"aaa"`, `"bbb"`, or `"ccc"` as a substring.
- `s` contains **at most** `a` occurrences of the letter `'a'`.
- `s` contains **at most** `b` occurrences of the letter `'b'`.
- `s` contains **at most** `c` occurrences of the letter `'c'`.

Given three integers `a`, `b`, and `c`, return *the **longest possible happy** string*. If there are multiple longest happy strings, return *any of them*. If there is no such string, return *the empty string* `""`.

A **substring** is a contiguous sequence of characters within a string.

Example 1:

```
Input: a = 1, b = 1, c = 7
Output: "ccaccbcc"
Explanation: "ccbccacc" would also be a correct answer.
```

Example 2:

```
Input: a = 7, b = 1, c = 0
Output: "aabaa"
Explanation: It is the only correct answer in this case.
```

Constraints:

- `0 <= a, b, c <= 100`
- `a + b + c > 0`

SOLUTION (PYTHON 3)

Solution 1: Greedy + Priority Queue

How to think about it

a+b+c≤ 300 would allow search, but the optimum follows a local rule: always spend the letter that remains most often, without three identical characters in a row. If the last two characters are already that letter, take the second-most instead. A max-heap by remaining count implements this: pop, append if legal, otherwise pop the next, then push leftovers back. Stop when no letter can be appended, which yields the longest happy string.

The greedy strategy is to prioritize the selection of characters with the most remaining occurrences. By using a priority queue or sorting, we ensure that the character selected each time is the one with the most remaining occurrences (to avoid having three consecutive identical characters, in some cases, we need to select the character with the second most remaining occurrences).

Python 3

```
class Solution:
    def longestDiverseString(self, a: int, b: int, c: int) -> str:
        h = []
        if a > 0:
            heappush(h, [-a, 'a'])
        if b > 0:
            heappush(h, [-b, 'b'])
        if c > 0:
            heappush(h, [-c, 'c'])

        ans = []
        while len(h) > 0:
            cur = heappop(h)
            if len(ans) >= 2 and ans[-1] == cur[1] and ans[-2] == cur[1]:
                if len(h) == 0:
                    break
                nxt = heappop(h)
                ans.append(nxt[1])
                if -nxt[0] > 1:
                    nxt[0] += 1
                    heappush(h, nxt)
                heappush(h, cur)
            else:
                ans.append(cur[1])
                if -cur[0] > 1:
                    cur[0] += 1
                    heappush(h, cur)

        return ''.join(ans)
```

Complexity. Time: O(n), n = a + b + c (a heap of at most 3 letters). Space: O(n).

Easy · Array

leetcode.com/problems/summary-ranges

★ **TOP 10 PROBLEM** in Intervals: master this one first

PROBLEM

You are given a **sorted unique** integer array `nums`.

A **range** `[a,b]` is the set of all integers from `a` to `b` (inclusive).

Return *the **smallest sorted** list of ranges that **cover all the numbers in the array exactly***. That is, each element of `nums` is covered by exactly one of the ranges, and there is no integer `x` such that `x` is in one of the ranges but not in `nums`.

Each range `[a,b]` in the list should be output as:

- `"a->b"` if `a != b`
- `"a"` if `a == b`

Example 1:

```
Input: nums = [0,1,2,4,5,7]
Output: ["0->2","4->5","7"]
Explanation: The ranges are:
[0,2] --> "0->2"
[4,5] --> "4->5"
[7,7] --> "7"
```

Example 2:

```
Input: nums = [0,2,3,4,6,8,9]
Output: ["0","2->4","6","8->9"]
Explanation: The ranges are:
[0,0] --> "0"
[2,4] --> "2->4"
[6,6] --> "6"
[8,9] --> "8->9"
```

Constraints:

- `0 <= nums.length <= 20`
- -2^{31} `<= nums[i] <=` $2^{31} - 1$
- All the values of `nums` are **unique**.
- `nums` is sorted in ascending order.

SOLUTION (PYTHON 3)

Solution 1: Two Pointers

How to think about it

The array is sorted and unique, so a range is a maximal run of neighbors that differ by 1. One scan can cut the runs. Pointers i,j mark a segment until nums[j+1]≠ nums[j]+1, then format a singleton or a→b.

We can use two pointers i and j to find the left and right endpoints of each interval.

Traverse the array, when j + 1 < n and nums[j + 1] = nums[j] + 1, move j to the right, otherwise the interval [i, j] has been found, add it to the answer, then move i to the position of j + 1, and continue to find the next interval.

Time complexity O(n), where n is the length of the array. Space complexity O(1).

Python 3

```python
class Solution:
    def summaryRanges(self, nums: List[int]) -> List[str]:
        def f(i: int, j: int) -> str:
            return str(nums[i]) if i == j else f'{nums[i]}->{nums[j]}'

        i = 0
        n = len(nums)
        ans = []
        while i < n:
            j = i
            while j + 1 < n and nums[j + 1] == nums[j] + 1:
                j += 1
            ans.append(f(i, j))
            i = j + 1
        return ans
```

            nums.extend(range(int(a), int(b) + 1))
        else:
            nums.append(int(text))
    return nums
```

PART 2 · INTERVALS · PROBLEM 2 OF 6

252. Meeting Rooms

Easy · Array, Sorting, Quick Sort

leetcode.com/problems/meeting-rooms

★ **TOP 10 PROBLEM** in Intervals: master this one first

PROBLEM

You are given an array of meeting times `intervals` where `intervals[i] = [start_i, end_i]`.

A person can attend all meetings if no two meeting intervals overlap. Meetings ending at time `t` and starting at time `t` **do not** overlap.

Return `true` if a person can attend all meetings. Otherwise, return `false`.

Example 1:

```
Input: intervals = [[0,30],[5,10],[15,20]]
Output: false
```

Example 2:

```
Input: intervals = [[7,10],[2,4]]
Output: true
```

Constraints:

- `0 <= intervals.length <= 10^4`
- `intervals[i].length == 2`
- `0 <= start_i < end_i <= 10^6`

SOLUTION (PYTHON 3)

Solution 1: Sorting

How to think about it

One person cannot attend two overlapping meetings. After sorting by start time, it is enough that each meeting ends no later than the next one starts.

We sort the meetings based on their start times, and then iterate through the sorted meetings. If the start time of the current meeting is less than the end time of the previous meeting, it indicates that there is an overlap between the two meetings, and we return `false`. Otherwise, we continue iterating.

If no overlap is found by the end of the iteration, we return `true`.

The time complexity is O(n × log n), and the space complexity is O(log n), where n is the number of meetings.

Python 3

```python
class Solution:
    def canAttendMeetings(self, intervals: List[List[int]]) -> bool:
        intervals.sort()
        return all(a[1] <= b[0] for a, b in pairwise(intervals))
```

    return slots
```

PART 2 · INTERVALS · PROBLEM 3 OF 6

253. Meeting Rooms II

Medium · Greedy, Array, Two Pointers, Prefix Sum, Sorting, Heap (Priority Queue)

leetcode.com/problems/meeting-rooms-ii

★ **TOP 10 PROBLEM** in Intervals: master this one first

PROBLEM

Given an array of meeting time intervals `intervals` where `intervals[i] = [start_i, end_i]`, return *the minimum number of conference rooms required*.

Example 1:

```
Input: intervals = [[0,30],[5,10],[15,20]]
Output: 2
```

Example 2:

```
Input: intervals = [[7,10],[2,4]]
Output: 1
```

Constraints:

- `1 <= intervals.length <= 10^4`
- `0 <= start_i < end_i <= 10^6`

SOLUTIONS (PYTHON 3)

Solution 1: Difference Array

How to think about it

The number of rooms is the peak number of meetings underway. Add 1 at each start and -1 at each end; the prefix sum is the occupancy. A difference array up to the latest end time, then one scan, yields that peak.

We can implement this using a difference array.

First, we find the maximum end time of all the meetings, denoted as m. Then, we create a difference array d of length m + 1. For each meeting, we add to the corresponding positions in the difference array: d[l] = d[l] + 1 for the start time, and d[r] = d[r] - 1 for the end time.

Next, we calculate the prefix sum of the difference array and find the maximum value of the prefix sum, which represents the minimum number of meeting rooms required.

The time complexity is O(n + m) and the space complexity is O(m), where n is the number of meetings and m is the maximum end time.

Python 3

```python
class Solution:
    def minMeetingRooms(self, intervals: List[List[int]]) -> int:
        m = max(e[1] for e in intervals)
        d = [0] * (m + 1)
        for l, r in intervals:
            d[l] += 1
            d[r] -= 1
        ans = s = 0
        for v in d:
            s += v
            ans = max(ans, s)
        return ans
```

Solution 2: Difference (Hash Map)

> **How to think about it**
> A large time horizon wastes an O(m) array. A hash map stores updates only at endpoints; sorting the keys and taking a prefix-sum peak is equivalent.

If the meeting times span a large range, we can use a hash map instead of a difference array.

First, we create a hash map d, where we add to the corresponding positions for each meeting's start time and end time: d[l] = d[l] + 1 for the start time, and d[r] = d[r] - 1 for the end time.

Then, we sort the hash map by its keys, calculate the prefix sum of the hash map, and find the maximum value of the prefix sum, which represents the minimum number of meeting rooms required.

The time complexity is O(n × log n) and the space complexity is O(n), where n is the number of meetings.

Python 3

```python
class Solution:
    def minMeetingRooms(self, intervals: List[List[int]]) -> int:
        d = defaultdict(int)
        for l, r in intervals:
            d[l] += 1
            d[r] -= 1
        ans = s = 0
        for _, v in sorted(d.items()):
            s += v
            ans = max(ans, s)
        return ans
```

```

PART 2 · INTERVALS · PROBLEM 4 OF 6

1229. Meeting Scheduler

Medium · Array, Two Pointers, Sorting

leetcode.com/problems/meeting-scheduler

★ **TOP 10 PROBLEM** in Intervals: master this one first

PROBLEM

Given the availability time slots arrays `slots1` and `slots2` of two people and a meeting duration `duration`, return the **earliest time slot** that works for both of them and is of duration `duration`.

If there is no common time slot that satisfies the requirements, return an **empty array**.

The format of a time slot is an array of two elements `[start, end]` representing an inclusive time range from `start` to `end`.

It is guaranteed that no two availability slots of the same person intersect with each other. That is, for any two time slots `[start1, end1]` and `[start2, end2]` of the same person, either `start1 > end2` or `start2 > end1`.

Example 1:

```
Input: slots1 = [[10,50],[60,120],[140,210]], slots2 = [[0,15],[60,70]], duration = 8
Output: [60,68]
```

Example 2:

```
Input: slots1 = [[10,50],[60,120],[140,210]], slots2 = [[0,15],[60,70]], duration = 12
Output: []
```

Constraints:

- `1 <= slots1.length, slots2.length <= 10^4`
- `slots1[i].length, slots2[i].length == 2`
- `slots1[i][0] < slots1[i][1]`
- `slots2[i][0] < slots2[i][1]`
- `0 <= slots1[i][j], slots2[i][j] <= 10^9`
- `1 <= duration <= 10^6`

SOLUTION (PYTHON 3)

Solution 1: Sorting + Two Pointers

How to think about it

Each person has up to 10^4 slots; checking every pair is O(mn). After sorting by start, an overlap can only involve the two current slots: start is the max of starts, end the min of ends. If the overlap is long enough, we return the earliest such interval. Otherwise the slot that ends first cannot form an earlier feasible overlap with later slots of the other person, so we advance that pointer. Sorting walks candidates in time order; two pointers discard a hopeless slot each step, for a linear number of comparisons.

We can sort the free time intervals of both people, then use two pointers to traverse the two arrays and find the intersection of the free time intervals of both people. If the length of the intersection is greater than or equal to `duration`, return the start time of the intersection and the start time plus `duration`. Otherwise, if the end time of the first person's free time interval is less than the end time of the second person's free time interval, move the first person's pointer; otherwise, move the second person's pointer. Continue traversing until a suitable time interval is found or the traversal ends.

The time complexity is O(m × log m + n × log n), and the space complexity is O(log m + log n). Here, m and n are the lengths of the two arrays, respectively.

Python 3

```python
class Solution:
    def minAvailableDuration(
        self, slots1: List[List[int]], slots2: List[List[int]], duration: int
    ) -> List[int]:
        slots1.sort()
        slots2.sort()
        m, n = len(slots1), len(slots2)
        i = j = 0
        while i < m and j < n:
            start = max(slots1[i][0], slots2[j][0])
            end = min(slots1[i][1], slots2[j][1])
            if end - start >= duration:
                return [start, start + duration]
            if slots1[i][1] < slots2[j][1]:
                i += 1
            else:
                j += 1
        return []
```

2054. Two Best Non-Overlapping Events

Medium · Array, Binary Search, Dynamic Programming, Sorting, Heap (Priority Queue)

leetcode.com/problems/two-best-non-overlapping-events

★ **TOP 10 PROBLEM** in Intervals: master this one first

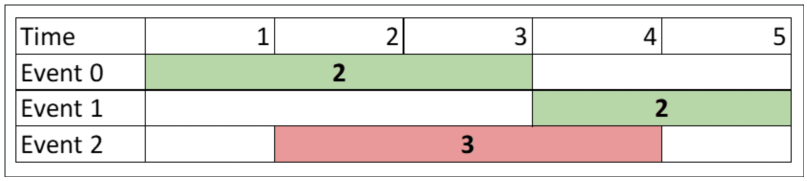
PROBLEM

You are given a **0-indexed** 2D integer array of `events` where `events[i] = [startTime`$_i$`, endTime`$_i$`, value`$_i$`]`. The i^{th} event starts at `startTime`$_i$ and ends at `endTime`$_i$, and if you attend this event, you will receive a value of `value`$_i$. You can choose **at most two non-overlapping** events to attend such that the sum of their values is **maximized**.

Return *this* ***maximum*** *sum.*

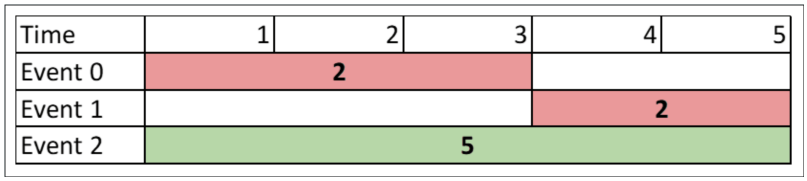
Note that the start time and end time is **inclusive**: that is, you cannot attend two events where one of them starts and the other ends at the same time. More specifically, if you attend an event with end time `t`, the next event must start at or after `t + 1`.

Example 1:



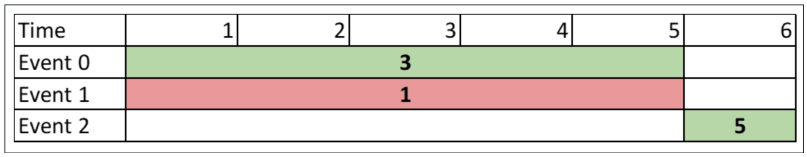
```
Input: events = [[1,3,2],[4,5,2],[2,4,3]]
Output: 4
Explanation: Choose the green events, 0 and 1 for a sum of 2 + 2 = 4.
```

Example 2:



```
Input: events = [[1,3,2],[4,5,2],[1,5,5]]
Output: 5
Explanation: Choose event 2 for a sum of 5.
```

Example 3:



```
Input: events = [[1,5,3],[1,5,1],[6,6,5]]
Output: 8
Explanation: Choose events 0 and 2 for a sum of 3 + 5 = 8.
```

Constraints:

- `2 <= events.length <= 10`^{5}
- `events[i].length == 3`
- `1 <= startTime`$_i$ `<= endTime`$_i$ `<= 10`^{9}
- `1 <= value`$_i$ `<= 10`^{6}

SOLUTION (PYTHON 3)

Solution 1: Sorting + Binary Search

How to think about it

Pick at most two non-overlapping events of maximum value. Pairwise search is quadratic for n ≤ 10^5. After sorting by start, the best single event in a suffix is a static array. f[i] is that suffix maximum. For each event as the first, binary-search the first start after its end and add f[idx] (or take the event alone). Sort plus binary search is O(n log n).

We can sort the events by their start times, and then preprocess the maximum value starting from each event, i.e., f[i] represents the maximum value of choosing one event from the i-th event to the last event.

Then we enumerate each event. For each event, we use binary search to find the first event whose start time is greater than the end time of the current event, denoted as idx. The maximum value starting from the current event is f[idx] plus the value of the current event, which is the maximum value that can be obtained by choosing the current event as the first event. We take the maximum value among all these values.

The time complexity is O(n × log n), and the space complexity is O(n). Here, n is the number of events.

Python 3

```python
class Solution:
    def maxTwoEvents(self, events: List[List[int]]) -> int:
        events.sort()
        n = len(events)
        f = [events[-1][2]] * n
        for i in range(n - 2, -1, -1):
            f[i] = max(f[i + 1], events[i][2])
        ans = 0
        for _, e, v in events:
            idx = bisect_right(events, e, key=lambda x: x[0])
            if idx < n:
                v += f[idx]
            ans = max(ans, v)
        return ans
```

2402. Meeting Rooms III

Hard · Array, Hash Table, Sorting, Simulation, Heap (Priority Queue)

leetcode.com/problems/meeting-rooms-iii

★ **TOP 10 PROBLEM** in Intervals: master this one first

PROBLEM

You are given an integer `n`. There are `n` rooms numbered from `0` to `n - 1`.

You are given a 2D integer array `meetings` where `meetings[i] = [start_i, end_i]` means that a meeting will be held during the **half-closed** time interval `[start_i, end_i)`. All the values of `start_i` are **unique**.

Meetings are allocated to rooms in the following manner:

1. Each meeting will take place in the unused room with the **lowest** number.
2. If there are no available rooms, the meeting will be delayed until a room becomes free. The delayed meeting should have the **same** duration as the original meeting.
3. When a room becomes unused, meetings that have an earlier original **start** time should be given the room.

Return *the **number** of the room that held the most meetings.* If there are multiple rooms, return *the room with the **lowest** number.*

A **half-closed interval** `[a, b)` is the interval between `a` and `b` **including** `a` and **not including** `b`.

Example 1:

```
Input: n = 2, meetings = [[0,10],[1,5],[2,7],[3,4]]
Output: 0
Explanation:
- At time 0, both rooms are not being used. The first meeting starts in room 0.
- At time 1, only room 1 is not being used. The second meeting starts in room 1.
- At time 2, both rooms are being used. The third meeting is delayed.
- At time 3, both rooms are being used. The fourth meeting is delayed.
- At time 5, the meeting in room 1 finishes. The third meeting starts in room 1 for the time period
[5,10).
- At time 10, the meetings in both rooms finish. The fourth meeting starts in room 0 for the time
period [10,11).
Both rooms 0 and 1 held 2 meetings, so we return 0.
```

Example 2:

```
Input: n = 3, meetings = [[1,20],[2,10],[3,5],[4,9],[6,8]]
Output: 1
Explanation:
- At time 1, all three rooms are not being used. The first meeting starts in room 0.
- At time 2, rooms 1 and 2 are not being used. The second meeting starts in room 1.
- At time 3, only room 2 is not being used. The third meeting starts in room 2.
- At time 4, all three rooms are being used. The fourth meeting is delayed.
- At time 5, the meeting in room 2 finishes. The fourth meeting starts in room 2 for the time period
[5,10).
- At time 6, all three rooms are being used. The fifth meeting is delayed.
- At time 10, the meetings in rooms 1 and 2 finish. The fifth meeting starts in room 1 for the time
period [10,12).
Room 0 held 1 meeting while rooms 1 and 2 each held 2 meetings, so we return 1.
```

Constraints:

- `1 <= n <= 100`
- `1 <= meetings.length <= 10^5`
- `meetings[i].length == 2`

- $0 <= start_i < end_i <= 5 * 10^5$
- All the values of $start_i$ are **unique**.

SOLUTION (PYTHON 3)

Solution 1: Priority Queue (Min-Heap)

How to think about it

With $n \leq 100$ and $m \leq 10^5$, scanning every room for each meeting is O(mn) and tight. Start times are distinct, so meetings must be assigned in time order. Idle rooms are chosen by the smallest index; busy rooms leave by earliest end time. Two heaps maintain these sets. After sorting meetings by start, return finished rooms to the idle heap; take the smallest idle index if any, otherwise delay the earliest-ending room by the meeting length. A delayed end time is the previous end plus the duration, and a long chain exceeds 2^{31}, so that timestamp is 64-bit.

We define two priority queues to represent idle meeting rooms and busy meeting rooms respectively. The idle meeting rooms idle are sorted by **index**; the busy meeting rooms busy are sorted by **end time and index**.

First, sort the meetings by start time, then iterate through the meetings. For each meeting:

- If there are busy meeting rooms with end time less than or equal to the current meeting's start time, add them to the idle meeting rooms queue idle;
- If there are idle meeting rooms available, take the room with the smallest index from the idle queue idle and add it to the busy queue busy;
- If there are no idle meeting rooms, find the room with the earliest end time and smallest index from the busy queue busy, and add it back to the busy queue busy.

The time complexity is O(m (log m + log n)), and the space complexity is O(n + m), where n and m are the number of meeting rooms and meetings respectively.

Python 3

```python
class Solution:
    def mostBooked(self, n: int, meetings: List[List[int]]) -> int:
        meetings.sort(key=lambda x: x[0])
        busy = []
        idle = list(range(n))
        heapify(idle)
        cnt = [0] * n
        for s, e in meetings:
            while busy and busy[0][0] <= s:
                heappush(idle, heappop(busy)[1])
            i = 0
            if idle:
                i = heappop(idle)
                heappush(busy, (e, i))
            else:
                time_end, i = heappop(busy)
                heappush(busy, (time_end + e - s, i))
            cnt[i] += 1
        ans = 0
        for i in range(n):
            if cnt[ans] < cnt[i]:
                ans = i
        return ans

PART 2 · DATA STRUCTURE DESIGN · PROBLEM 1 OF 9

359. Logger Rate Limiter

Easy · Design, Hash Table, Data Stream

leetcode.com/problems/logger-rate-limiter

★ **TOP 10 PROBLEM** in Data Structure Design: master this one first

PROBLEM

Design a logger system that receives a stream of messages along with their timestamps. Each **unique** message should only be printed **at most every 10 seconds** (i.e. a message printed at timestamp `t` will prevent other identical messages from being printed until timestamp `t + 10`).

All messages will come in chronological order. Several messages may arrive at the same timestamp.

Implement the `Logger` class:

- `Logger()` Initializes the `logger` object.
- `bool shouldPrintMessage(int timestamp, string message)` Returns `true` if the `message` should be printed in the given `timestamp`, otherwise returns `false`.

Example 1:

```
Input
["Logger", "shouldPrintMessage", "shouldPrintMessage", "shouldPrintMessage", "shouldPrintMessage",
"shouldPrintMessage", "shouldPrintMessage"]
[[], [1, "foo"], [2, "bar"], [3, "foo"], [8, "bar"], [10, "foo"], [11, "foo"]]
Output
[null, true, true, false, false, false, true]

Explanation
Logger logger = new Logger();
logger.shouldPrintMessage(1, "foo"); // return true, next allowed timestamp for "foo" is 1 + 10 = 11
logger.shouldPrintMessage(2, "bar"); // return true, next allowed timestamp for "bar" is 2 + 10 = 12
logger.shouldPrintMessage(3, "foo"); // 3 < 11, return false
logger.shouldPrintMessage(8, "bar"); // 8 < 12, return false
logger.shouldPrintMessage(10, "foo"); // 10 < 11, return false
logger.shouldPrintMessage(11, "foo"); // 11 >= 11, return true, next allowed timestamp for "foo" is 11
+ 10 = 21
```

Constraints:

- `0 <= timestamp <= 10^9`
- Every `timestamp` will be passed in non-decreasing order (chronological order).
- `1 <= message.length <= 30`
- At most `10^4` calls will be made to `shouldPrintMessage`.

SOLUTION (PYTHON 3)

Solution 1: Hash Table

How to think about it

The same message prints at most once per 10 seconds; timestamps are nondecreasing. Scanning a log each time is unnecessary. A map stores the next allowed time. Reject if `timestamp` is still before that; otherwise set it to t+10 and print.

We use a hash table ts to store the next available print timestamp for each message. When the `shouldPrintMessage` method is called, we check whether the current timestamp is greater than or equal to the next available print timestamp for the message. If so, we update the next available print timestamp to the current timestamp plus 10 and return `true`;

otherwise, we return `false`.

The time complexity is O(1). The space complexity is O(m), where m is the number of distinct messages.

Python 3

```
class Logger:

    def __init__(self):
        self.ts = {}

    def shouldPrintMessage(self, timestamp: int, message: str) -> bool:
        t = self.ts.get(message, 0)
        if t > timestamp:
            return False
        self.ts[message] = timestamp + 10
        return True

# Your Logger object will be instantiated and called as such:
# obj = Logger()
# param_1 = obj.shouldPrintMessage(timestamp,message)
```

        self.last[message] = timestamp
        self.queue.append((timestamp, message))
        return True
```

PART 2 · DATA STRUCTURE DESIGN · PROBLEM 2 OF 9

271. Encode and Decode Strings

Medium · Design, Array, String

leetcode.com/problems/encode-and-decode-strings

★ **TOP 10 PROBLEM** in Data Structure Design: master this one first

PROBLEM

Design an algorithm to encode **a list of strings** to **a string**. The encoded string is then sent over the network and is decoded back to the original list of strings.

Machine 1 (sender) has the function:

```
string encode(vector<string> strs) {
  // ... your code
  return encoded_string;
}
```

Machine 2 (receiver) has the function:

```
vector<string> decode(string s) {
  //... your code
  return strs;
}
```

So Machine 1 does:

```
string encoded_string = encode(strs);
```

and Machine 2 does:

```
vector<string> strs2 = decode(encoded_string);
```

`strs2` in Machine 2 should be the same as `strs` in Machine 1.

Implement the `encode` and `decode` methods.

You are not allowed to solve the problem using any serialize methods (such as `eval`).

Example 1:

```
Input: dummy_input = ["Hello","World"]
Output: ["Hello","World"]
Explanation:
Machine 1:
Codec encoder = new Codec();
String msg = encoder.encode(strs);
Machine 1 ---msg---> Machine 2

Machine 2:
Codec decoder = new Codec();
String[] strs = decoder.decode(msg);
```

Example 2:

```
Input: dummy_input = [""]
Output: [""]
```

Constraints:

- `1 <= strs.length <= 200`
- `0 <= strs[i].length <= 200`

- `strs[i]` contains any possible characters out of `256` valid ASCII characters.

Follow up: Could you write a generalized algorithm to work on any possible set of characters?

SOLUTION (PYTHON 3)

Solution 1: Encode String Length

> **How to think about it**
>
> A raw delimiter can appear inside a string. Prefixing a fixed-width length makes the split unambiguous. Encode writes a 4-character length then the payload; decode reads that length and slices.

During encoding, we convert the length of the string into a fixed 4-digit string, add the string itself, and append it to the result string in sequence.

During decoding, we first take the first four digits of the string to get the length, and then cut the following string according to the length. We cut it in sequence until we get the list of strings.

The time complexity is O(n).

Python 3

```python
class Codec:
    def encode(self, strs: List[str]) -> str:
        """Encodes a list of strings to a single string."""
        ans = []
        for s in strs:
            ans.append('{:4}'.format(len(s)) + s)
        return ''.join(ans)

    def decode(self, s: str) -> List[str]:
        """Decodes a single string to a list of strings."""
        ans = []
        i, n = 0, len(s)
        while i < n:
            size = int(s[i : i + 4])
            i += 4
            ans.append(s[i : i + size])
            i += size
        return ans

# Your Codec object will be instantiated and called as such:
# codec = Codec()
# codec.decode(codec.encode(strs))
```

            i += 1
    return result
```

PART 2 · DATA STRUCTURE DESIGN · PROBLEM 3 OF 9

362. Design Hit Counter

Medium · Design, Queue, Array, Binary Search, Data Stream

leetcode.com/problems/design-hit-counter

★ **TOP 10 PROBLEM** in Data Structure Design: master this one first

PROBLEM

Design a hit counter which counts the number of hits received in the past `5` minutes (i.e., the past `300` seconds).

Your system should accept a `timestamp` parameter (**in seconds** granularity), and you may assume that calls are being made to the system in chronological order (i.e., `timestamp` is monotonically increasing). Several hits may arrive roughly at the same time.

Implement the `HitCounter` class:

- `HitCounter()` Initializes the object of the hit counter system.
- `void hit(int timestamp)` Records a hit that happened at `timestamp` (**in seconds**). Several hits may happen at the same `timestamp`.
- `int getHits(int timestamp)` Returns the number of hits in the past 5 minutes from `timestamp` (i.e., the past `300` seconds).

Example 1:

```
Input
["HitCounter", "hit", "hit", "hit", "getHits", "hit", "getHits", "getHits"]
[[], [1], [2], [3], [4], [300], [300], [301]]
Output
[null, null, null, null, 3, null, 4, 3]

Explanation
HitCounter hitCounter = new HitCounter();
hitCounter.hit(1); // hit at timestamp 1.
hitCounter.hit(2); // hit at timestamp 2.
hitCounter.hit(3); // hit at timestamp 3.
hitCounter.getHits(4); // get hits at timestamp 4, return 3.
hitCounter.hit(300); // hit at timestamp 300.
hitCounter.getHits(300); // get hits at timestamp 300, return 4.
hitCounter.getHits(301); // get hits at timestamp 301, return 3.
```

Constraints:

- `1 <= timestamp <= 2 * 10^9`
- All the calls are being made to the system in chronological order (i.e., `timestamp` is monotonically increasing).
- At most `300` calls will be made to `hit` and `getHits`.

Follow up: What if the number of hits per second could be huge? Does your design scale?

SOLUTION (PYTHON 3)

Solution 1: Binary Search

How to think about it

Count hits in the last 300 seconds. Timestamps increase. A queue that drops stale hits works; a list plus binary search is shorter. `hit` appends; `getHits` bisects the first index ≥ timestamp-299 and returns the suffix length.

Since `timestamp` is monotonically increasing, we can use an array `ts` to store all `timestamp`s. Then in the `getHits` method, we use binary search to find the first position that is greater than or equal to `timestamp - 300 + 1`, and then return the length of `ts` minus this position.

In terms of time complexity, the time complexity of the `hit` method is O(1), and the time complexity of the `getHits` method is O(log n). Where n is the length of `ts`.

Python 3

```
class HitCounter:

    def __init__(self):
        self.ts = []

    def hit(self, timestamp: int) -> None:
        self.ts.append(timestamp)

    def getHits(self, timestamp: int) -> int:
        return len(self.ts) - bisect_left(self.ts, timestamp - 300 + 1)

# Your HitCounter object will be instantiated and called as such:
# obj = HitCounter()
# obj.hit(timestamp)
# param_2 = obj.getHits(timestamp)
```

        return len(self.times) - bisect.bisect_right(self.times, timestamp - window)

# ============================================================
# FOLLOW-UP 2: Constant memory: 300 buckets (one per
# second of the last five minutes)
# ============================================================

# ---- follow-up 2: function ----
# Answer: Bucket i holds the hits of the second whose time
# mod 300 is i; reset a bucket when its second is old.
# Time: hit O(1), get_hits O(300) = O(1).  Space: O(300).
class HitCounterBuckets:
    def __init__(self):
        self.times = [0] * 300
        self.hits = [0] * 300

    def hit(self, timestamp):
```

```
        i = timestamp % 300
        if self.times[i] != timestamp:
            self.times[i] = timestamp
            self.hits[i] = 0
        self.hits[i] += 1

    def get_hits(self, timestamp):
        return sum(h for t, h in zip(self.times, self.hits) if timestamp - t < 300)
```

PART 2 · DATA STRUCTURE DESIGN · PROBLEM 4 OF 9

432. All O`one Data Structure

Hard · Design, Hash Table, Linked List, Doubly-Linked List

leetcode.com/problems/all-oone-data-structure

★ **TOP 10 PROBLEM** in Data Structure Design: master this one first

PROBLEM

Design a data structure to store the strings' count with the ability to return the strings with minimum and maximum counts.

Implement the `AllOne` class:

- `AllOne()` Initializes the object of the data structure.
- `inc(String key)` Increments the count of the string `key` by `1`. If `key` does not exist in the data structure, insert it with count `1`.
- `dec(String key)` Decrements the count of the string `key` by `1`. If the count of `key` is `0` after the decrement, remove it from the data structure. It is guaranteed that `key` exists in the data structure before the decrement.
- `getMaxKey()` Returns one of the keys with the maximal count. If no element exists, return an empty string `""`.
- `getMinKey()` Returns one of the keys with the minimum count. If no element exists, return an empty string `""`.

Note that each function must run in `O(1)` average time complexity.

Example 1:

```
Input
["AllOne", "inc", "inc", "getMaxKey", "getMinKey", "inc", "getMaxKey", "getMinKey"]
[[], ["hello"], ["hello"], [], [], ["leet"], [], []]
Output
[null, null, null, "hello", "hello", null, "hello", "leet"]

Explanation
AllOne allOne = new AllOne();
allOne.inc("hello");
allOne.inc("hello");
allOne.getMaxKey(); // return "hello"
allOne.getMinKey(); // return "hello"
allOne.inc("leet");
allOne.getMaxKey(); // return "hello"
allOne.getMinKey(); // return "leet"
```

Constraints:

- `1 <= key.length <= 10`
- `key` consists of lowercase English letters.
- It is guaranteed that for each call to `dec`, `key` is existing in the data structure.
- At most $5 * 10^4$ calls will be made to `inc`, `dec`, `getMaxKey`, and `getMinKey`.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

inc, dec, getMaxKey and getMinKey all need amortized O(1). A hash map updates a count in O(1) but cannot report the extremes; an ordered set would take logarithmic time. Keys that share a count sit in one doubly linked bucket, and buckets form a ring ordered by count. A map sends each key to its bucket. Increment and decrement move a key only to an adjacent count, inserting or deleting an empty bucket when needed. The ring's successor and predecessor are the min and max counts. Keys never jump over buckets, so the list is never scanned.

Python 3

```python
class Node:
    def __init__(self, key='', cnt=0):
        self.prev = None
        self.next = None
        self.cnt = cnt
        self.keys = {key}

    def insert(self, node):
        node.prev = self
        node.next = self.next
        node.prev.next = node
        node.next.prev = node
        return node

    def remove(self):
        self.prev.next = self.next
        self.next.prev = self.prev

class AllOne:
    def __init__(self):
        self.root = Node()
        self.root.next = self.root
        self.root.prev = self.root
        self.nodes = {}

    def inc(self, key: str) -> None:
        root, nodes = self.root, self.nodes
        if key not in nodes:
            if root.next == root or root.next.cnt > 1:
                nodes[key] = root.insert(Node(key, 1))
            else:
                root.next.keys.add(key)
                nodes[key] = root.next
        else:
            curr = nodes[key]
            next = curr.next
            if next == root or next.cnt > curr.cnt + 1:
                nodes[key] = curr.insert(Node(key, curr.cnt + 1))
            else:
                next.keys.add(key)
                nodes[key] = next
            curr.keys.discard(key)
            if not curr.keys:
                curr.remove()

    def dec(self, key: str) -> None:
        root, nodes = self.root, self.nodes
        curr = nodes[key]
        if curr.cnt == 1:
            nodes.pop(key)
        else:
            prev = curr.prev
            if prev == root or prev.cnt < curr.cnt - 1:
                nodes[key] = prev.insert(Node(key, curr.cnt - 1))
            else:
                prev.keys.add(key)
                nodes[key] = prev
        curr.keys.discard(key)
        if not curr.keys:
            curr.remove()

    def getMaxKey(self) -> str:
        return next(iter(self.root.prev.keys))

    def getMinKey(self) -> str:
```

```
        return next(iter(self.root.next.keys))

# Your AllOne object will be instantiated and called as such:
# obj = AllOne()
# obj.inc(key)
# obj.dec(key)
# param_3 = obj.getMaxKey()
# param_4 = obj.getMinKey()
```

588. Design In-Memory File System

Hard · Design, Trie, Hash Table, String, Sorting

leetcode.com/problems/design-in-memory-file-system

★ **TOP 10 PROBLEM** in Data Structure Design: master this one first

PROBLEM

Design a data structure that simulates an in-memory file system.

Implement the FileSystem class:

- `FileSystem()` Initializes the object of the system.
- `List<String> ls(String path)` The answer should in **lexicographic order**.
  - If `path` is a file path, returns a list that only contains this file's name.
  - If `path` is a directory path, returns the list of file and directory names **in this directory**.
- `void mkdir(String path)` Makes a new directory according to the given `path`. The given directory path does not exist. If the middle directories in the path do not exist, you should create them as well.
- `void addContentToFile(String filePath, String content)`
  - If `filePath` does not exist, creates that file containing given `content`.
  - If `filePath` already exists, appends the given `content` to original content.
- `String readContentFromFile(String filePath)` Returns the content in the file at `filePath`.

Example 1:

Operation	Output	Explanation
FileSystem fs = new FileSystem()	null	The constructor returns nothing.
fs.ls("/")	[]	Initially, directory `/` has nothing. So return empty list.
fs.mkdir("/a/b/c")	null	Create directory `a` in directory `/`. Then create directory `b` in directory `a`. Finally, create directory `c` in directory `b`.
fs.addContentToFile("/a/b/c/d","hello")	null	Create a file named `d` with content `"hello"` in directory `/a/b/c`.
fs.ls("/")	["a"]	Only directory `a` is in directory `/`.
fs.readContentFromFile("/a/b/c/d")	"hello"	Output the file content.

```
Input
["FileSystem", "ls", "mkdir", "addContentToFile", "ls", "readContentFromFile"]
[[], ["/"], ["/a/b/c"], ["/a/b/c/d", "hello"], ["/"], ["/a/b/c/d"]]
Output
[null, [], null, null, ["a"], "hello"]

Explanation
FileSystem fileSystem = new FileSystem();
fileSystem.ls("/"); // return []
fileSystem.mkdir("/a/b/c");
fileSystem.addContentToFile("/a/b/c/d", "hello");
fileSystem.ls("/"); // return ["a"]
fileSystem.readContentFromFile("/a/b/c/d"); // return "hello"
```

Constraints:

- `1 <= path.length, filePath.length <= 100`
- `path` and `filePath` are absolute paths which begin with `'/'` and do not end with `'/'` except that the path is just `"/"`.
- You can assume that all directory names and file names only contain lowercase letters, and the same names will not exist in the same directory.
- You can assume that all operations will be passed valid parameters, and users will not attempt to retrieve file content or list a directory or file that does not exist.
- You can assume that the parent directory for the file in `addContentToFile` will exist.
- `1 <= content.length <= 50`
- At most `300` calls will be made to `ls`, `mkdir`, `addContentToFile`, and `readContentFromFile`.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

A file system is hierarchical: list, mkdir, append, read. A flat map of full paths works, but sharing prefixes and listing a directory is awkward. A trie keyed by path segments stores children, a file flag, and content chunks. `insert` creates nodes; `search` walks to the target. `ls` returns a file name or the sorted child names. Cost follows path depth.

Python 3

```python
class Trie:
    def __init__(self):
        self.name = None
        self.isFile = False
        self.content = []
        self.children = {}

    def insert(self, path, isFile):
        node = self
        ps = path.split('/')
        for p in ps[1:]:
            if p not in node.children:
                node.children[p] = Trie()
            node = node.children[p]
        node.isFile = isFile
        if isFile:
            node.name = ps[-1]
        return node

    def search(self, path):
        node = self
        if path == '/':
            return node
        ps = path.split('/')
        for p in ps[1:]:
            if p not in node.children:
                return None
            node = node.children[p]
        return node

class FileSystem:
    def __init__(self):
        self.root = Trie()

    def ls(self, path: str) -> List[str]:
        node = self.root.search(path)
        if node is None:
            return []
        if node.isFile:
            return [node.name]
        return sorted(node.children.keys())

    def mkdir(self, path: str) -> None:
        self.root.insert(path, False)

    def addContentToFile(self, filePath: str, content: str) -> None:
        node = self.root.insert(filePath, True)
        node.content.append(content)

    def readContentFromFile(self, filePath: str) -> str:
        node = self.root.search(filePath)
        return ''.join(node.content)

# Your FileSystem object will be instantiated and called as such:
# obj = FileSystem()
# param_1 = obj.ls(path)
# obj.mkdir(path)
# obj.addContentToFile(filePath,content)
```

```python
# param_4 = obj.readContentFromFile(filePath)
```

Complexity. Time: O(L) per path operation (L = path length); ls adds O(k log k) for k entries. Space: O(total length of all paths and contents).

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

Built on the solutions above: helper functions, then the function for each follow-up. No tests and no restating of the question.

```
# FOLLOW-UPS (answered below, in this order):
# 1. Delete a file or a whole folder
# 2. Find every file with a given name

# ============================================================
# FOLLOW-UP 1: Delete a file or a whole folder
# ============================================================

# ---- follow-up 1: function ----
# Answer: Walk to the parent folder and remove the name.
# Time: each operation O(path length), ls adds O(k log k).
# Space: O(total content).

            return True
        return False

# ============================================================
# FOLLOW-UP 2: Find every file with a given name
```

```
# ============================================================

# ---- follow-up 2: function ----
# Answer: Walk the whole tree and collect the paths of
```

```
# files with that name.
# Time: O(n + f log f), f = matches.  Space: O(depth + f).
def find_files(fs, name):
    result = []

    def go(node, path):
        for key, child in node.items():
            if isinstance(child, str):
                if key == name:
                    result.append(path + "/" + key)
            else:
                go(child, path + "/" + key)

    go(fs.root, "")
    return sorted(result)
```

642. Design Search Autocomplete System

Hard · Depth-First Search, Design, Trie, String, Data Stream, Sorting, Heap (Priority Queue)

leetcode.com/problems/design-search-autocomplete-system

★ **TOP 10 PROBLEM** in Data Structure Design: master this one first

PROBLEM

Design a search autocomplete system for a search engine. Users may input a sentence (at least one word and end with a special character `'#'`).

You are given a string array `sentences` and an integer array `times` both of length `n` where `sentences[i]` is a previously typed sentence and `times[i]` is the corresponding number of times the sentence was typed. For each input character except `'#'`, return the top `3` historical hot sentences that have the same prefix as the part of the sentence already typed.

Here are the specific rules:

- The hot degree for a sentence is defined as the number of times a user typed the exactly same sentence before.
- The returned top `3` hot sentences should be sorted by hot degree (The first is the hottest one). If several sentences have the same hot degree, use ASCII-code order (smaller one appears first).
- If less than `3` hot sentences exist, return as many as you can.
- When the input is a special character, it means the sentence ends, and in this case, you need to return an empty list.

Implement the `AutocompleteSystem` class:

- `AutocompleteSystem(String[] sentences, int[] times)` Initializes the object with the `sentences` and `times` arrays.
- `List<String> input(char c)` This indicates that the user typed the character `c`.
  - Returns an empty array `[]` if `c == '#'` and stores the inputted sentence in the system.
  - Returns the top `3` historical hot sentences that have the same prefix as the part of the sentence already typed. If there are fewer than `3` matches, return them all.

Example 1:

```
Input
["AutocompleteSystem", "input", "input", "input", "input"]
[[["i love you", "island", "iroman", "i love leetcode"], [5, 3, 2, 2]], ["i"], [" "], ["a"], ["#"]]
Output
[null, ["i love you", "island", "i love leetcode"], ["i love you", "i love leetcode"], [], []]

Explanation
AutocompleteSystem obj = new AutocompleteSystem(["i love you", "island", "iroman", "i love leetcode"],
[5, 3, 2, 2]);
obj.input("i"); // return ["i love you", "island", "i love leetcode"]. There are four sentences that
have prefix "i". Among them, "ironman" and "i love leetcode" have same hot degree. Since ' ' has ASCII
code 32 and 'r' has ASCII code 114, "i love leetcode" should be in front of "ironman". Also we only
need to output top 3 hot sentences, so "ironman" will be ignored.
obj.input(" "); // return ["i love you", "i love leetcode"]. There are only two sentences that have
prefix "i ".
obj.input("a"); // return []. There are no sentences that have prefix "i a".
obj.input("#"); // return []. The user finished the input, the sentence "i a" should be saved as a
historical sentence in system. And the following input will be counted as a new search.
```

Constraints:

- `n == sentences.length`
- `n == times.length`
- `1 <= n <= 100`

- `1 <= sentences[i].length <= 100`
- `1 <= times[i] <= 50`
- `c` is a lowercase English letter, a hash `'#'`, or space `' '`.
- Each tested sentence will be a sequence of characters `c` that end with the character `'#'`.
- Each tested sentence will have a length in the range `[1, 200]`.
- The words in each input sentence are separated by single spaces.
- At most `5000` calls will be made to `input`.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Each typed character must yield the three hottest sentences with that prefix. Scanning every sentence on every keystroke is slow. A trie stores sentence and heat. After walking the current prefix, DFS the subtree, sort by (-heat, lex), and keep three. `#` inserts the finished sentence back.

Python 3

```python
class Trie:
    def __init__(self):
        self.children = [None] * 27
        self.v = 0
        self.w = ''

    def insert(self, w, t):
        node = self
        for c in w:
            idx = 26 if c == ' ' else ord(c) - ord('a')
            if node.children[idx] is None:
                node.children[idx] = Trie()
            node = node.children[idx]
        node.v += t
        node.w = w

    def search(self, pref):
        node = self
        for c in pref:
            idx = 26 if c == ' ' else ord(c) - ord('a')
            if node.children[idx] is None:
                return None
            node = node.children[idx]
        return node

class AutocompleteSystem:
    def __init__(self, sentences: List[str], times: List[int]):
        self.trie = Trie()
        for a, b in zip(sentences, times):
            self.trie.insert(a, b)
        self.t = []

    def input(self, c: str) -> List[str]:
        def dfs(node):
            if node is None:
                return
            if node.v:
                res.append((node.v, node.w))
            for nxt in node.children:
                dfs(nxt)

        if c == '#':
            s = ''.join(self.t)
            self.trie.insert(s, 1)
            self.t = []
            return []

        res = []
        self.t.append(c)
        node = self.trie.search(''.join(self.t))
        if node is None:
            return res
        dfs(node)
        res.sort(key=lambda x: (-x[0], x[1]))
        return [v[1] for v in res[:3]]

# Your AutocompleteSystem object will be instantiated and called as such:
# obj = AutocompleteSystem(sentences, times)
```

```python
# param_1 = obj.input(c)
```

Complexity. Time: constructor O(total letters); input O(p + S log S), p = typed length, S = sentences under the prefix. Space: O(27 * total letters).

PART 2 · DATA STRUCTURE DESIGN · PROBLEM 7 OF 9

716. Max Stack

Hard · Stack, Design, Linked List, Doubly-Linked List, Ordered Set

leetcode.com/problems/max-stack

★ **TOP 10 PROBLEM** in Data Structure Design: master this one first

PROBLEM

Design a max stack data structure that supports the stack operations and supports finding the stack's maximum element.

Implement the `MaxStack` class:

- `MaxStack()` Initializes the stack object.
- `void push(int x)` Pushes element `x` onto the stack.
- `int pop()` Removes the element on top of the stack and returns it.
- `int top()` Gets the element on the top of the stack without removing it.
- `int peekMax()` Retrieves the maximum element in the stack without removing it.
- `int popMax()` Retrieves the maximum element in the stack and removes it. If there is more than one maximum element, only remove the **top-most** one.

You must come up with a solution that supports `O(1)` for each `top` call and `O(logn)` for each other call.

Example 1:

```
Input
["MaxStack", "push", "push", "push", "top", "popMax", "top", "peekMax", "pop", "top"]
[[], [5], [1], [5], [], [], [], [], [], []]
Output
[null, null, null, null, 5, 5, 1, 5, 1, 5]

Explanation
MaxStack stk = new MaxStack();
stk.push(5); // [5] the top of the stack and the maximum number is 5.
stk.push(1); // [5, 1] the top of the stack is 1, but the maximum is 5.
stk.push(5); // [5, 1, 5] the top of the stack is 5, which is also the maximum, because it is the top most one.
stk.top(); // return 5, [5, 1, 5] the stack did not change.
stk.popMax(); // return 5, [5, 1] the stack is changed now, and the top is different from the max.
stk.top(); // return 1, [5, 1] the stack did not change.
stk.peekMax(); // return 5, [5, 1] the stack did not change.
stk.pop(); // return 1, [5] the top of the stack and the max element is now 5.
stk.top(); // return 5, [5] the stack did not change.
```

Constraints:

- -10^7 <= x <= 10^7
- At most 10^5 calls will be made to `push`, `pop`, `top`, `peekMax`, and `popMax`.
- There will be **at least one element** in the stack when `pop`, `top`, `peekMax`, or `popMax` is called.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Besides a normal stack we must peek the maximum and pop the most recent occurrence of it. One stack cannot delete in the middle; dual stacks find the max but cannot unlink an arbitrary node. A doubly linked list preserves push order and unlinks in O(1). An ordered set of those nodes, keyed by value, finds the current max in logarithmic time. Both structures share nodes, so every delete updates both. push appends and inserts; pop removes the tail; popMax takes the last ordered node and unlinks it. Writes are O(log n).

Python 3

```
class Node:
    def __init__(self, val=0):
        self.val = val
        self.prev: Union[Node, None] = None
        self.next: Union[Node, None] = None

class DoubleLinkedList:
    def __init__(self):
        self.head = Node()
        self.tail = Node()
        self.head.next = self.tail
        self.tail.prev = self.head

    def append(self, val) -> Node:
        node = Node(val)
        node.next = self.tail
        node.prev = self.tail.prev
        self.tail.prev = node
        node.prev.next = node
        return node

    @staticmethod
    def remove(node) -> Node:
        node.prev.next = node.next
        node.next.prev = node.prev
        return node

    def pop(self) -> Node:
        return self.remove(self.tail.prev)

    def peek(self):
        return self.tail.prev.val

class MaxStack:
    def __init__(self):
        self.stk = DoubleLinkedList()
        self.sl = SortedList(key=lambda x: x.val)

    def push(self, x: int) -> None:
        node = self.stk.append(x)
        self.sl.add(node)

    def pop(self) -> int:
        node = self.stk.pop()
        self.sl.remove(node)
        return node.val

    def top(self) -> int:
        return self.stk.peek()

    def peekMax(self) -> int:
        return self.sl[-1].val

    def popMax(self) -> int:
        node = self.sl.pop()
        DoubleLinkedList.remove(node)
        return node.val
```

```
# Your MaxStack object will be instantiated and called as such:
# obj = MaxStack()
# obj.push(x)
# param_2 = obj.pop()
# param_3 = obj.top()
# param_4 = obj.peekMax()
```

```
# param_5 = obj.popMax()
```

PART 2 · DATA STRUCTURE DESIGN · PROBLEM 8 OF 9

895. Maximum Frequency Stack

Hard · Stack, Design, Hash Table, Ordered Set

leetcode.com/problems/maximum-frequency-stack

★ **TOP 10 PROBLEM** in Data Structure Design: master this one first

PROBLEM

Design a stack-like data structure to push elements to the stack and pop the most frequent element from the stack.

Implement the `FreqStack` class:

- `FreqStack()` constructs an empty frequency stack.
- `void push(int val)` pushes an integer `val` onto the top of the stack.
- `int pop()` removes and returns the most frequent element in the stack.
  - If there is a tie for the most frequent element, the element closest to the stack's top is removed and returned.

Example 1:

```
Input
["FreqStack", "push", "push", "push", "push", "push", "push", "pop", "pop", "pop", "pop"]
[[], [5], [7], [5], [7], [4], [5], [], [], [], []]
Output
[null, null, null, null, null, null, null, 5, 7, 5, 4]

Explanation
FreqStack freqStack = new FreqStack();
freqStack.push(5); // The stack is [5]
freqStack.push(7); // The stack is [5,7]
freqStack.push(5); // The stack is [5,7,5]
freqStack.push(7); // The stack is [5,7,5,7]
freqStack.push(4); // The stack is [5,7,5,7,4]
freqStack.push(5); // The stack is [5,7,5,7,4,5]
freqStack.pop(); // return 5, as 5 is the most frequent. The stack becomes [5,7,5,7,4].
freqStack.pop(); // return 7, as 5 and 7 is the most frequent, but 7 is closest to the top. The stack
becomes [5,7,5,4].
freqStack.pop(); // return 5, as 5 is the most frequent. The stack becomes [5,7,4].
freqStack.pop(); // return 4, as 4, 5 and 7 is the most frequent, but 4 is closest to the top. The
stack becomes [5,7].
```

Constraints:

- $0 <= val <= 10^9$
- At most $2 * 10^4$ calls will be made to `push` and `pop`.
- It is guaranteed that there will be at least one element in the stack before calling `pop`.

SOLUTIONS (PYTHON 3)

Solution 1: Hash Table + Priority Queue (Max Heap)

How to think about it

Pop the current most frequent value, breaking ties by recency. Up to $2 \cdot 10^4$ operations, so scanning the stack is too slow. We need both frequency and a timestamp. A map stores frequencies; a heap stores (-freq,-ts,val). After popping, decrement that value's frequency. Stale heap entries are left behind and will not be chosen while a newer, higher frequency exists.

According to the problem description, we need to design a data structure that supports popping out the element with the highest frequency. If multiple elements have the same frequency, the element closest to the top of the stack should be

popped out.

We can use a hash table cnt to record the frequency of each element, and a priority queue (max heap) q to maintain the frequency of elements and their corresponding timestamps.

When performing a push operation, we first increment the current timestamp, i.e., ts ← ts + 1; then we increment the frequency of the element val, i.e., cnt[val] ← cnt[val] + 1, and finally, we add the triplet (cnt[val], ts, val) to the priority queue q. The time complexity of the push operation is O(log n).

When performing a pop operation, we directly pop an element from the priority queue q. Since the elements in the priority queue q are sorted in descending order of frequency, the popped element is definitely the one with the highest frequency. If multiple elements have the same frequency, the element closest to the top of the stack is popped out, i.e., the element with the largest timestamp is popped out. After popping, we decrement the frequency of the popped element, i.e., cnt[val] ← cnt[val] - 1. The time complexity of the pop operation is O(log n).

Python 3

```python
class FreqStack:
    def __init__(self):
        self.cnt = defaultdict(int)
        self.q = []
        self.ts = 0

    def push(self, val: int) -> None:
        self.ts += 1
        self.cnt[val] += 1
        heappush(self.q, (-self.cnt[val], -self.ts, val))

    def pop(self) -> int:
        val = heappop(self.q)[2]
        self.cnt[val] -= 1
        return val

# Your FreqStack object will be instantiated and called as such:
# obj = FreqStack()
# obj.push(val)
# param_2 = obj.pop()
```

Solution 2: Double Hash Tables

> **How to think about it**
>
> The heap retains stale frequency records. Bucketing by frequency is cleaner: level f is a stack of values whose current frequency is f. Push appends to level f+1 and updates the maximum frequency; pop takes the top of the highest level and decreases the maximum when that level empties. Each operation is amortized O(1).

In Solution 1, in order to pop out the required element, we maintained a priority queue and had to operate on it each time, which has a time complexity of O(log n). If we can find the required element in O(1) time, then the time complexity of each operation of the entire data structure can be reduced to O(1).

In fact, we can use a variable mx to record the current maximum frequency, a hash table d to record the list of elements corresponding to each frequency, and as in Solution 1, a hash table cnt to record the frequency of each element.

When performing a push operation, we increment the frequency of the element, i.e., cnt[val] ← cnt[val] + 1, and then add the element val to the corresponding frequency list in the hash table d, i.e., d[cnt[val]].push(val). If the current element's frequency is greater than mx, then update mx, i.e., mx ← cnt[val]. The time complexity of the push operation is O(1).

When performing a pop operation, we take the list of elements with frequency mx from the hash table d, pop out the last element val in the list, and then remove val from the hash table d, i.e., d[mx].pop(). Finally, we decrement the frequency of val, i.e., cnt[val] ← cnt[val] - 1. If the list d[mx] is empty, it means that all elements with the current maximum frequency have been popped out, and we need to decrement mx, i.e., mx ← mx - 1. The time complexity of the pop operation is O(1).

Python 3

```
class FreqStack:
    def __init__(self):
        self.cnt = defaultdict(int)
        self.d = defaultdict(list)
        self.mx = 0

    def push(self, val: int) -> None:
        self.cnt[val] += 1
        self.d[self.cnt[val]].append(val)
        self.mx = max(self.mx, self.cnt[val])

    def pop(self) -> int:
        val = self.d[self.mx].pop()
        self.cnt[val] -= 1
        if not self.d[self.mx]:
            self.mx -= 1
        return val

# Your FreqStack object will be instantiated and called as such:
# obj = FreqStack()
# obj.push(val)
# param_2 = obj.pop()
```

2296. Design a Text Editor

Hard · Stack, Design, Linked List, String, Doubly-Linked List, Simulation

leetcode.com/problems/design-a-text-editor

★ **TOP 10 PROBLEM** in Data Structure Design: master this one first

PROBLEM

Design a text editor with a cursor that can do the following:

- **Add** text to where the cursor is.
- **Delete** text from where the cursor is (simulating the backspace key).
- **Move** the cursor either left or right.

When deleting text, only characters to the left of the cursor will be deleted. The cursor will also remain within the actual text and cannot be moved beyond it. More formally, we have that `0 <= cursor.position <= currentText.length` always holds.

Implement the `TextEditor` class:

- `TextEditor()` Initializes the object with empty text.
- `void addText(string text)` Appends `text` to where the cursor is. The cursor ends to the right of `text`.
- `int deleteText(int k)` Deletes `k` characters to the left of the cursor. Returns the number of characters actually deleted.
- `string cursorLeft(int k)` Moves the cursor to the left `k` times. Returns the last `min(10, len)` characters to the left of the cursor, where `len` is the number of characters to the left of the cursor.
- `string cursorRight(int k)` Moves the cursor to the right `k` times. Returns the last `min(10, len)` characters to the left of the cursor, where `len` is the number of characters to the left of the cursor.

Example 1:

```
Input
["TextEditor", "addText", "deleteText", "addText", "cursorRight", "cursorLeft", "deleteText",
"cursorLeft", "cursorRight"]
[[], ["leetcode"], [4], ["practice"], [3], [8], [10], [2], [6]]
Output
[null, null, 4, null, "etpractice", "leet", 4, "", "practi"]

Explanation
TextEditor textEditor = new TextEditor(); // The current text is "|". (The '|' character represents
the cursor)
textEditor.addText("leetcode"); // The current text is "leetcode|".
textEditor.deleteText(4); // return 4
                          // The current text is "leet|".
                          // 4 characters were deleted.
textEditor.addText("practice"); // The current text is "leetpractice|".
textEditor.cursorRight(3); // return "etpractice"
                           // The current text is "leetpractice|".
                           // The cursor cannot be moved beyond the actual text and thus did not move.
                           // "etpractice" is the last 10 characters to the left of the cursor.
textEditor.cursorLeft(8); // return "leet"
                          // The current text is "leet|practice".
                          // "leet" is the last min(10, 4) = 4 characters to the left of the cursor.
textEditor.deleteText(10); // return 4
                           // The current text is "|practice".
                           // Only 4 characters were deleted.
textEditor.cursorLeft(2); // return ""
                          // The current text is "|practice".
                          // The cursor cannot be moved beyond the actual text and thus did not move.
                          // "" is the last min(10, 0) = 0 characters to the left of the cursor.
textEditor.cursorRight(6); // return "practi"
                           // The current text is "practi|ce".
                           // "practi" is the last min(10, 6) = 6 characters to the left of the
cursor.
```

Constraints:

- `1 <= text.length, k <= 40`
- `text` consists of lowercase English letters.
- At most `2 * 10^4` calls **in total** will be made to `addText`, `deleteText`, `cursorLeft` and `cursorRight`.

Follow-up: Could you find a solution with time complexity of `O(k)` per call?

SOLUTION (PYTHON 3)

> **How to think about it**
>
> The editor inserts, deletes, and moves a cursor; there are 2× 10^4 calls and each text is short. Concatenating a whole string on every move would copy too much. The cursor splits the text into two stacks with amortized O(1) edits at the split. left is left of the cursor, right is right of it (tops face the cursor). Insert and delete touch only left; moves pour up to k characters between the stacks. The last ten characters of left are returned.

We can use two stacks, left and right, where the stack left stores the characters to the left of the cursor, and the stack right stores the characters to the right of the cursor.

- When calling the addText method, we push the characters in text onto the left stack one by one. The time complexity is O(|text|).
- When calling the deleteText method, we pop characters from the left stack up to k times. The time complexity is O(k).
- When calling the cursorLeft method, we pop characters from the left stack up to k times, then push the popped characters onto the right stack one by one, and finally return up to 10 characters from the left stack. The time complexity

is O(k).

- When calling the cursorRight method, we pop characters from the right stack up to k times, then push the popped characters onto the left stack one by one, and finally return up to 10 characters from the left stack. The time complexity is O(k).

Python 3

```
class TextEditor:
    def __init__(self):
        self.left = []
        self.right = []

    def addText(self, text: str) -> None:
        self.left.extend(list(text))

    def deleteText(self, k: int) -> int:
        k = min(k, len(self.left))
        for _ in range(k):
            self.left.pop()
        return k

    def cursorLeft(self, k: int) -> str:
        k = min(k, len(self.left))
        for _ in range(k):
            self.right.append(self.left.pop())
        return ''.join(self.left[-10:])

    def cursorRight(self, k: int) -> str:
        k = min(k, len(self.right))
        for _ in range(k):
            self.left.append(self.right.pop())
        return ''.join(self.left[-10:])

# Your TextEditor object will be instantiated and called as such:
# obj = TextEditor()
# obj.addText(text)
# param_2 = obj.deleteText(k)
# param_3 = obj.cursorLeft(k)
# param_4 = obj.cursorRight(k)
```

455. Assign Cookies

Easy · Greedy, Array, Two Pointers, Sorting, Quick Sort

leetcode.com/problems/assign-cookies

★ **TOP 10 PROBLEM** in Greedy: master this one first

PROBLEM

Assume you are an awesome parent and want to give your children some cookies. But, you should give each child at most one cookie.

Each child `i` has a greed factor `g[i]`, which is the minimum size of a cookie that the child will be content with; and each cookie `j` has a size `s[j]`. If `s[j] >= g[i]`, we can assign the cookie `j` to the child `i`, and the child `i` will be content. Your goal is to maximize the number of your content children and output the maximum number.

Example 1:

```
Input: g = [1,2,3], s = [1,1]
Output: 1
Explanation: You have 3 children and 2 cookies. The greed factors of 3 children are 1, 2, 3.
And even though you have 2 cookies, since their size is both 1, you could only make the child whose
greed factor is 1 content.
You need to output 1.
```

Example 2:

```
Input: g = [1,2], s = [1,2,3]
Output: 2
Explanation: You have 2 children and 3 cookies. The greed factors of 2 children are 1, 2.
You have 3 cookies and their sizes are big enough to gratify all of the children,
You need to output 2.
```

Constraints:

- $1 <= g.length <= 3 * 10^4$
- $0 <= s.length <= 3 * 10^4$
- $1 <= g[i], s[j] <= 2^{31} - 1$

Note: This question is the same as 2410: Maximum Matching of Players With Trainers.

SOLUTION (PYTHON 3)

Solution 1: Sorting + Two Pointers

How to think about it

Each cookie feeds at most one child; we want as many content children as possible. Small cookies should go to small appetites, otherwise a large cookie is wasted. Sort both arrays. A cookie pointer skips sizes that are too small and advances together with the child when the size is enough. Exhausting the cookies returns how many children were fed. After sorting, the two pointers always try the current cookie on the easiest remaining child.

According to the problem description, we should prioritize giving cookies to children with smaller appetites, so as to satisfy as many children as possible.

Therefore, we first sort the two arrays, and then use two pointers i and j to point to the head of arrays g and s respectively. Each time we compare the size of g[i] and s[j]:

- If s[j] < g[i], it means that the current cookie s[j] cannot satisfy the current child g[i]. We should allocate a larger cookie to the current child, so j should move to the right by one. If j goes out of bounds, it means that the current child cannot be satisfied. At this time, the number of successfully allocated children is i, and we can return directly.

- If s[j] ≥ g[i], it means that the current cookie s[j] can satisfy the current child g[i]. We allocate the current cookie to the current child, so both i and j should move to the right by one.

If we have traversed the array g, it means that all children have been allocated cookies, and we can return the total number of children.

The time complexity is O(m × log m + n × log n), and the space complexity is O(log m + log n). Where m and n are the lengths of arrays g and s respectively.

Python 3

```
class Solution:
    def findContentChildren(self, g: List[int], s: List[int]) -> int:
        g.sort()
        s.sort()
        j = 0
        for i, x in enumerate(g):
            while j < len(s) and s[j] < g[i]:
                j += 1
            if j >= len(s):
                return i
            j += 1
        return len(g)
```

    return i
```

PART 2 · GREEDY · PROBLEM 2 OF 8

3074. Apple Redistribution into Boxes

Easy · Greedy, Array, Sorting

leetcode.com/problems/apple-redistribution-into-boxes

★ **TOP 10 PROBLEM** in Greedy: master this one first

PROBLEM

You are given an array `apple` of size `n` and an array `capacity` of size `m`.

There are `n` packs where the i^{th} pack contains `apple[i]` apples. There are `m` boxes as well, and the i^{th} box has a capacity of `capacity[i]` apples.

Return *the **minimum** number of boxes you need to select to redistribute these* `n` *packs of apples into boxes.*

Note that, apples from the same pack can be distributed into different boxes.

Example 1:

```
Input: apple = [1,3,2], capacity = [4,3,1,5,2]
Output: 2
Explanation: We will use boxes with capacities 4 and 5.
It is possible to distribute the apples as the total capacity is greater than or equal to the total
number of apples.
```

Example 2:

```
Input: apple = [5,5,5], capacity = [2,4,2,7]
Output: 4
Explanation: We will need to use all the boxes.
```

Constraints:

- `1 <= n == apple.length <= 50`
- `1 <= m == capacity.length <= 50`
- `1 <= apple[i], capacity[i] <= 50`
- The input is generated such that it's possible to redistribute packs of apples into boxes.

SOLUTION (PYTHON 3)

Solution 1: Greedy + Sorting

How to think about it

Apples may be reboxed arbitrarily; we want the fewest boxes. n,m ≤ 50. Only the sum of capacities versus the total number of apples matters. Larger boxes reach that sum sooner. Sort capacities decreasingly, subtract from the apple total, and return how many boxes were used.

To minimize the number of boxes needed, we should prioritize using boxes with larger capacities. Therefore, we can sort the boxes in descending order of capacity, and then use the boxes one by one until all the apples are packed. We return the number of boxes used at this point.

The time complexity is O(m × log m + n) and the space complexity is O(log m), where m and n are the lengths of the arrays capacity and apple respectively.

Python 3

```python
class Solution:
    def minimumBoxes(self, apple: List[int], capacity: List[int]) -> int:
        capacity.sort(reverse=True)
        s = sum(apple)
        for i, c in enumerate(capacity, 1):
            s -= c
            if s <= 0:
                return i
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

Built on the solutions above: helper functions, then the function for each follow-up. No tests and no restating of the question.

```python
# FOLLOW-UPS (answered below, in this order):
# 1. Return the boxes that are used
# 2. How many boxes are used and how much capacity is left
# unused

# ============================================================
# FOLLOW-UP 1: Return the boxes that are used
# ============================================================

# ---- follow-up 1: function ----
# Answer: Sort the capacities from big to small and take
# boxes until all apples fit.
# Time: O(m log m).  Space: O(m).
def boxes_used(apple, capacity):
    total = sum(apple)
    chosen = []
    for c in sorted(capacity, reverse=True):
        if total <= 0:
            break
        chosen.append(c)
        total -= c
    return chosen

# ============================================================
# FOLLOW-UP 2: How many boxes are used and how much
# capacity is left unused
# ============================================================

# ---- follow-up 2: function ----
# Answer: Take the biggest boxes first; the unused
# capacity is the total of the chosen boxes minus the
# apples.
# Time: O(m log m).  Space: O(m).
def boxes_and_unused(apple, capacity):
    total = sum(apple)
    used = 0
    held = 0
    for c in sorted(capacity, reverse=True):
        if held >= total:
            break
        used += 1
        held += c
    return used, held - total
```

PART 2 · GREEDY · PROBLEM 3 OF 8

826. Most Profit Assigning Work

Medium · Greedy, Array, Two Pointers, Binary Search, Sorting

leetcode.com/problems/most-profit-assigning-work

★ **TOP 10 PROBLEM** in Greedy: master this one first

PROBLEM

You have `n` jobs and `m` workers. You are given three arrays: `difficulty`, `profit`, and `worker` where:

- `difficulty[i]` and `profit[i]` are the difficulty and the profit of the i^{th} job, and
- `worker[j]` is the ability of j^{th} worker (i.e., the j^{th} worker can only complete a job with difficulty at most `worker[j]`).

Every worker can be assigned **at most one job**, but one job can be **completed multiple times**.

- For example, if three workers attempt the same job that pays `$1`, then the total profit will be `$3`. If a worker cannot complete any job, their profit is `$0`.

Return the maximum profit we can achieve after assigning the workers to the jobs.

Example 1:

```
Input: difficulty = [2,4,6,8,10], profit = [10,20,30,40,50], worker = [4,5,6,7]
Output: 100
Explanation: Workers are assigned jobs of difficulty [4,4,6,6] and they get a profit of [20,20,30,30]
separately.
```

Example 2:

```
Input: difficulty = [85,47,57], profit = [24,66,99], worker = [40,25,25]
Output: 0
```

Constraints:

- `n == difficulty.length`
- `n == profit.length`
- `m == worker.length`
- `1 <= n, m <= 10^4`
- `1 <= difficulty[i], profit[i], worker[i] <= 10^5`

SOLUTIONS (PYTHON 3)

Solution 1: Sorting + Two Pointers

How to think about it

A worker takes the most profitable job whose difficulty is at most their ability. Scanning every job per worker is slow for $n,m \le 10^4$. Sort workers by ability and jobs by difficulty, then advance a pointer: ability is monotone, so we can maintain the best profit so far. Each worker reads that maximum in O(1).

We can sort the jobs in ascending order of ability, and then sort the jobs in ascending order of difficulty.

Then we traverse the workers. For each worker, we find the job with the maximum profit that he can complete, and then add this profit to the answer.

The time complexity is $O(n \times \log n + m \times \log m)$, and the space complexity is $O(n)$. Where n and m are the lengths of the arrays `profit` and `worker` respectively.

Python 3

```python
class Solution:
    def maxProfitAssignment(
        self, difficulty: List[int], profit: List[int], worker: List[int]
    ) -> int:
        worker.sort()
        jobs = sorted(zip(difficulty, profit))
        ans = mx = i = 0
        for w in worker:
            while i < len(jobs) and jobs[i][0] <= w:
                mx = max(mx, jobs[i][1])
                i += 1
            ans += mx
        return ans
```

Solution 2: Dynamic Programming

> **How to think about it**
>
> The two-pointer method sorts both arrays. Difficulty is at most 10^5, so f[d] can store the best profit of exact difficulty d, then a prefix maximum gives the best job of difficulty ≤ i. Each worker is a table lookup. Workers need not be sorted, which is convenient when the difficulty range is modest.

Let's denote m = max(difficulty) and define an array f of length m + 1, where f[i] represents the maximum profit among jobs with difficulty less than or equal to i, initially f[i] = 0.

Then, we iterate over the jobs, and for each job (d, p), if d ≤ m, we update f[d] = max(f[d], p).

Next, we iterate from 1 to m, and for each i, we update f[i] = max(f[i], f[i - 1]).

Finally, we iterate over the workers, and for each worker w, we add f[w] to the answer.

The time complexity is O(n + M), and the space complexity is O(M). Here, n is the length of the `profit` array, and M is the maximum value in the `difficulty` array.

Python 3

```python
class Solution:
    def maxProfitAssignment(
        self, difficulty: List[int], profit: List[int], worker: List[int]
    ) -> int:
        m = max(difficulty)
        f = [0] * (m + 1)
        for d, p in zip(difficulty, profit):
            f[d] = max(f[d], p)
        for i in range(1, m + 1):
            f[i] = max(f[i], f[i - 1])
        return sum(f[min(w, m)] for w in worker)
```

PART 2 · GREEDY · PROBLEM 4 OF 8

1488. Avoid Flood in The City

Medium · Greedy, Array, Hash Table, Binary Search, Heap (Priority Queue)

leetcode.com/problems/avoid-flood-in-the-city

★ **TOP 10 PROBLEM** in Greedy: master this one first

PROBLEM

Your country has 10^9 lakes. Initially, all the lakes are empty, but when it rains over the n^{th} lake, the n^{th} lake becomes full of water. If it rains over a lake that is **full of water**, there will be a **flood**. Your goal is to avoid floods in any lake.

Given an integer array `rains` where:

- `rains[i] > 0` means there will be rains over the `rains[i]` lake.
- `rains[i] == 0` means there are no rains this day and you **must** choose **one lake** this day and **dry it**.

Return *an array* `ans` where:

- `ans.length == rains.length`
- `ans[i] == -1` if `rains[i] > 0`.
- `ans[i]` is the lake you choose to dry in the `ith` day if `rains[i] == 0`.

If there are multiple valid answers return **any** of them. If it is impossible to avoid flood return **an empty array**.

Notice that if you chose to dry a full lake, it becomes empty, but if you chose to dry an empty lake, nothing changes.

Example 1:

```
Input: rains = [1,2,3,4]
Output: [-1,-1,-1,-1]
Explanation: After the first day full lakes are [1]
After the second day full lakes are [1,2]
After the third day full lakes are [1,2,3]
After the fourth day full lakes are [1,2,3,4]
There's no day to dry any lake and there is no flood in any lake.
```

Example 2:

```
Input: rains = [1,2,0,0,2,1]
Output: [-1,-1,2,1,-1,-1]
Explanation: After the first day full lakes are [1]
After the second day full lakes are [1,2]
After the third day, we dry lake 2. Full lakes are [1]
After the fourth day, we dry lake 1. There is no full lakes.
After the fifth day, full lakes are [2].
After the sixth day, full lakes are [1,2].
It is easy that this scenario is flood-free. [-1,-1,1,2,-1,-1] is another acceptable scenario.
```

Example 3:

```
Input: rains = [1,2,0,1,2]
Output: []
Explanation: After the second day, full lakes are [1,2]. We have to dry one lake in the third day.
After that, it will rain over lakes [1,2]. It's easy to prove that no matter which lake you choose to
dry in the 3rd day, the other one will flood.
```

Constraints:

- `1 <= rains.length <= 10^5`
- `0 <= rains[i] <= 10^9`

SOLUTION (PYTHON 3)

Solution 1: Greedy + Binary Search

How to think about it

$n \le 10^5$. A lake that rains a second time must have been dried after the previous rain. A dry day should be spent on the lake that will rain again soonest among those still full. Store dry days in a sorted list and the last rain day of each lake in a map. On a repeat rain, binary-search the first dry day after that last rain; if none exists, fail. Unused dry days become 1.

We store all sunny days in the sunny array or a sorted set, and use the hash table rainy to record the last rainy day for each lake. We initialize the answer array ans with each element set to -1.

Next, we traverse the rains array. For each rainy day i, if rainy[rains[i]] exists, it means that the lake has rained before, so we need to find the first date in the sunny array that is greater than rainy[rains[i]], and replace it with the rainy day. Otherwise, it means that the flood cannot be prevented, and we return an empty array. For each non-rainy day i, we store i in the sunny array and set ans[i] to 1.

After the traversal, we return the answer array.

The time complexity is O(n × log n), and the space complexity is O(n). Here, n is the length of the rains array.

Python 3

```
class Solution:
    def avoidFlood(self, rains: List[int]) -> List[int]:
        n = len(rains)
        ans = [-1] * n
        sunny = SortedList()
        rainy = {}
        for i, v in enumerate(rains):
            if v:
                if v in rainy:
                    idx = sunny.bisect_right(rainy[v])
                    if idx == len(sunny):
                        return []
                    ans[sunny[idx]] = v
                    sunny.discard(sunny[idx])
                rainy[v] = i
            else:
                sunny.add(i)
                ans[i] = 1
        return ans
```

1717. Maximum Score From Removing Substrings

Medium · Stack, Greedy, String

leetcode.com/problems/maximum-score-from-removing-substrings

★ **TOP 10 PROBLEM** in Greedy: master this one first

PROBLEM

You are given a string `s` and two integers `x` and `y`. You can perform two types of operations any number of times.

- Remove substring `"ab"` and gain `x` points.
  - For example, when removing `"ab"` from `"cabxbae"` it becomes `"cxbae"`.
- Remove substring `"ba"` and gain `y` points.
  - For example, when removing `"ba"` from `"cabxbae"` it becomes `"cabxe"`.

Return *the maximum points you can gain after applying the above operations on* `s`.

Example 1:

```
Input: s = "cdbcbbaaabab", x = 4, y = 5
Output: 19
Explanation:
- Remove the "ba" underlined in "cdbcbbaaabab". Now, s = "cdbcbbaaab" and 5 points are added to the score.
- Remove the "ab" underlined in "cdbcbbaaab". Now, s = "cdbcbbaa" and 4 points are added to the score.
- Remove the "ba" underlined in "cdbcbbaa". Now, s = "cdbcba" and 5 points are added to the score.
- Remove the "ba" underlined in "cdbcba". Now, s = "cdbc" and 5 points are added to the score.
Total score = 5 + 4 + 5 + 5 = 19.
```

Example 2:

```
Input: s = "aabbaaxybbaabb", x = 5, y = 4
Output: 20
```

Constraints:

- `1 <= s.length <= 10^5`
- `1 <= x, y <= 10^4`
- `s` consists of lowercase English letters.

SOLUTION (PYTHON 3)

Solution 1: Greedy

How to think about it

Deleting ab scores x and ba scores y; each deletion changes adjacency. Searching deletion orders is infeasible on long strings. A run of only a and b always ends with a single letter; the number of operations is fixed by the two counts. Higher-scoring pairs should be taken first. Swap letters and scores when x<y. While scanning, match the high-score pair against a counter; at a separator or the end, settle the low-score pair with $\min(cnt_a, cnt_b)$.

We can assume that the score of substring "ab" is always no less than the score of substring "ba". If not, we can swap "a" and "b", and simultaneously swap x and y.

Next, we only need to consider the case where the string contains only "a" and "b". If the string contains other characters, we can treat them as split points, dividing the string into several substrings that contain only "a" and "b", and then calculate the score for each substring separately.

We observe that for a substring containing only "a" and "b", no matter what operations we take, we will eventually be left with only one type of character, or an empty string. Since each operation removes one "a" and one "b" simultaneously, the total number of operations is fixed. We can greedily remove "ab" first, then remove "ba", which ensures the maximum score.

Therefore, we can use two variables cnt1 and cnt2 to record the counts of "a" and "b" respectively, then traverse the string and update cnt1 and cnt2 according to different cases of the current character, while calculating the score.

For the current character c being traversed:

- If c is "a", since we want to remove "ab" first, we don't eliminate this character at this time, only increment cnt1;
- If c is "b", if cnt1 > 0 at this time, we can eliminate one "ab" and add x points; otherwise, we can only increment cnt2;
- If c is another character, then for this substring, we have cnt2 "b"s and cnt1 "a"s left. We can eliminate min(cnt1, cnt2) "ba"s and add several y points.

After traversal, we need to handle the remaining "ba"s and add several y points.

The time complexity is O(n), where n is the length of string s. The space complexity is O(1).

Python 3

```python
class Solution:
    def maximumGain(self, s: str, x: int, y: int) -> int:
        a, b = "a", "b"
        if x < y:
            x, y = y, x
            a, b = b, a
        ans = cnt1 = cnt2 = 0
        for c in s:
            if c == a:
                cnt1 += 1
            elif c == b:
                if cnt1:
                    ans += x
                    cnt1 -= 1
                else:
                    cnt2 += 1
            else:
                ans += min(cnt1, cnt2) * y
                cnt1 = cnt2 = 0
        ans += min(cnt1, cnt2) * y
        return ans
```

```

PART 2 · GREEDY · PROBLEM 6 OF 8

1871. Jump Game VII

Medium · String, Dynamic Programming, Prefix Sum, Sliding Window

leetcode.com/problems/jump-game-vii

★ **TOP 10 PROBLEM** in Greedy: master this one first

PROBLEM

You are given a **0-indexed** binary string `s` and two integers `minJump` and `maxJump`. In the beginning, you are standing at index `0`, which is equal to `'0'`. You can move from index `i` to index `j` if the following conditions are fulfilled:

- `i + minJump <= j <= min(i + maxJump, s.length - 1)`, and
- `s[j] == '0'`.

Return `true` *if you can reach index* `s.length - 1` *in* `s`, *or* `false` *otherwise.*

Example 1:

```
Input: s = "011010", minJump = 2, maxJump = 3
Output: true
Explanation:
In the first step, move from index 0 to index 3.
In the second step, move from index 3 to index 5.
```

Example 2:

```
Input: s = "01101110", minJump = 2, maxJump = 3
Output: false
```

Constraints:

- `2 <= s.length <= 10^5`
- `s[i]` is either `'0'` or `'1'`.
- `s[0] == '0'`
- `1 <= minJump <= maxJump < s.length`

SOLUTION (PYTHON 3)

Solution 1: Prefix Sum + Dynamic Programming

How to think about it

From index 0 we may jump to a `'0'` whose distance lies in [minJump,maxJump]. Checking the jump window from every index is too slow for n≤ 10^5. f[i] is true iff s[i]='0' and some reachable index sits in [i-maxJump,i-minJump]. A prefix sum of f answers that range in O(1), so we fill f from left to right.

We define a prefix sum array pre of length n+1, where pre[i] represents the number of reachable positions in the first i positions of s. We define a boolean array f of length n, where f[i] indicates whether s[i] is reachable. Initially, pre[1] = 1 and f[0] = true.

Consider $i \in [1, n)$, if s[i] = 0, then we need to determine whether there exists a position j in the first i positions of s, such that j is reachable and the distance from j to i is within [minJump, maxJump]. If such a position j exists, then we have f[i] = true, otherwise f[i] = false. When determining whether j exists, we can use the prefix sum array pre to determine whether such a position j exists in O(1) time.

The final answer is f[n-1].

The time complexity is O(n), and the space complexity is O(n). Here, n is the length of the string s.

Python 3

```python
class Solution:
    def canReach(self, s: str, minJump: int, maxJump: int) -> bool:
        n = len(s)
        pre = [0] * (n + 1)
        pre[1] = 1
        f = [True] + [False] * (n - 1)
        for i in range(1, n):
            if s[i] == "0":
                l, r = max(0, i - maxJump), i - minJump
                f[i] = l <= r and pre[r + 1] - pre[l] > 0
            pre[i + 1] = pre[i] + f[i]
        return f[-1]
```

```

PART 2 · GREEDY · PROBLEM 7 OF 8

757. Set Intersection Size At Least Two

Hard · Greedy, Array, Sorting

leetcode.com/problems/set-intersection-size-at-least-two

★ **TOP 10 PROBLEM** in Greedy: master this one first

PROBLEM

You are given a 2D integer array `intervals` where `intervals[i] = [start_i, end_i]` represents all the integers from `start_i` to `end_i` inclusively.

A **containing set** is an array `nums` where each interval from `intervals` has **at least two** integers in `nums`.

- For example, if `intervals = [[1,3], [3,7], [8,9]]`, then `[1,2,4,7,8,9]` and `[2,3,4,8,9]` are **containing sets**.

Return *the minimum possible size of a containing set*.

Example 1:

```
Input: intervals = [[1,3],[3,7],[8,9]]
Output: 5
Explanation: let nums = [2, 3, 4, 8, 9].
It can be shown that there cannot be any containing array of size 4.
```

Example 2:

```
Input: intervals = [[1,3],[1,4],[2,5],[3,5]]
Output: 3
Explanation: let nums = [2, 3, 4].
It can be shown that there cannot be any containing array of size 2.
```

Example 3:

```
Input: intervals = [[1,2],[2,3],[2,4],[4,5]]
Output: 5
Explanation: let nums = [1, 2, 3, 4, 5].
It can be shown that there cannot be any containing array of size 4.
```

Constraints:

- `1 <= intervals.length <= 3000`
- `intervals[i].length == 2`
- `0 <= start_i < end_i <= 10^8`

SOLUTION (PYTHON 3)

Solution 1: Sorting + Greedy

How to think about it

Pick as few points as possible so every interval contains at least two. 3000 intervals rule out subsets. Points should sit as far right as possible to be reused. Sort by end, then by start descending, so tighter intervals come first. Keep the last two placed points s<e. Skip if both lie in the interval; if only e does, add b; if neither does, add b-1 and b. Each step adds the fewest, rightmost points.

We want to select as few integer points as possible on the number line such that each interval contains at least two points. A classic and effective strategy is to sort intervals by their right endpoints and try to place selected points towards the right side of intervals, so that these points can cover more subsequent intervals.

First, sort all intervals by the following rules:

1. Sort by right endpoint in ascending order;
2. If right endpoints are equal, sort by left endpoint in descending order.

The reason for this sorting is: intervals with smaller right endpoints have less "operational space" and should be satisfied first; when right endpoints are equal, intervals with larger left endpoints are narrower and should be prioritized.

Next, we use two variables s and e to record the **second-to-last point** and **last point** that are common to all currently processed intervals. Initially, s = e = -1, indicating that no points have been placed yet.

Then we process the sorted intervals [a, b] one by one, and discuss three cases based on their relationship with {s, e}:

1. **If a ≤ s**: The current interval already contains both points s and e, so no additional points are needed.
2. **If s < a ≤ e**: The current interval only contains one point (i.e., e), and needs one more point. To make the new point most helpful for subsequent intervals, we choose the rightmost point b in the interval. Update ans = ans + 1, and set the new two points to {e, b}.
3. **If a > e**: The current interval does not contain either of the existing two points, so two points need to be added. The optimal choice is to place {b - 1, b} at the rightmost side of the interval. Update ans = ans + 2, and set the new two points to {b - 1, b}.

Finally, return the total number of points placed, ans.

The time complexity is O(n × log n) and the space complexity is O(log n), where n is the number of intervals.

Python 3

```python
class Solution:
    def intersectionSizeTwo(self, intervals: List[List[int]]) -> int:
        intervals.sort(key=lambda x: (x[1], -x[0]))
        s = e = -1
        ans = 0
        for a, b in intervals:
            if a <= s:
                continue
            if a > e:
                ans += 2
                s, e = b - 1, b
            else:
                ans += 1
                s, e = e, b
        return ans
```

            chosen.append(value)
            inside += 1
    return sorted(chosen)
```

PART 2 · GREEDY · PROBLEM 8 OF 8

857. Minimum Cost to Hire K Workers

Hard · Greedy, Array, Sorting, Heap (Priority Queue)

leetcode.com/problems/minimum-cost-to-hire-k-workers

★ **TOP 10 PROBLEM** in Greedy: master this one first

PROBLEM

There are `n` workers. You are given two integer arrays `quality` and `wage` where `quality[i]` is the quality of the i^{th} worker and `wage[i]` is the minimum wage expectation for the i^{th} worker.

We want to hire exactly `k` workers to form a **paid group**. To hire a group of `k` workers, we must pay them according to the following rules:

1. Every worker in the paid group must be paid at least their minimum wage expectation.
2. In the group, each worker's pay must be directly proportional to their quality. This means if a worker's quality is double that of another worker in the group, then they must be paid twice as much as the other worker.

Given the integer `k`, return *the least amount of money needed to form a paid group satisfying the above conditions*. Answers within 10^{-5} of the actual answer will be accepted.

Example 1:

```
Input: quality = [10,20,5], wage = [70,50,30], k = 2
Output: 105.00000
Explanation: We pay 70 to 0th worker and 35 to 2nd worker.
```

Example 2:

```
Input: quality = [3,1,10,10,1], wage = [4,8,2,2,7], k = 3
Output: 30.66667
Explanation: We pay 4 to 0th worker, 13.33333 to 2nd and 3rd workers separately.
```

Constraints:

- `n == quality.length == wage.length`
- `1 <= k <= n <=` 10^4
- `1 <= quality[i], wage[i] <=` 10^4

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Everyone is paid at one ratio, at least their wage expectation; we pick k workers to minimize total pay. The ratio is the max wage/quality in the group. Subsets are impossible for n≤ 10^4. Insert workers by increasing ratio so the current ratio covers the group. A max-heap drops the largest quality to keep size k. Whenever the group has k people, update with current ratio times total quality.

Python 3

```python
class Solution:
    def mincostToHireWorkers(
        self, quality: List[int], wage: List[int], k: int
    ) -> float:
        t = sorted(zip(quality, wage), key=lambda x: x[1] / x[0])
        ans, tot = inf, 0
        h = []
        for q, w in t:
            tot += q
            heappush(h, -q)
            if len(h) == k:
                ans = min(ans, w / q * tot)
                tot += heappop(h)
        return ans
```

Complexity. Time: O(n log n). Space: O(n).

690. Employee Importance

Medium · Tree, Depth-First Search, Breadth-First Search, Array, Hash Table

leetcode.com/problems/employee-importance

★ **TOP 10 PROBLEM** in Depth First Search (DFS): master this one first

PROBLEM

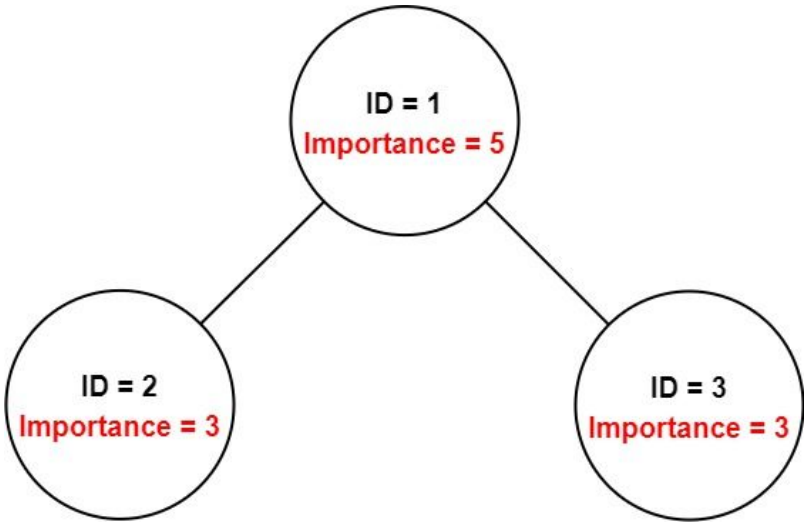
You have a data structure of employee information, including the employee's unique ID, importance value, and direct subordinates' IDs.

You are given an array of employees `employees` where:

- `employees[i].id` is the ID of the i^{th} employee.
- `employees[i].importance` is the importance value of the i^{th} employee.
- `employees[i].subordinates` is a list of the IDs of the direct subordinates of the i^{th} employee.

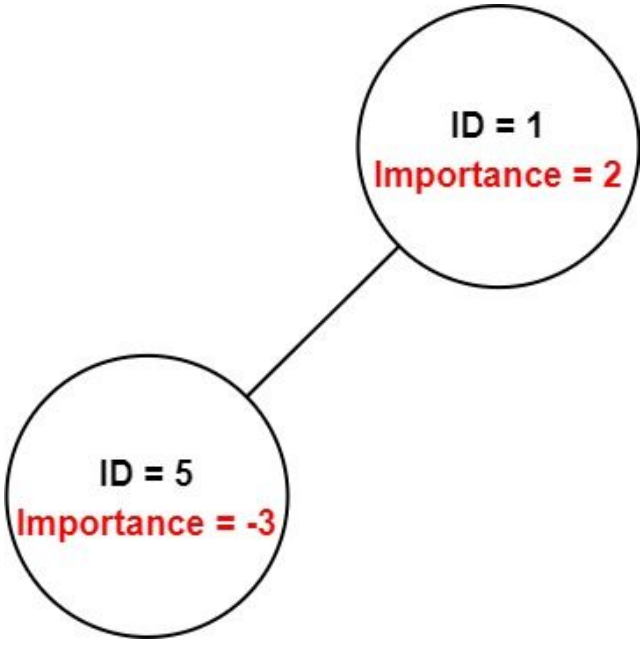
Given an integer `id` that represents an employee's ID, return *the **total** importance value of this employee and all their direct and indirect subordinates*.

Example 1:



```
Input: employees = [[1,5,[2,3]],[2,3,[]],[3,3,[]]], id = 1
Output: 11
Explanation: Employee 1 has an importance value of 5 and has two direct subordinates: employee 2 and
employee 3.
They both have an importance value of 3.
Thus, the total importance value of employee 1 is 5 + 3 + 3 = 11.
```

Example 2:



```
Input: employees = [[1,2,[5]],[5,-3,[]]], id = 5
Output: -3
Explanation: Employee 5 has an importance value of -3 and has no direct subordinates.
Thus, the total importance value of employee 5 is -3.
```

Constraints:

- `1 <= employees.length <= 2000`
- `1 <= employees[i].id <= 2000`
- All `employees[i].id` are **unique**.
- `-100 <= employees[i].importance <= 100`
- One employee has at most one direct leader and may have several subordinates.
- The IDs in `employees[i].subordinates` are valid IDs.

SOLUTION (PYTHON 3)

Solution 1: Hash Table + DFS

> **How to think about it**
>
> Importance is the employee plus every subordinate. Looking up ids in the raw list is linear per hop. Map id to the object, then DFS from the given id: `importance` plus the sum of recursive calls on subordinates.

We use a hash table d to store all employee information, where the key is the employee's ID, and the value is the employee object. Then we start a depth-first search from the given employee ID. Each time we traverse to an employee, we add the employee's importance to the answer, and recursively traverse all the subordinates of the employee, adding the importance of the subordinates to the answer as well.

The time complexity is O(n), and the space complexity is O(n). Where n is the number of employees.

Python 3

```
"""
# Definition for Employee.
class Employee:
    def __init__(self, id: int, importance: int, subordinates: List[int]):
        self.id = id
        self.importance = importance
        self.subordinates = subordinates
"""

class Solution:
    def getImportance(self, employees: List["Employee"], id: int) -> int:
        def dfs(i: int) -> int:
            return d[i].importance + sum(dfs(j) for j in d[i].subordinates)

        d = {e.id: e for e in employees}
        return dfs(id)
```

785. Is Graph Bipartite

Medium · Depth-First Search, Breadth-First Search, Union Find, Graph, Graph Coloring, Bipartite Graph

leetcode.com/problems/is-graph-bipartite

★ **TOP 10 PROBLEM** in Depth First Search (DFS): master this one first

PROBLEM

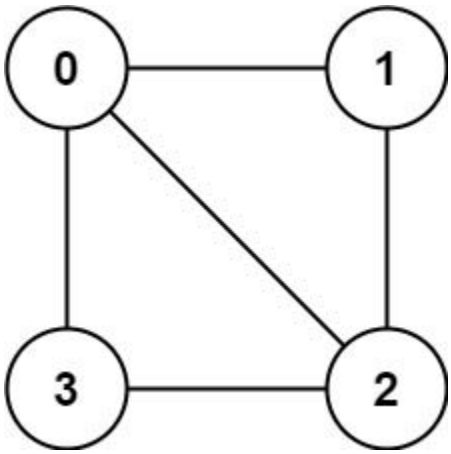
There is an **undirected** graph with `n` nodes, where each node is numbered between `0` and `n - 1`. You are given a 2D array `graph`, where `graph[u]` is an array of nodes that node `u` is adjacent to. More formally, for each `v` in `graph[u]`, there is an undirected edge between node `u` and node `v`. The graph has the following properties:

- There are no self-edges (`graph[u]` does not contain `u`).
- There are no parallel edges (`graph[u]` does not contain duplicate values).
- If `v` is in `graph[u]`, then `u` is in `graph[v]` (the graph is undirected).
- The graph may not be connected, meaning there may be two nodes `u` and `v` such that there is no path between them.

A graph is **bipartite** if the nodes can be partitioned into two independent sets `A` and `B` such that **every** edge in the graph connects a node in set `A` and a node in set `B`.

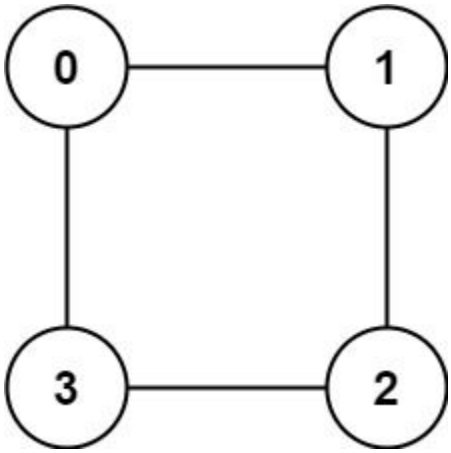
Return `true` *if and only if it is* ***bipartite***.

Example 1:



```
Input: graph = [[1,2,3],[0,2],[0,1,3],[0,2]]
Output: false
Explanation: There is no way to partition the nodes into two independent sets such that every edge
connects a node in one and a node in the other.
```

Example 2:



```
Input: graph = [[1,3],[0,2],[1,3],[0,2]]
Output: true
Explanation: We can partition the nodes into two sets: {0, 2} and {1, 3}.
```

Constraints:

- `graph.length == n`
- `1 <= n <= 100`
- `0 <= graph[u].length < n`
- `0 <= graph[u][i] <= n - 1`
- `graph[u]` does not contain `u`.
- All the values of `graph[u]` are **unique**.
- If `graph[u]` contains `v`, then `graph[v]` contains `u`.

SOLUTIONS (PYTHON 3)

Solution 1: Coloring Method to Determine Bipartite Graph

How to think about it

Decide whether an undirected graph is bipartite. n≤ 100. DFS from each uncolored vertex with two colors; a neighbor already colored the same fails. The graph may be disconnected, so every component is colored.

Traverse all nodes for coloring. For example, initially color them white, and use DFS to color the adjacent nodes with another color. If the target color to be colored is different from the color that the node has already been colored, it means that it cannot form a bipartite graph.

The time complexity is O(n), and the space complexity is O(n). Where n is the number of nodes.

Python 3

```python
class Solution:
    def isBipartite(self, graph: List[List[int]]) -> bool:
        def dfs(a: int, c: int) -> bool:
            color[a] = c
            for b in graph[a]:
                if color[b] == c or (color[b] == 0 and not dfs(b, -c)):
                    return False
            return True

        n = len(graph)
        color = [0] * n
        for i in range(n):
            if color[i] == 0 and not dfs(i, 1):
                return False
        return True
```

Solution 2: Union-Find

> **How to think about it**
>
> Coloring is equivalent to union-find: all neighbors of a belong to one part, not a's. If a and a neighbor share a root, fail; otherwise union the neighbors together.

For this problem, if it is a bipartite graph, then all adjacent nodes of each vertex in the graph should belong to the same set and not be in the same set as the vertex. Therefore, we can use the union-find method. Traverse each vertex in the graph, and if it is found that the current vertex and its corresponding adjacent nodes are in the same set, it means that it is not a bipartite graph. Otherwise, merge the adjacent nodes of the current node.

The time complexity is O(n × log n), and the space complexity is O(n). Where n is the number of nodes.

Python 3

```
class Solution:
    def isBipartite(self, graph: List[List[int]]) -> bool:
        def find(x: int) -> int:
            if p[x] != x:
                p[x] = find(p[x])
            return p[x]

        p = list(range(len(graph)))
        for a, bs in enumerate(graph):
            for b in bs:
                pa, pb = find(a), find(b)
                if pa == pb:
                    return False
                p[pb] = find(bs[0])
        return True
```

1192. Critical Connections in a Network

Hard · Depth-First Search, Graph, Bridge, Biconnected Component

leetcode.com/problems/critical-connections-in-a-network

★ **TOP 10 PROBLEM** in Depth First Search (DFS): master this one first

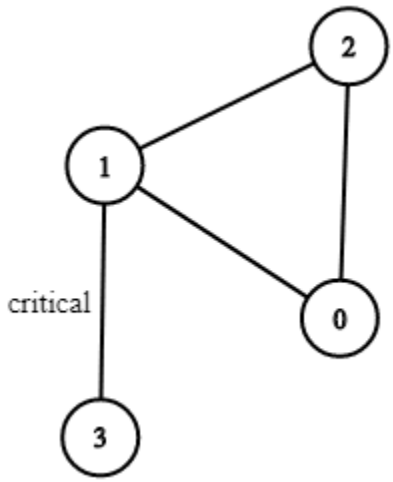
PROBLEM

There are `n` servers numbered from `0` to `n - 1` connected by undirected server-to-server `connections` forming a network where `connections[i] = [a_i, b_i]` represents a connection between servers a_i and b_i. Any server can reach other servers directly or indirectly through the network.

A *critical connection* is a connection that, if removed, will make some servers unable to reach some other server.

Return all critical connections in the network in any order.

Example 1:



```
Input: n = 4, connections = [[0,1],[1,2],[2,0],[1,3]]
Output: [[1,3]]
Explanation: [[3,1]] is also accepted.
```

Example 2:

```
Input: n = 2, connections = [[0,1]]
Output: [[0,1]]
```

Constraints:

- `2 <= n <= 10^5`
- `n - 1 <= connections.length <= 10^5`
- `0 <= a_i, b_i <= n - 1`
- `a_i != b_i`
- There are no repeated connections.

SOLUTION (PYTHON 3)

Solution 1: Tarjan Algorithm

How to think about it

A critical connection is a bridge. Testing each edge with union-find or BFS is too slow on a large edge set. Tarjan's DFS keeps discovery time dfn and earliest ancestor low; a tree edge with low[v]>dfn[u] is a bridge. Skip the parent in an undirected graph so the tree edge is not treated as a back edge.

The "critical connections" in this problem can be considered as "bridges".

"Bridges": In a connected undirected graph, if removing a certain edge makes the graph disconnected, then this edge can be considered as a "bridge".

Correspondingly, there is also the concept of "articulation points".

"Articulation Points": In a connected undirected graph, if removing a certain point and all edges connected to it makes the graph disconnected, then this point can be considered as an "articulation point".

There is an algorithm called the Tarjan algorithm for finding "bridges" and "articulation points" in a graph. This algorithm uses a depth-first search (DFS) method that first recursively visits adjacent nodes and then visits the node itself. By recording the "order of visit: DFN" and updating the "earliest backtrackable node: low" when visiting the node itself after recursion ends, it can find the "bridges" and "articulation points" of the graph in O(n) time. Also, this algorithm can be used to find strongly connected components in directed graphs.

Python 3

```
class Solution:
    def criticalConnections(
        self, n: int, connections: List[List[int]]
    ) -> List[List[int]]:
        def tarjan(a: int, fa: int):
            nonlocal now
            now += 1
            dfn[a] = low[a] = now
            for b in g[a]:
                if b == fa:
                    continue
                if not dfn[b]:
                    tarjan(b, a)
                    low[a] = min(low[a], low[b])
                    if low[b] > dfn[a]:
                        ans.append([a, b])
                else:
                    low[a] = min(low[a], dfn[b])

        g = [[] for _ in range(n)]
        for a, b in connections:
            g[a].append(b)
            g[b].append(a)

        dfn = [0] * n
        low = [0] * n
        now = 0
        ans = []
        tarjan(0, -1)
        return ans
```

2246. Longest Path With Different Adjacent Characters

Hard · Tree, Depth-First Search, Graph, Topological Sort, Array, String

leetcode.com/problems/longest-path-with-different-adjacent-characters

★ **TOP 10 PROBLEM** in Depth First Search (DFS): master this one first

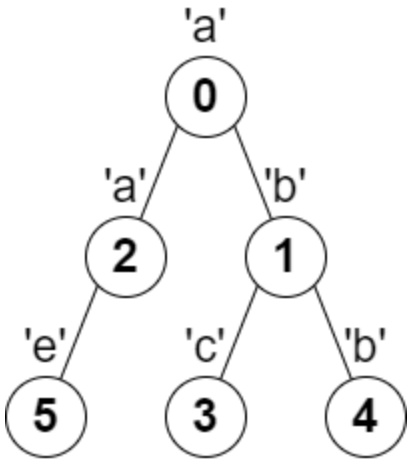
PROBLEM

You are given a **tree** (i.e. a connected, undirected graph that has no cycles) **rooted** at node `0` consisting of `n` nodes numbered from `0` to `n - 1`. The tree is represented by a **0-indexed** array `parent` of size `n`, where `parent[i]` is the parent of node `i`. Since node `0` is the root, `parent[0] == -1`.

You are also given a string `s` of length `n`, where `s[i]` is the character assigned to node `i`.

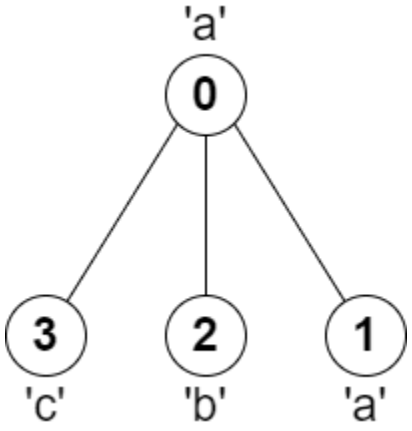
Return *the length of the **longest path** in the tree such that no pair of **adjacent** nodes on the path have the same character assigned to them.*

Example 1:



```
Input: parent = [-1,0,0,1,1,2], s = "abacbe"
Output: 3
Explanation: The longest path where each two adjacent nodes have different characters in the tree is
the path: 0 -> 1 -> 3. The length of this path is 3, so 3 is returned.
It can be proven that there is no longer path that satisfies the conditions.
```

Example 2:



```
Input: parent = [-1,0,0,0], s = "aabc"
Output: 3
Explanation: The longest path where each two adjacent nodes have different characters is the path: 2
-> 0 -> 3. The length of this path is 3, so 3 is returned.
```

Constraints:

- `n == parent.length == s.length`
- `1 <= n <= 10^5`
- `0 <= parent[i] <= n - 1` for all `i >= 1`
- `parent[0] == -1`
- `parent` represents a valid tree.
- `s` consists of only lowercase English letters.

SOLUTIONS (PYTHON 3)

Solution 1: Tree-shaped DP

How to think about it

We want the longest tree path whose adjacent labels differ. $n \le 10^5$ forbids pairing endpoints. A path either stays in one subtree or is the join of two downward chains at a vertex. DFS returns the longest downward chain whose first step has a different character. For each child, join the current best chain with the new one when labels differ, and keep the best downward length. Adding one at the end counts the node itself.

First, we construct an adjacency list g based on the array parent, where g[i] represents all child nodes of node i.

Then we start DFS from the root node. For each node i, we traverse each child node j in g[i]. If s[i] ≠ s[j], then we can start from node i, pass through node j, and reach a leaf node. The length of this path is x = 1 + dfs(j). We use mx to record the longest path length starting from node i. At the same time, we update the answer ans = max(ans, mx + x) during the traversal process.

Finally, we return ans + 1.

The time complexity is O(n), and the space complexity is O(n), where n is the number of nodes.

Python 3

```python
class Solution:
    def longestPath(self, parent: List[int], s: str) -> int:
        def dfs(i: int) -> int:
            mx = 0
            nonlocal ans
            for j in g[i]:
                x = dfs(j) + 1
                if s[i] != s[j]:
                    ans = max(ans, mx + x)
                    mx = max(mx, x)
            return mx

        g = defaultdict(list)
        for i in range(1, len(parent)):
            g[parent[i]].append(i)
        ans = 0
        dfs(0)
        return ans + 1
```

Solution 2: Tree DP + Explicit Stack

How to think about it

We want the longest tree path whose adjacent labels differ. With $n \le 10^5$, recursing from the root for every downward chain is too deep: a chain makes the call depth n. Such a path either stays inside one subtree or joins two downward chains at one vertex. When a node is left, each child's downward length is already known. The chain can be attached only when s[i] ≠ s[j], and its length is the child's length plus one. Join that chain with the best one already seen, then keep the longer of the two as this node's downward chain. An explicit stack of (node, state) runs the postorder. On entry we push the exit marker and then the children, and on exit we update the answer and the downward length. Adding one at the end counts the nodes on the path.

First, we construct an adjacency list g based on the array parent, where g[i] represents all child nodes of node i.

An explicit stack walks from the root in postorder. When node i is left, each child j contributes x, one more than the longest chain downward from j. If s[i] ≠ s[j], update the answer with ans = max(ans, mx + x) and then set mx = max(mx, x). Here mx is the longest downward chain from i whose first step has a different character.

Finally, we return ans + 1.

The time complexity is O(n), and the space complexity is O(n), where n is the number of nodes.

Python 3

```python
class Solution:
    def longestPath(self, parent: List[int], s: str) -> int:
        n = len(parent)
        g = [[] for _ in range(n)]
        for i in range(1, n):
            g[parent[i]].append(i)
        down = [0] * n
        ans = 0
        stk = [(0, 0)]
        while stk:
            i, state = stk.pop()
            if state == 0:
                stk.append((i, 1))
                for j in g[i]:
                    stk.append((j, 0))
            else:
                mx = 0
                for j in g[i]:
                    x = down[j] + 1
                    if s[i] != s[j]:
                        ans = max(ans, mx + x)
                        mx = max(mx, x)
                down[i] = mx
        return ans + 1
```

286. Walls and Gates

Medium · Breadth-First Search, Array, Matrix

leetcode.com/problems/walls-and-gates

★ **TOP 10 PROBLEM** in Breadth First Search (BFS): master this one first

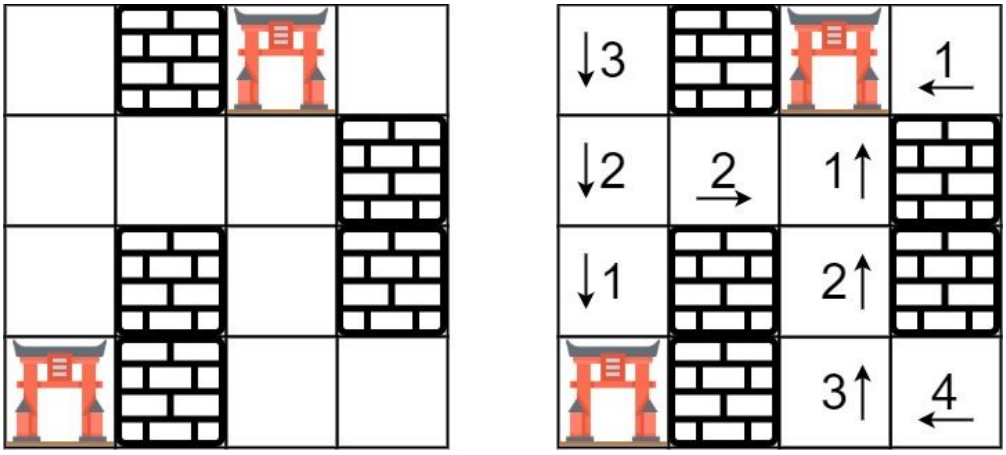
PROBLEM

You are given an `m x n` grid `rooms` initialized with these three possible values.

- `-1` A wall or an obstacle.
- `0` A gate.
- `INF` Infinity means an empty room. We use the value $2^{31} - 1 = 2147483647$ to represent `INF` as you may assume that the distance to a gate is less than `2147483647`.

Fill each empty room with the distance to *its nearest gate*. If it is impossible to reach a gate, it should be filled with `INF`.

Example 1:



```
Input: rooms = [[2147483647,-1,0,2147483647],[2147483647,2147483647,2147483647,-1],[2147483647,-1,2147483647,-1],[0,-1,2147483647,2147483647]]
Output: [[3,-1,0,1],[2,2,1,-1],[1,-1,2,-1],[0,-1,3,4]]
```

Example 2:

```
Input: rooms = [[-1]]
Output: [[-1]]
```

Constraints:

- `m == rooms.length`
- `n == rooms[i].length`
- `1 <= m, n <= 250`
- `rooms[i][j]` is `-1`, `0`, or $2^{31} - 1$.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Each empty room wants the distance to the nearest gate. A BFS from every room repeats work. A multi-source BFS from all gates reaches each room first at its shortest distance. Enqueue every gate and expand level by level, writing only into rooms that are still empty.

Python 3

```
class Solution:
    def wallsAndGates(self, rooms: List[List[int]]) -> None:
        """
        Do not return anything, modify rooms in-place instead.
        """
        m, n = len(rooms), len(rooms[0])
        inf = 2**31 - 1
        q = deque([(i, j) for i in range(m) for j in range(n) if rooms[i][j] == 0])
        d = 0
        while q:
            d += 1
            for _ in range(len(q)):
                i, j = q.popleft()
                for a, b in [[0, 1], [0, -1], [1, 0], [-1, 0]]:
                    x, y = i + a, j + b
                    if 0 <= x < m and 0 <= y < n and rooms[x][y] == inf:
                        rooms[x][y] = d
                        q.append((x, y))
```

Complexity. Time: O(m * n). Space: O(m * n).

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

1102. Path With Maximum Minimum Value

Medium · Depth-First Search, Breadth-First Search, Union Find, Array, Binary Search, Matrix, Dijkstra, Heap (Priority Queue)

leetcode.com/problems/path-with-maximum-minimum-value

★ **TOP 10 PROBLEM** in Breadth First Search (BFS): master this one first

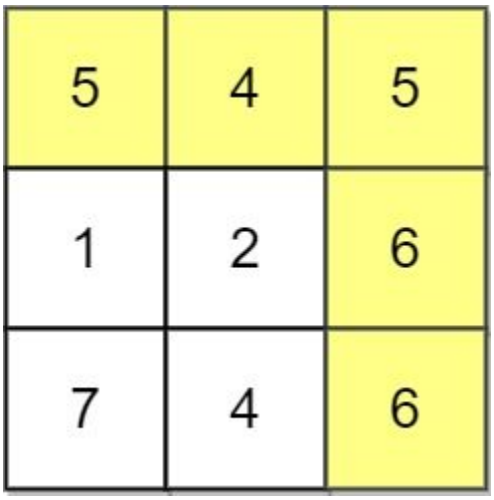
PROBLEM

Given an `m x n` integer matrix `grid`, return *the maximum **score** of a path starting at* `(0, 0)` *and ending at* `(m - 1, n - 1)` moving in the 4 cardinal directions.

The **score** of a path is the minimum value in that path.

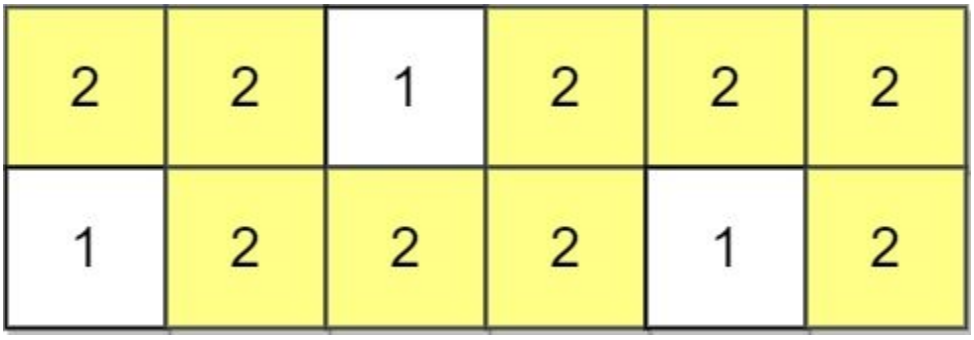
- For example, the score of the path `8 → 4 → 5 → 9` is `4`.

Example 1:



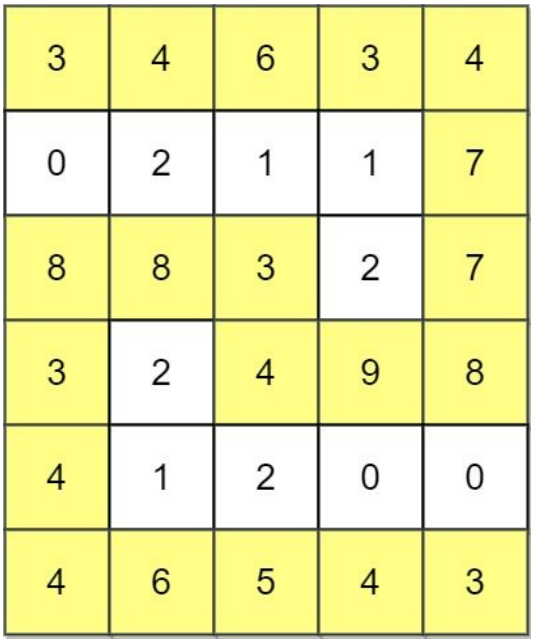
```
Input: grid = [[5,4,5],[1,2,6],[7,4,6]]
Output: 4
Explanation: The path with the maximum score is highlighted in yellow.
```

Example 2:



```
Input: grid = [[2,2,1,2,2,2],[1,2,2,2,1,2]]
Output: 2
```

Example 3:



```
Input: grid = [[3,4,6,3,4],[0,2,1,1,7],[8,8,3,2,7],[3,2,4,9,8],[4,1,2,0,0],[4,6,5,4,3]]
Output: 3
```

Constraints:

- `m == grid.length`
- `n == grid[i].length`
- `1 <= m, n <= 100`
- `0 <= grid[i][j] <= 10^9`

SOLUTIONS (PYTHON 3)

Solution 1: Sorting + Union-Find

> **How to think about it**
>
> The score of a path is its minimum cell, and we want the maximum such score from the top-left to the bottom-right. Enumerating all paths is not viable. Insert cells in decreasing value and union each with already-inserted neighbors. The value just inserted is the lowest score allowed so far; the first time the start and end share a component, no smaller cell can raise that minimum, so that value is the answer.

First, we construct a triplet (v, i, j) for each element in the matrix, where v represents the element value, and i and j represent the row and column of the element in the matrix, respectively. Then we sort these triplets in descending order by element value and store them in a list q.

Next, we take out the triplets from q in order, use the corresponding element value as the score of the path, and mark the position as visited. Then we check the four adjacent positions (up, down, left, and right) of this position. If an adjacent position has been visited, we merge this position with the current position. If we find that the position (0, 0) and the position (m - 1, n - 1) have been merged, we can directly return the score of the current path as the answer.

The time complexity is $O(m \times n \times (\log (m \times n) + \alpha(m \times n)))$, where m and n are the number of rows and columns of the matrix, respectively.

Python 3

```python
class Solution:
    def maximumMinimumPath(self, grid: List[List[int]]) -> int:
        def find(x: int) -> int:
            if p[x] != x:
                p[x] = find(p[x])
            return p[x]

        m, n = len(grid), len(grid[0])
        p = list(range(m * n))
        q = [(v, i, j) for i, row in enumerate(grid) for j, v in enumerate(row)]
        q.sort()
        ans = 0
        dirs = (-1, 0, 1, 0, -1)
        vis = set()
        while find(0) != find(m * n - 1):
            v, i, j = q.pop()
            ans = v
            vis.add((i, j))
            for a, b in pairwise(dirs):
                x, y = i + a, j + b
                if (x, y) in vis:
                    p[find(i * n + j)] = find(x * n + y)
        return ans
```

Solution 2

How to think about it

Method 1 path-compresses on a raw parent array. Method 2 uses a union-by-size `UnionFind`, which keeps trees shallower and the API regular. Cells are still inserted in decreasing order, stopping when start and end become connected.

Python 3

```python
class UnionFind:
    __slots__ = ("p", "size")

    def __init__(self, n):
        self.p = list(range(n))
        self.size = [1] * n

    def find(self, x: int) -> int:
        if self.p[x] != x:
            self.p[x] = self.find(self.p[x])
        return self.p[x]

    def union(self, a: int, b: int) -> bool:
        pa, pb = self.find(a), self.find(b)
        if pa == pb:

1197. Minimum Knight Moves

Medium · Breadth-First Search, Bidirectional Search, A* Search, Heuristic Search

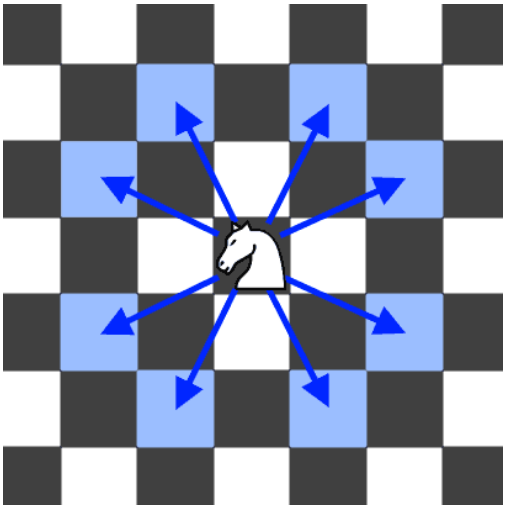
leetcode.com/problems/minimum-knight-moves

★ **TOP 10 PROBLEM** in Breadth First Search (BFS): master this one first

PROBLEM

In an **infinite** chess board with coordinates from `-infinity` to `+infinity`, you have a **knight** at square `[0, 0]`.

A knight has 8 possible moves it can make, as illustrated below. Each move is two squares in a cardinal direction, then one square in an orthogonal direction.



Return *the minimum number of steps needed to move the knight to the square* `[x, y]`. It is guaranteed the answer exists.

Example 1:

```
Input: x = 2, y = 1
Output: 1
Explanation: [0, 0] → [2, 1]
```

Example 2:

```
Input: x = 5, y = 5
Output: 4
Explanation: [0, 0] → [2, 1] → [4, 2] → [3, 4] → [5, 5]
```

Constraints:

- `-300 <= x, y <= 300`
- `0 <= |x| + |y| <= 300`

SOLUTIONS (PYTHON 3)

Solution 1: BFS

How to think about it

A knight has eight jumps; the minimum number of moves is a grid shortest path. BFS from (0,0) returns the layer that first hits (x,y). The coordinate range is bounded; a visited set prevents requeueing. Quadrant symmetry can shrink the search, but plain BFS already passes.

This problem can be solved using the BFS shortest path model. The search space for this problem is not large, so we can directly use the naive BFS. The solution below also provides the code for bidirectional BFS for reference.

Bidirectional BFS is a common optimization method for BFS. The main implementation ideas are as follows:

1. Create two queues, q1 and q2, for "start -> end" and "end -> start" search directions, respectively.
2. Create two hash maps, m1 and m2, to record the visited nodes and their corresponding expansion times (steps).
3. During each search, prioritize the queue with fewer elements for search expansion. If a node visited from the other direction is found during the expansion, it means the shortest path has been found.
4. If one of the queues is empty, it means that the search in the current direction cannot continue, indicating that the start and end points are not connected, and there is no need to continue the search.

Python 3

```python
class Solution:
    def minKnightMoves(self, x: int, y: int) -> int:
        q = deque([(0, 0)])
        ans = 0
        vis = {(0, 0)}
        dirs = ((-2, 1), (-1, 2), (1, 2), (2, 1), (2, -1), (1, -2), (-1, -2), (-2, -1))
        while q:
            for _ in range(len(q)):
                i, j = q.popleft()
                if (i, j) == (x, y):
                    return ans
                for a, b in dirs:
                    c, d = i + a, j + b
                    if (c, d) not in vis:
                        vis.add((c, d))
                        q.append((c, d))
            ans += 1
        return -1
```

Complexity. Time: O(max(|x|, |y|)^2). Space: O(max(|x|, |y|)^2).

Solution 2: Bidirectional BFS

> **How to think about it**
>
> Method 1 grows from one side and the frontier widens far from the origin. Bidirectional BFS expands from both ends, always stepping the smaller queue; the first shared cell is the shortest path and typically visits fewer cells.

Search knight jumps from both ends until the two sides meet.

Python 3

```
class Solution:
    def minKnightMoves(self, x: int, y: int) -> int:
        def extend(m1, m2, q):
            for _ in range(len(q)):
                i, j = q.popleft()
                step = m1[(i, j)]
                for a, b in (
                    (-2, 1),
                    (-1, 2),
                    (1, 2),
                    (2, 1),
                    (2, -1),
                    (1, -2),
                    (-1, -2),
                    (-2, -1),
                ):
                    x, y = i + a, j + b
                    if (x, y) in m1:
                        continue
                    if (x, y) in m2:
                        return step + 1 + m2[(x, y)]
                    q.append((x, y))
                    m1[(x, y)] = step + 1
            return -1

        if (x, y) == (0, 0):
            return 0
        q1, q2 = deque([(0, 0)]), deque([(x, y)])
        m1, m2 = {(0, 0): 0}, {(x, y): 0}
        while q1 and q2:
            t = extend(m1, m2, q1) if len(q1) <= len(q2) else extend(m2, m1, q2)
            if t != -1:
                return t
        return -1
```

Complexity. Time: O(max(|x|, |y|)^2) in the worst case, but much faster in practice (two searches meet in the middle). Space: O(max(|x|, |y|)^2).

2290. Minimum Obstacle Removal to Reach Corner

Hard · Breadth-First Search, Graph, Array, Matrix, Shortest Path, Dijkstra, Heap (Priority Queue), 0-1 BFS

leetcode.com/problems/minimum-obstacle-removal-to-reach-corner

★ **TOP 10 PROBLEM** in Breadth First Search (BFS): master this one first

PROBLEM

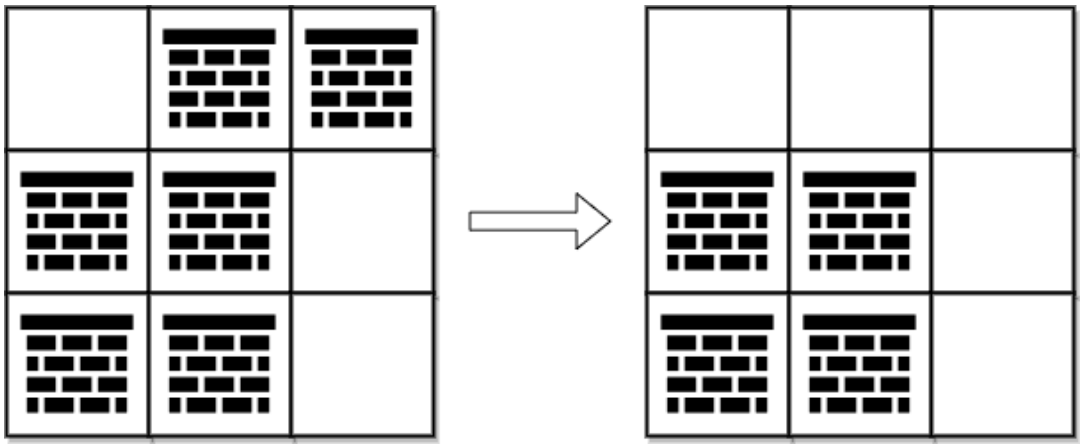
You are given a **0-indexed** 2D integer array `grid` of size `m x n`. Each cell has one of two values:

- `0` represents an **empty** cell,
- `1` represents an **obstacle** that may be removed.

You can move up, down, left, or right from and to an empty cell.

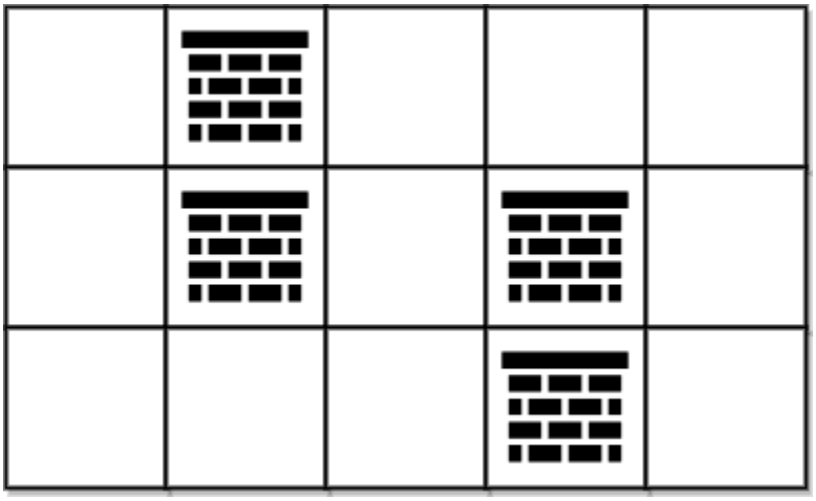
Return *the **minimum** number of **obstacles** to **remove** so you can move from the upper left corner* `(0, 0)` *to the lower right corner* `(m - 1, n - 1)`.

Example 1:



```
Input: grid = [[0,1,1],[1,1,0],[1,1,0]]
Output: 2
Explanation: We can remove the obstacles at (0, 1) and (0, 2) to create a path from (0, 0) to (2, 2).
It can be shown that we need to remove at least 2 obstacles, so we return 2.
Note that there may be other ways to remove 2 obstacles to create a path.
```

Example 2:



```
Input: grid = [[0,1,0,0,0],[0,1,0,1,0],[0,0,0,1,0]]
Output: 0
Explanation: We can move from (0, 0) to (2, 4) without removing any obstacles, so we return 0.
```

Constraints:

- `m == grid.length`
- `n == grid[i].length`
- `1 <= m, n <= 10^5`
- `2 <= m * n <= 10^5`
- `grid[i][j]` is either `0` **or** `1`.
- `grid[0][0] == grid[m - 1][n - 1] == 0`

SOLUTION (PYTHON 3)

Solution 1: Double-Ended Queue BFS

How to think about it

We walk from the top-left to the bottom-right; entering an obstacle costs one removal. mn ≤ 10^5 forbids searching subsets. Empty cells have weight 0 and obstacles weight 1, so this is a 0-1 shortest path for a deque BFS. Push a neighbor to the front when the cell is empty, and to the back when it is an obstacle. The first time we reach the exit is the minimum number of removals.

This problem is essentially a shortest path model, but we need to find the minimum number of obstacles to remove.

In an undirected graph with edge weights of only 0 and 1, we can use a double-ended queue to perform BFS. The principle is that if the weight of the current point that can be expanded is 0, it is added to the front of the queue; if the weight is 1, it is added to the back of the queue.

If the weight of an edge is 0, then the newly expanded node has the same weight as the current front node, and it can obviously be used as the starting point for the next expansion.

The time complexity is O(m × n), and the space complexity is O(m × n). Where m and n are the number of rows and columns of the grid, respectively.

Similar problems:

- 1368. Minimum Cost to Make at Least One Valid Path in a Grid

Python 3

```python
class Solution:
    def minimumObstacles(self, grid: List[List[int]]) -> int:
        m, n = len(grid), len(grid[0])
        q = deque([(0, 0, 0)])
        vis = set()
        dirs = (-1, 0, 1, 0, -1)
        while 1:
            i, j, k = q.popleft()
            if i == m - 1 and j == n - 1:
                return k
            if (i, j) in vis:
                continue
            vis.add((i, j))
            for a, b in pairwise(dirs):
                x, y = i + a, j + b
                if 0 <= x < m and 0 <= y < n:
                    if grid[x][y] == 0:
                        q.appendleft((x, y, k))
                    else:
                        q.append((x, y, k + 1))

leetcode.com/problems/alien-dictionary

★ **TOP 10 PROBLEM** in Topological Sort: master this one first

PROBLEM

There is a new alien language that uses the English alphabet. However, the order of the letters is unknown to you.

You are given a list of strings `words` from the alien language's dictionary. Now it is claimed that the strings in `words` are **sorted lexicographically** by the rules of this new language.

If this claim is incorrect, and the given arrangement of string in `words` cannot correspond to any order of letters, return `""`.

Otherwise, return *a string of the unique letters in the new alien language sorted in **lexicographically increasing order** by the new language's rules.* If there are multiple solutions, return ***any of them***.

Example 1:

```
Input: words = ["wrt","wrf","er","ett","rftt"]
Output: "wertf"
```

Example 2:

```
Input: words = ["z","x"]
Output: "zx"
```

Example 3:

```
Input: words = ["z","x","z"]
Output: ""
Explanation: The order is invalid, so return "".
```

Constraints:

- `1 <= words.length <= 100`
- `1 <= words[i].length <= 100`
- `words[i]` consists of only lowercase English letters.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

The alien order is a DAG whose edges come from the first differing letters of adjacent words. A later word that is a prefix of an earlier one, or a reverse edge, makes the order impossible. Topologically sort the letters that appear: enqueue indegree 0, and the dequeue order is a valid alphabet. Too few letters means a cycle.

Python 3

```
class Solution:
    def alienOrder(self, words: List[str]) -> str:

leetcode.com/problems/graph-valid-tree

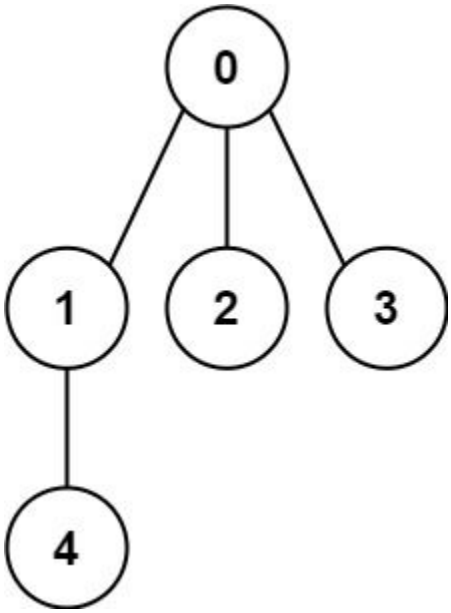
★ **TOP 10 PROBLEM** in Union Find: master this one first

PROBLEM

You have a graph of `n` nodes labeled from `0` to `n - 1`. You are given an integer n and a list of `edges` where `edges[i] = [a_i, b_i]` indicates that there is an undirected edge between nodes `a_i` and `b_i` in the graph.

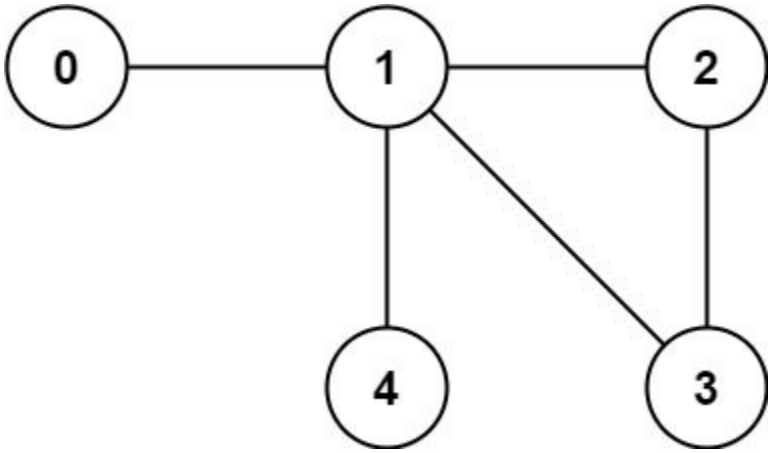
Return `true` *if the edges of the given graph make up a valid tree, and* `false` *otherwise*.

Example 1:



```
Input: n = 5, edges = [[0,1],[0,2],[0,3],[1,4]]
Output: true
```

Example 2:



```
Input: n = 5, edges = [[0,1],[1,2],[2,3],[1,3],[1,4]]
Output: false
```

Constraints:

- `1 <= n <= 2000`
- `0 <= edges.length <= 5000`
- `edges[i].length == 2`
- $0 \le a_i, b_i < n$
- $a_i \ne b_i$
- There are no self-loops or repeated edges.

SOLUTIONS (PYTHON 3)

Solution 1: Union-Find

> **How to think about it**
>
> An undirected graph is a tree iff it is connected and acyclic, so it has exactly n-1 edges. Union-find reports a cycle when an edge joins two nodes already in the same set. Each successful union decreases the component count; it must be 1 at the end.

To determine whether it is a tree, the following two conditions must be met:

1. The number of edges is equal to the number of nodes minus one;
2. There is no cycle.

We can use a union-find set to determine whether there is a cycle. We traverse the edges, if two nodes are already in the same set, it means there is a cycle. Otherwise, we merge the two nodes into the same set. Then we decrease the number of connected components by one, and finally check whether the number of connected components is 1.

The time complexity is $O(n \times \log n)$, and the space complexity is $O(n)$, where n is the number of nodes.

Python 3

```python
class Solution:
    def validTree(self, n: int, edges: List[List[int]]) -> bool:
        def find(x: int) -> int:
            if p[x] != x:
                p[x] = find(p[x])
            return p[x]

        p = list(range(n))
        for a, b in edges:
            pa, pb = find(a), find(b)
            if pa == pb:
                return False
            p[pa] = pb
            n -= 1
        return n == 1
```

Solution 2: DFS

> **How to think about it**
>
> Union-find checks cycles on edges. We can instead require |E|=n-1 and DFS from 0: visiting n nodes means the graph is connected and has no spare edge.

We can also use depth-first search to determine whether there is a cycle. We can use an array vis to record the visited nodes. During the search, we first mark the node as visited, then traverse the nodes adjacent to this node. If the adjacent node has been visited, we skip it, otherwise we recursively visit the adjacent node. Finally, we check whether all nodes have been visited. If there are nodes that have not been visited, it means that it cannot form a tree, so we return `false`.

The time complexity is $O(n)$, and the space complexity is $O(n)$, where n is the number of nodes.

Python 3

```
class Solution:
    def validTree(self, n: int, edges: List[List[int]]) -> bool:
        def dfs(i: int):
            vis.add(i)
            for j in g[i]:
                if j not in vis:
                    dfs(j)

        if len(edges) != n - 1:
            return False
        g = [[] for _ in range(n)]
        for a, b in edges:
            g[a].append(b)
            g[b].append(a)
        vis = set()
        dfs(0)
        return len(vis) == n
```

323. Number of Connected Components in an Undirected Graph

Medium · Depth-First Search, Breadth-First Search, Union Find, Graph

leetcode.com/problems/number-of-connected-components-in-an-undirected-graph

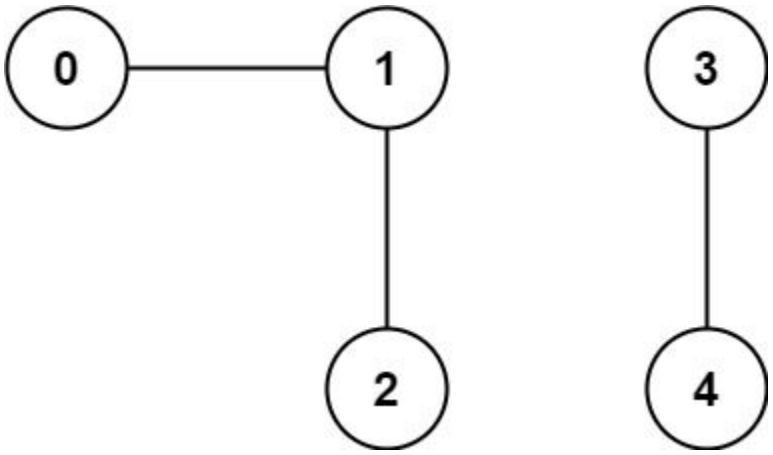
★ **TOP 10 PROBLEM** in Union Find: master this one first

PROBLEM

You have a graph of `n` nodes labeled from 0 to `n - 1`. You are given an integer `n` and an array `edges` where `edges[i] = [a_i, b_i]` indicates that there is an edge between `a_i` and `b_i` in the graph.

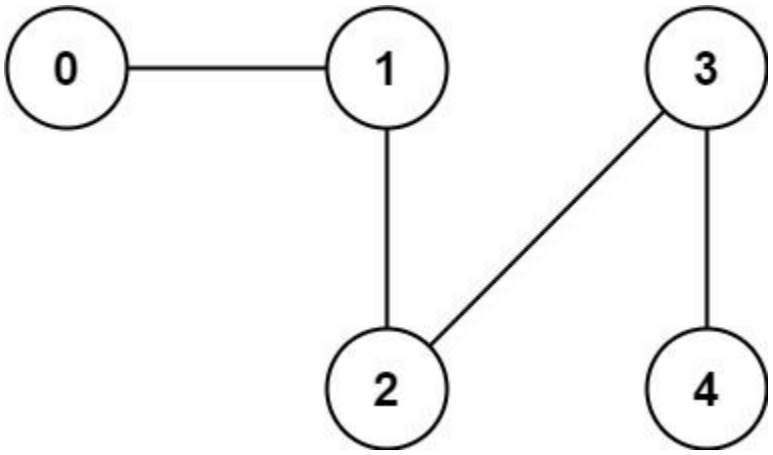
Return *the number of connected components in the graph*.

Example 1:



```
Input: n = 5, edges = [[0,1],[1,2],[3,4]]
Output: 2
```

Example 2:



```
Input: n = 5, edges = [[0,1],[1,2],[2,3],[3,4]]
Output: 1
```

Constraints:

- `1 <= n <= 2000`
- `1 <= edges.length <= 5000`

- `edges[i] = [a_i, b_i]`
- `a_i != b_i`
- There are no repeated edges.

SOLUTIONS (PYTHON 3)

Solution 1: DFS

> **How to think about it**
>
> Count connected components in an undirected graph. Start a search at each unseen node and increment once per new component. O(n+m) fits the limits. Build the adjacency list and DFS: return 0 if seen, otherwise mark, recurse on neighbors, and return 1. Summing over all nodes is the count.

First, we construct an adjacency list g based on the given edges, where g[i] represents all neighbor nodes of node i.

Then we traverse all nodes. For each node, we use DFS to traverse all its adjacent nodes and mark them as visited until all its adjacent nodes have been visited. In this way, we have found a connected component, and the answer is incremented by one. Then we continue to traverse the next unvisited node until all nodes have been visited.

The time complexity is O(n + m), and the space complexity is O(n + m). Where n and m are the number of nodes and edges, respectively.

Python 3

```python
class Solution:
    def countComponents(self, n: int, edges: List[List[int]]) -> int:
        def dfs(i: int) -> int:
            if i in vis:
                return 0
            vis.add(i)
            for j in g[i]:
                dfs(j)
            return 1

        g = [[] for _ in range(n)]
        for a, b in edges:
            g[a].append(b)
            g[b].append(a)
        vis = set()
        return sum(dfs(i) for i in range(n))
```

Solution 2: Union-Find

> **How to think about it**
>
> DFS needs the graph and a call stack. Union-find merges endpoints; a successful union decrements the component count from n. No explicit adjacency list is required.

We can use a union-find set to maintain the connected components in the graph.

First, we initialize a union-find set, then traverse all the edges. For each edge (a, b), we merge nodes a and b into the same connected component. If the merge is successful, it means that nodes a and b were not in the same connected component before, and the number of connected components decreases by one.

Finally, we return the number of connected components.

The time complexity is O(n + m × α(n)), and the space complexity is O(n). Where n and m are the number of nodes and edges, respectively, and α(n) is the inverse of the Ackermann function, which can be regarded as a very small constant.

Python 3

```python
class UnionFind:
    def __init__(self, n):
        self.p = list(range(n))
        self.size = [1] * n

    def find(self, x):
        if self.p[x] != x:
            self.p[x] = self.find(self.p[x])
        return self.p[x]

    def union(self, a, b):
        pa, pb = self.find(a), self.find(b)
        if pa == pb:
            return False
        if self.size[pa] > self.size[pb]:
            self.p[pb] = pa
            self.size[pa] += self.size[pb]
        else:
            self.p[pa] = pb
            self.size[pb] += self.size[pa]
        return True

class Solution:
    def countComponents(self, n: int, edges: List[List[int]]) -> int:
        uf = UnionFind(n)
        for a, b in edges:
            n -= uf.union(a, b)
        return n
```

Solution 3: BFS

> **How to think about it**
>
> Solution 1 expands each component with an explicit stack. A queue expands the same component in breadth-first order, and each new search still increments the count. Time stays O(n + m).

We can also use BFS (Breadth-First Search) to count the number of connected components in the graph.

Similar to Solution 1, we first construct an adjacency list g based on the given edges. Then we traverse all nodes. For each node, if it has not been visited, we start BFS traversal from this node, marking all its adjacent nodes as visited, until all its adjacent nodes have been visited. In this way, we have found a connected component, and the answer is incremented by one.

After traversing all nodes, we get the number of connected components in the graph.

The time complexity is O(n + m), and the space complexity is O(n + m). Where n and m are the number of nodes and edges, respectively.

Python 3

```python
class Solution:
    def countComponents(self, n: int, edges: List[List[int]]) -> int:
        g = [[] for _ in range(n)]
        for a, b in edges:
            g[a].append(b)
            g[b].append(a)
        vis = set()
        ans = 0
        for i in range(n):
            if i in vis:
                continue
            vis.add(i)
            q = deque([i])
            while q:
                a = q.popleft()
                for b in g[a]:
                    if b not in vis:
                        vis.add(b)
                        q.append(b)
            ans += 1
        return ans
```

Solution 4: Explicit Stack

> **How to think about it**
>
> The number of connected components is the number of searches that start at an unvisited node and cover its component. With n ≤ 2000, one O(n + m) traversal is enough. Recursing along a chain uses a call depth equal to the node count and overflows Python once the chain reaches length 1000. Each new component is therefore expanded on a stack: a node is marked when it is pushed, and unvisited neighbors are pushed after it is popped. Marking on push keeps every node out of the stack more than once. Each new start increments the answer.

Build an adjacency list g from the given edges. g[i] holds every neighbor of node i.

Scan the nodes. When node i is still unvisited, increment the answer, push i, and mark it visited. While the stack is not empty, pop node u and push every neighbor that has not been visited, marking it at the same time. That search covers the component of i. Continue with the next unvisited node until every node has been seen. The order of the neighbors does not change the number of components.

The time complexity is O(n + m), and the space complexity is O(n + m). Where n and m are the number of nodes and edges, respectively.

Python 3

```python
class Solution:
    def countComponents(self, n: int, edges: List[List[int]]) -> int:
        g = [[] for _ in range(n)]
        for a, b in edges:
            g[a].append(b)
            g[b].append(a)
        vis = [False] * n
        ans = 0
        for i in range(n):
            if vis[i]:
                continue
            ans += 1
            stk = [i]
            vis[i] = True
            while stk:
                u = stk.pop()
                for v in g[u]:
                    if not vis[v]:
                        vis[v] = True
                        stk.append(v)
        return ans
```

399. Evaluate Division

Medium · Depth-First Search, Breadth-First Search, Union Find, Graph, Array, String, Shortest Path, Floyd–Warshall, Bellman–Ford

leetcode.com/problems/evaluate-division

★ **TOP 10 PROBLEM** in Union Find: master this one first

PROBLEM

You are given an array of variable pairs `equations` and an array of real numbers `values`, where `equations[i] = [A_i, B_i]` and `values[i]` represent the equation $A_i / B_i = values[i]$. Each A_i or B_i is a string that represents a single variable.

You are also given some `queries`, where `queries[j] = [C_j, D_j]` represents the j^{th} query where you must find the answer for $C_j / D_j = ?$.

Return *the answers to all queries*. If a single answer cannot be determined, return `-1.0`.

Note: The input is always valid. You may assume that evaluating the queries will not result in division by zero and that there is no contradiction.

Note: The variables that do not occur in the list of equations are undefined, so the answer cannot be determined for them.

Example 1:

```
Input: equations = [["a","b"],["b","c"]], values = [2.0,3.0], queries =
[["a","c"],["b","a"],["a","e"],["a","a"],["x","x"]]
Output: [6.00000,0.50000,-1.00000,1.00000,-1.00000]
Explanation:
Given: a / b = 2.0, b / c = 3.0
queries are: a / c = ?, b / a = ?, a / e = ?, a / a = ?, x / x = ?
return: [6.0, 0.5, -1.0, 1.0, -1.0 ]
note: x is undefined => -1.0
```

Example 2:

```
Input: equations = [["a","b"],["b","c"],["bc","cd"]], values = [1.5,2.5,5.0], queries =
[["a","c"],["c","b"],["bc","cd"],["cd","bc"]]
Output: [3.75000,0.40000,5.00000,0.20000]
```

Example 3:

```
Input: equations = [["a","b"]], values = [0.5], queries = [["a","b"],["b","a"],["a","c"],["x","y"]]
Output: [0.50000,2.00000,-1.00000,-1.00000]
```

Constraints:

- `1 <= equations.length <= 20`
- `equations[i].length == 2`
- `1 <= A_i.length, B_i.length <= 5`
- `values.length == equations.length`
- `0.0 < values[i] <= 20.0`
- `1 <= queries.length <= 20`
- `queries[i].length == 2`
- `1 <= C_j.length, D_j.length <= 5`
- A_i, B_i, C_j, D_j consist of lower case English letters and digits.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Given a/b values, answer other ratios. Graph search multiplies along a path; weighted union-find is lighter with many variables. w[x] is x relative to its root. `find` multiplies weights on compression. Union of a/b=v sets w[pa]=w[b]· v/w[a]. A query is -1 if the variables are missing or in different components, else w[c]/w[d].

Python 3

```
class Solution:
    def calcEquation(
        self, equations: List[List[str]], values: List[float], queries: List[List[str]]
    ) -> List[float]:
        def find(x):
            if p[x] != x:
                origin = p[x]
                p[x] = find(p[x])
                w[x] *= w[origin]
            return p[x]

        w = defaultdict(lambda: 1)
        p = defaultdict()
        for a, b in equations:
            p[a], p[b] = a, b
        for i, v in enumerate(values):
            a, b = equations[i]
            pa, pb = find(a), find(b)
            if pa == pb:
                continue
            p[pa] = pb
            w[pa] = w[b] * v / w[a]
        return [
            -1 if c not in p or d not in p or find(c) != find(d) else w[c] / w[d]
            for c, d in queries
        ]
```

Complexity. Time: O((e + q) * alpha), e = equations, q = queries. Space: O(e).

305. Number of Islands II

Hard · Union Find, Array, Hash Table

leetcode.com/problems/number-of-islands-ii

★ **TOP 10 PROBLEM** in Union Find: master this one first

PROBLEM

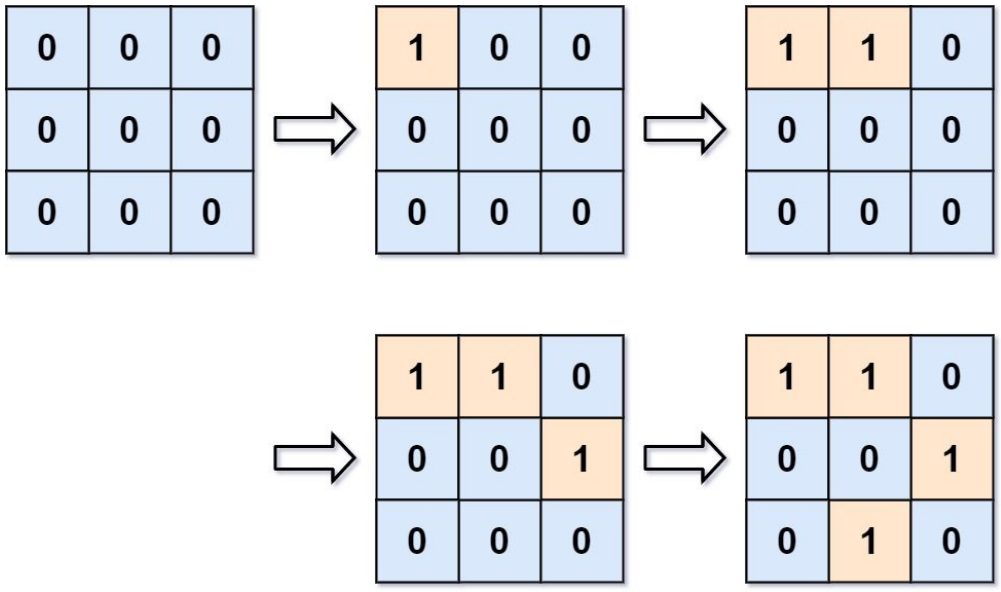
You are given an empty 2D binary grid `grid` of size `m x n`. The grid represents a map where `0`'s represent water and `1`'s represent land. Initially, all the cells of `grid` are water cells (i.e., all the cells are `0`'s).

We may perform an add land operation which turns the water at position into a land. You are given an array `positions` where `positions[i] = [r_i, c_i]` is the position `(r_i, c_i)` at which we should operate the `i^th` operation.

Return *an array of integers* `answer` *where* `answer[i]` *is the number of islands after turning the cell* `(r_i, c_i)` *into a land*.

An **island** is surrounded by water and is formed by connecting adjacent lands horizontally or vertically. You may assume all four edges of the grid are all surrounded by water.

Example 1:



```
Input: m = 3, n = 3, positions = [[0,0],[0,1],[1,2],[2,1]]
Output: [1,1,2,3]
Explanation:
Initially, the 2d grid is filled with water.
- Operation #1: addLand(0, 0) turns the water at grid[0][0] into a land. We have 1 island.
- Operation #2: addLand(0, 1) turns the water at grid[0][1] into a land. We still have 1 island.
- Operation #3: addLand(1, 2) turns the water at grid[1][2] into a land. We have 2 islands.
- Operation #4: addLand(2, 1) turns the water at grid[2][1] into a land. We have 3 islands.
```

Example 2:

```
Input: m = 1, n = 1, positions = [[0,0]]
Output: [1]
```

Constraints:

- `1 <= m, n, positions.length <= 10^4`
- `1 <= m * n <= 10^4`
- `positions[i].length == 2`

- $0 <= r_i < m$
- $0 <= c_i < n$

Follow up: Could you solve it in time complexity $O(k \log(mn))$, where $k == positions.length$?

SOLUTION (PYTHON 3)

Solution 1: Union-Find

How to think about it

Land cells arrive over time and we must report the island count after each one. Restarting DFS/BFS on the whole grid per operation multiplies grid size by the number of updates. A new land cell starts as its own island, then merges with land in the four neighbors. Union-find tracks components: merge only when a neighbor is already land and in a different set, and decrement the count. Re-adding the same cell is a no-op. Each operation is nearly constant, so the total grows linearly with k.

We use a two-dimensional array grid to represent a map, where 0 and 1 represent water and land respectively. Initially, all cells in grid are water cells (i.e., all cells are 0), and we use a variable cnt to record the number of islands. The connectivity between islands can be maintained by a union-find set uf.

Next, we traverse each position (i, j) in the array positions. If grid[i][j] is 1, it means that this position is already land, and we directly add cnt to the answer; otherwise, we change the value of grid[i][j] to 1, and increase the value of cnt by 1. Then, we traverse the four directions of up, down, left, and right of this position. If a certain direction is 1, and this position does not belong to the same connected component as (i, j), then we merge this position with (i, j), and decrease the value of cnt by 1. After traversing the four directions of up, down, left, and right of this position, we add cnt to the answer.

The time complexity is O(k × α(m × n)) or O(k × log(m × n)), where k is the length of positions, and α is the inverse function of the Ackermann function. In this problem, α(m × n) can be considered as a very small constant.

Python 3

```python
class UnionFind:
    def __init__(self, n: int):
        self.p = list(range(n))
        self.size = [1] * n

    def find(self, x: int):
        if self.p[x] != x:
            self.p[x] = self.find(self.p[x])
        return self.p[x]

    def union(self, a: int, b: int) -> bool:
        pa, pb = self.find(a - 1), self.find(b - 1)
        if pa == pb:
            return False
        if self.size[pa] > self.size[pb]:
            self.p[pb] = pa
            self.size[pa] += self.size[pb]
        else:
            self.p[pa] = pb
            self.size[pb] += self.size[pa]
        return True

class Solution:
    def numIslands2(self, m: int, n: int, positions: List[List[int]]) -> List[int]:
        uf = UnionFind(m * n)
        grid = [[0] * n for _ in range(m)]
        ans = []
        dirs = (-1, 0, 1, 0, -1)
        cnt = 0
        for i, j in positions:
            if grid[i][j]:
                ans.append(cnt)
                continue
            grid[i][j] = 1
            cnt += 1
            for a, b in pairwise(dirs):
                x, y = i + a, j + b
                if (
                    0 <= x < m
                    and 0 <= y < n
                    and grid[x][y]
                    and uf.union(i * n + j, x * n + y)
                ):
                    cnt -= 1
            ans.append(cnt)
        return ans
```

1135. Connecting Cities With Minimum Cost

Medium · Union Find, Graph, Minimum Spanning Tree, Heap (Priority Queue)

leetcode.com/problems/connecting-cities-with-minimum-cost

★ **TOP 10 PROBLEM** in Minimum Spanning Tree: master this one first

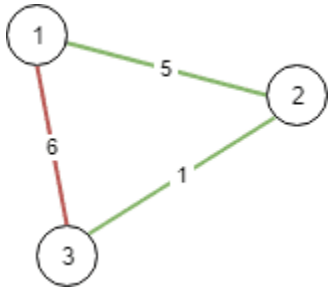
PROBLEM

There are `n` cities labeled from `1` to `n`. You are given the integer `n` and an array `connections` where `connections[i] = [x_i, y_i, cost_i]` indicates that the cost of connecting city `x_i` and city `y_i` (bidirectional connection) is `cost_i`.

Return *the minimum **cost** to connect all the `n` cities such that there is at least one path between each pair of cities*. If it is impossible to connect all the `n` cities, return `-1`,

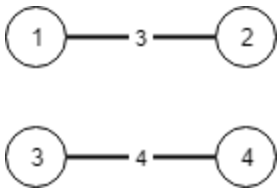
The **cost** is the sum of the connections' costs used.

Example 1:



```
Input: n = 3, connections = [[1,2,5],[1,3,6],[2,3,1]]
Output: 6
Explanation: Choosing any 2 edges will connect all cities so we choose the minimum 2.
```

Example 2:



```
Input: n = 4, connections = [[1,2,3],[3,4,4]]
Output: -1
Explanation: There is no way to connect all cities even if all edges are used.
```

Constraints:

- `1 <= n <= 10^4`
- `1 <= connections.length <= 10^4`
- `connections[i].length == 3`
- `1 <= x_i, y_i <= n`
- `x_i != y_i`
- `0 <= cost_i <= 10^5`

SOLUTION (PYTHON 3)

Solution 1: Kruskal's Algorithm

> **How to think about it**
>
> The cheapest way to connect n cities is a minimum spanning tree. Sort edges by cost and union endpoints that are still apart, adding the cost; when one component remains we have a tree. If edges run out first, the graph is disconnected and the answer is -1.

Kruskal's algorithm is a greedy algorithm used to compute the minimum spanning tree.

The basic idea of Kruskal's algorithm is to select the smallest edge from the edge set each time. If the two vertices connected by this edge are not in the same connected component, then add this edge to the minimum spanning tree, otherwise discard this edge.

For this problem, we can sort the edges in ascending order of connection cost, use a union-find set to maintain connected components, select the smallest edge each time, and if the two vertices connected by this edge are not in the same connected component, then merge these two vertices and accumulate the connection cost. If a situation occurs where the number of connected components is 1, it means that all vertices are connected, and we return the accumulated connection cost, otherwise, we return -1.

The time complexity is O(m × log m), and the space complexity is O(n). Here, m and n are the number of edges and vertices, respectively.

Python 3

```python
class Solution:
    def minimumCost(self, n: int, connections: List[List[int]]) -> int:
        def find(x):
            if p[x] != x:
                p[x] = find(p[x])
            return p[x]

        connections.sort(key=lambda x: x[2])
        p = list(range(n))
        ans = 0
        for x, y, cost in connections:
            x, y = x - 1, y - 1
            if find(x) == find(y):
                continue
            p[find(x)] = find(y)
            ans += cost
            n -= 1
            if n == 1:
                return ans
        return -1
```

```

PART 2 · MINIMUM SPANNING TREE · PROBLEM 2 OF 5

1584. Min Cost to Connect All Points

Medium · Union Find, Graph, Array, Kruskal, Minimum Spanning Tree, Prim, Borůvka

leetcode.com/problems/min-cost-to-connect-all-points

★ **TOP 10 PROBLEM** in Minimum Spanning Tree: master this one first

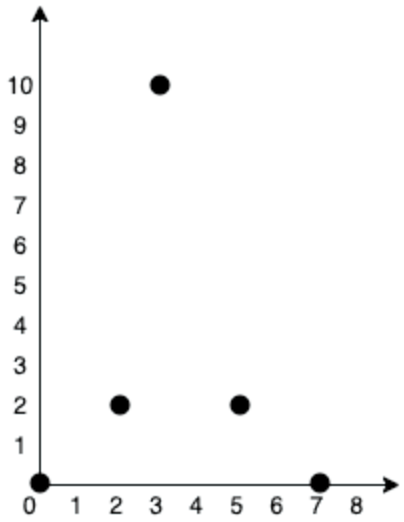
PROBLEM

You are given an array `points` representing integer coordinates of some points on a 2D-plane, where `points[i] = [x_i, y_i]`.

The cost of connecting two points `[x_i, y_i]` and `[x_j, y_j]` is the **manhattan distance** between them: `|x_i - x_j| + |y_i - y_j|`, where `|val|` denotes the absolute value of `val`.

Return *the minimum cost to make all points connected.* All points are connected if there is **exactly one** simple path between any two points.

Example 1:



```
Input: points = [[0,0],[2,2],[3,10],[5,2],[7,0]]
Output: 20
Explanation:

We can connect the points as shown above to get the minimum cost of 20.
Notice that there is a unique path between every pair of points.
```

Example 2:

```
Input: points = [[3,12],[-2,5],[-4,1]]
Output: 18
```

Constraints:

- `1 <= points.length <= 1000`
- `-10^6 <= x_i, y_i <= 10^6`
- All pairs `(x_i, y_i)` are distinct.

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

Connect all points by Manhattan distance and take a minimum spanning tree. n≤ 1000 yields a dense complete graph, which suits a dense MST algorithm. Plain Prim keeps each vertex's distance to the current tree, repeatedly adds the closest unused vertex, and relaxes the others. n rounds of an n-scan cost $O(n^2)$.

Python 3

```python
class Solution:
    def minCostConnectPoints(self, points: List[List[int]]) -> int:
        n = len(points)
        g = [[0] * n for _ in range(n)]
        dist = [inf] * n
        vis = [False] * n
        for i, (x1, y1) in enumerate(points):
            for j in range(i + 1, n):
                x2, y2 = points[j]
                t = abs(x1 - x2) + abs(y1 - y2)
                g[i][j] = g[j][i] = t
        dist[0] = 0
        ans = 0
        for _ in range(n):
            i = -1
            for j in range(n):
                if not vis[j] and (i == -1 or dist[j] < dist[i]):
                    i = j
            vis[i] = True
            ans += dist[i]
            for j in range(n):
                if not vis[j]:
                    dist[j] = min(dist[j], g[i][j])
        return ans
```

Solution 2

How to think about it

Prim is organized around a cut and an adjacency matrix. Kruskal sorts every edge and unions endpoints until the graph is connected. With $O(n^2)$ edges the sort dominates; the style is convenient when we prefer to iterate edges.

Python 3

```python
class Solution:
    def minCostConnectPoints(self, points: List[List[int]]) -> int:
        def find(x: int) -> int:
            if p[x] != x:
                p[x] = find(p[x])
            return p[x]

        n = len(points)
        g = []
        for i, (x1, y1) in enumerate(points):
            for j in range(i + 1, n):
                x2, y2 = points[j]
                t = abs(x1 - x2) + abs(y1 - y2)
                g.append((t, i, j))
        p = list(range(n))
        ans = 0
        for cost, i, j in sorted(g):
            pa, pb = find(i), find(j)
            if pa == pb:
                continue
            p[pa] = pb
            ans += cost
            n -= 1
            if n == 1:
                break
        return ans
```

1168. Optimize Water Distribution in a Village

Hard · Union Find, Graph, Kruskal, Minimum Spanning Tree, Prim, Heap (Priority Queue), Borůvka

leetcode.com/problems/optimize-water-distribution-in-a-village

★ **TOP 10 PROBLEM** in Minimum Spanning Tree: master this one first

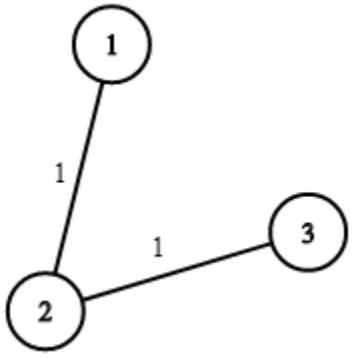
PROBLEM

There are `n` houses in a village. We want to supply water for all the houses by building wells and laying pipes.

For each house `i`, we can either build a well inside it directly with cost `wells[i - 1]` (note the `-1` due to **0-indexing**), or pipe in water from another well to it. The costs to lay pipes between houses are given by the array `pipes` where each `pipes[j] = [house1`$_j$`, house2`$_j$`, cost`$_j$`]` represents the cost to connect `house1`$_j$ and `house2`$_j$ together using a pipe. Connections are bidirectional, and there could be multiple valid connections between the same two houses with different costs.

Return *the minimum total cost to supply water to all houses*.

Example 1:



```
Input: n = 3, wells = [1,2,2], pipes = [[1,2,1],[2,3,1]]
Output: 3
Explanation: The image shows the costs of connecting houses using pipes.
The best strategy is to build a well in the first house with cost 1 and connect the other houses to it
with cost 2 so the total cost is 3.
```

Example 2:

```
Input: n = 2, wells = [1,1], pipes = [[1,2,1],[1,2,2]]
Output: 2
Explanation: We can supply water with cost two using one of the three options:
Option 1:
  - Build a well inside house 1 with cost 1.
  - Build a well inside house 2 with cost 1.
The total cost will be 2.
Option 2:
  - Build a well inside house 1 with cost 1.
  - Connect house 2 with house 1 with cost 1.
The total cost will be 2.
Option 3:
  - Build a well inside house 2 with cost 1.
  - Connect house 1 with house 2 with cost 1.
The total cost will be 2.
Note that we can connect houses 1 and 2 with cost 1 or with cost 2 but we will always choose the
cheapest option.
```

Constraints:

- $2 <= n <= 10^4$
- wells.length == n
- $0 <= wells[i] <= 10^5$
- $1 <= pipes.length <= 10^4$
- pipes[j].length == 3
- $1 <= house1_j, house2_j <= n$
- $0 <= cost_j <= 10^5$
- $house1_j != house2_j$

SOLUTIONS (PYTHON 3)

Solution 1: Kruskal's Algorithm (Minimum Spanning Tree)

How to think about it

A house may sink its own well or connect through pipes. Add a virtual node 0 whose edges to houses are well costs; the instance is an MST on n+1 vertices. Sort edges by cost and union them until n merges remain (all houses touch 0), which is the minimum cost.

We assume that there is a well with the number 0. Then we can consider the connectivity between each house and the well 0 as an edge, and the weight of each edge is the cost of building a well for that house. At the same time, we consider the connectivity between each house as an edge, and the weight of each edge is the cost of laying a pipe. In this way, we can transform this problem into finding the minimum spanning tree of an undirected graph.

We can use Kruskal's algorithm to find the minimum spanning tree of the undirected graph. First, we add an edge between the well 0 and the house to the pipes array, and then sort the pipes array in ascending order of edge weights. Then, we traverse each edge. If this edge connects different connected components, we choose this edge and merge the corresponding connected components. If the current connected component is exactly 1, then we have found the minimum spanning tree. The answer at this time is the current edge weight, and we return it.

The time complexity is O((m + n) × log (m + n)), and the space complexity is O(m + n). Here, m and n are the lengths of the pipes array and the wells array, respectively.

Python 3

```
class Solution:
    def minCostToSupplyWater(
        self, n: int, wells: List[int], pipes: List[List[int]]
    ) -> int:
        def find(x: int) -> int:
            if p[x] != x:
                p[x] = find(p[x])
            return p[x]

        for i, w in enumerate(wells, 1):
            pipes.append([0, i, w])
        pipes.sort(key=lambda x: x[2])
        p = list(range(n + 1))
        ans = 0
        for a, b, c in pipes:
            pa, pb = find(a), find(b)
            if pa != pb:
                p[pa] = pb
                n -= 1
                ans += c
                if n == 0:
                    return ans
```

Solution 2

How to think about it

Method 1 inlines union-find. Method 2 wraps union-by-size; `union` reports a real merge, and the loop only adds cost and counts. The graph and Kruskal order stay the same.

Python 3

```python
class UnionFind:
    __slots__ = ("p", "size")

    def __init__(self, n):
        self.p = list(range(n))
        self.size = [1] * n

    def find(self, x: int) -> int:
        if self.p[x] != x:
            self.p[x] = self.find(self.p[x])
        return self.p[x]

    def union(self, a: int, b: int) -> bool:
        pa, pb = self.find(a), self.find(b)
        if pa == pb:
            return False
        if self.size[pa] > self.size[pb]:
            self.p[pb] = pa
            self.size[pa] += self.size[pb]
        else:
            self.p[pa] = pb
            self.size[pb] += self.size[pa]
        return True

class Solution:
    def minCostToSupplyWater(
        self, n: int, wells: List[int], pipes: List[List[int]]
    ) -> int:
        for i, w in enumerate(wells, 1):
            pipes.append([0, i, w])
        pipes.sort(key=lambda x: x[2])
        uf = UnionFind(n + 1)
        ans = 0
        for a, b, c in pipes:
            if uf.union(a, b):
                ans += c
                n -= 1
                if n == 0:
                    return ans
```

Complexity. Time: O((n + m) log (n + m)), m = pipes. Space: O(n + m).

        if ra != rb:
            parent[ra] = rb
            if a != 0:
                built.append([a, b, cost])
    return built
```

1489. Find Critical and Pseudo-Critical Edges in Minimum Spanning Tree

Hard · Union Find, Graph, Kruskal, Minimum Spanning Tree, Prim, Sorting, Strongly Connected Component, Borůvka

leetcode.com/problems/find-critical-and-pseudo-critical-edges-in-minimum-spanning-tree

★ **TOP 10 PROBLEM** in Minimum Spanning Tree: master this one first

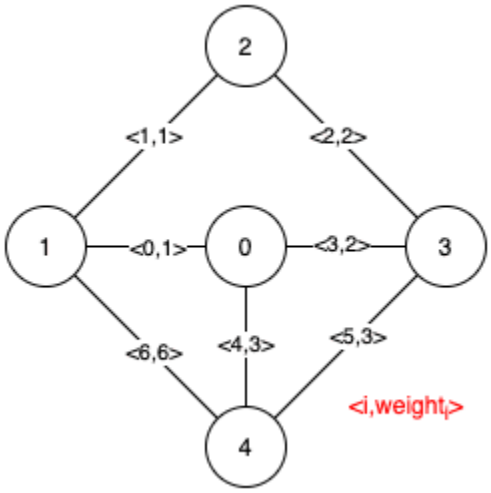
PROBLEM

Given a weighted undirected connected graph with `n` vertices numbered from `0` to `n - 1`, and an array `edges` where `edges[i] = [a_i, b_i, weight_i]` represents a bidirectional and weighted edge between nodes `a_i` and `b_i`. A minimum spanning tree (MST) is a subset of the graph's edges that connects all vertices without cycles and with the minimum possible total edge weight.

Find *all the critical and pseudo-critical edges in the given graph's minimum spanning tree (MST)*. An MST edge whose deletion from the graph would cause the MST weight to increase is called a *critical edge*. On the other hand, a pseudo-critical edge is that which can appear in some MSTs but not all.

Note that you can return the indices of the edges in any order.

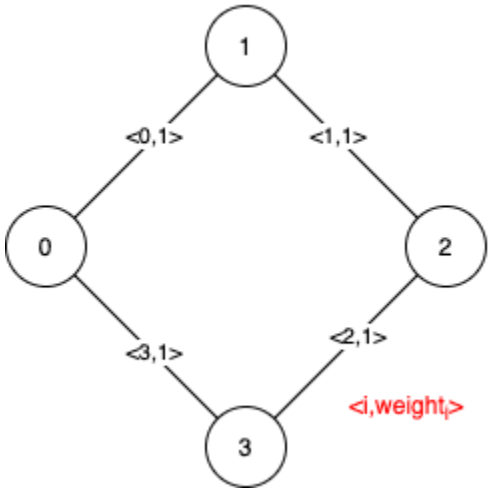
Example 1:



```
Input: n = 5, edges = [[0,1,1],[1,2,1],[2,3,2],[0,3,2],[0,4,3],[3,4,3],[1,4,6]]
Output: [[0,1],[2,3,4,5]]
Explanation: The figure above describes the graph.
The following figure shows all the possible MSTs:

Notice that the two edges 0 and 1 appear in all MSTs, therefore they are critical edges, so we return
them in the first list of the output.
The edges 2, 3, 4, and 5 are only part of some MSTs, therefore they are considered pseudo-critical
edges. We add them to the second list of the output.
```

Example 2:



```
Input: n = 4, edges = [[0,1,1],[1,2,1],[2,3,1],[0,3,1]]
Output: [[],[0,1,2,3]]
Explanation: We can observe that since all 4 edges have equal weight, choosing any 3 edges from the
given 4 will yield an MST. Therefore all 4 edges are pseudo-critical.
```

Constraints:

- `2 <= n <= 100`
- `1 <= edges.length <= min(200, n * (n - 1) / 2)`
- `edges[i].length == 3`
- `0 <= a_i < b_i < n`
- `1 <= weight_i <= 1000`
- All pairs `(a_i, b_i)` are **distinct**.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

n≤ 100 and at most 200 edges, so we can run MST many times. Kruskal first yields the MST weight v. An edge is critical iff deleting it disconnects the graph or raises the weight above v. Otherwise it is pseudo-critical iff forcing it in still achieves v. Test both for every edge.

Python 3

```python
class UnionFind:
    def __init__(self, n):
        self.p = list(range(n))
        self.n = n

    def union(self, a, b):
        if self.find(a) == self.find(b):
            return False
        self.p[self.find(a)] = self.find(b)
        self.n -= 1
        return True

    def find(self, x):
        if self.p[x] != x:
            self.p[x] = self.find(self.p[x])
        return self.p[x]

class Solution:
    def findCriticalAndPseudoCriticalEdges(
        self, n: int, edges: List[List[int]]
    ) -> List[List[int]]:
        for i, e in enumerate(edges):
            e.append(i)
        edges.sort(key=lambda x: x[2])
        uf = UnionFind(n)
        v = sum(w for f, t, w, _ in edges if uf.union(f, t))
        ans = [[], []]
        for f, t, w, i in edges:
            uf = UnionFind(n)
            k = sum(z for x, y, z, j in edges if j != i and uf.union(x, y))
            if uf.n > 1 or (uf.n == 1 and k > v):
                ans[0].append(i)
                continue

            uf = UnionFind(n)
            uf.union(f, t)
            k = w + sum(z for x, y, z, j in edges if j != i and uf.union(x, y))
            if k == v:
                ans[1].append(i)
        return ans
```

Complexity. Time: O(E^2 * alpha), E = number of edges. Space: O(n + E).

3600. Maximize Spanning Tree Stability with Upgrades

Hard · Greedy, Union Find, Graph, Binary Search, Minimum Spanning Tree

leetcode.com/problems/maximize-spanning-tree-stability-with-upgrades

★ **TOP 10 PROBLEM** in Minimum Spanning Tree: master this one first

PROBLEM

You are given an integer `n`, representing `n` nodes numbered from 0 to `n - 1` and a list of `edges`, where `edges[i] = [u_i, v_i, s_i, must_i]`:

- `u_i` and `v_i` indicates an undirected edge between nodes `u_i` and `v_i`.
- `s_i` is the strength of the edge.
- `must_i` is an integer (0 or 1). If `must_i == 1`, the edge **must** be included in the **spanning tree**. These edges **cannot** be **upgraded**.

You are also given an integer `k`, the **maximum** number of upgrades you can perform. Each upgrade **doubles** the strength of an edge, and each eligible edge (with `must_i == 0`) can be upgraded **at most** once.

The **stability** of a spanning tree is defined as the **minimum** strength score among all edges included in it.

Return the **maximum** possible stability of any valid spanning tree. If it is impossible to connect all nodes, return `-1`.

Note: A **spanning tree** of a graph with `n` nodes is a subset of the edges that connects all nodes together (i.e. the graph is **connected**) *without* forming any cycles, and uses **exactly** `n - 1` edges.

Example 1:

Input: n = 3, edges = [[0,1,2,1],[1,2,3,0]], k = 1

Output: 2

Explanation:

- Edge `[0,1]` with strength = 2 must be included in the spanning tree.
- Edge `[1,2]` is optional and can be upgraded from 3 to 6 using one upgrade.
- The resulting spanning tree includes these two edges with strengths 2 and 6.
- The minimum strength in the spanning tree is 2, which is the maximum possible stability.

Example 2:

Input: n = 3, edges = [[0,1,4,0],[1,2,3,0],[0,2,1,0]], k = 2

Output: 6

Explanation:

- Since all edges are optional and up to `k = 2` upgrades are allowed.
- Upgrade edges `[0,1]` from 4 to 8 and `[1,2]` from 3 to 6.
- The resulting spanning tree includes these two edges with strengths 8 and 6.
- The minimum strength in the tree is 6, which is the maximum possible stability.

Example 3:

Input: n = 3, edges = [[0,1,1,1],[1,2,1,1],[2,0,1,1]], k = 0

Output: -1

Explanation:

- All edges are mandatory and form a cycle, which violates the spanning tree property of acyclicity. Thus, the answer is -1.

Constraints:

- $2 <= n <= 10^5$

- $1 <= edges.length <= 10^5$
- $edges[i] = [u_i, v_i, s_i, must_i]$
- $0 <= u_i, v_i < n$
- $u_i != v_i$
- $1 <= s_i <= 10^5$
- $must_i$ is either 0 or 1.
- $0 <= k <= n$
- There are no duplicate edges.

SOLUTION (PYTHON 3)

Solution 1: Binary Search + Union-Find

How to think about it

Enumerating spanning trees and subsets of at most k upgrades is exponential and impossible for $n,m \le 10^5$. Stability is the tree's minimum edge strength, so feasibility of a threshold x is monotone and the maximum can be binary-searched. Must-edges cannot be upgraded, so their minimum strength mn is an upper bound. A cycle among must-edges, or a graph that stays disconnected after adding every edge, has no answer. For a candidate lim, union every edge with strength at least lim, then spend at most k upgrades on edges with $2s \ge lim$. Union-find decides connectivity, so a logarithmic number of checks yields the maximum feasible stability.

According to the problem description, the stability of a spanning tree is determined by the minimum strength edge in it. If a stability x is feasible, then for any y < x, stability y is also feasible. Therefore, we can use binary search to find the maximum stability.

We first add all required edges into the Union-Find and record the minimum strength mn among them. If there is a cycle among the required edges, return -1 directly. Then we add all edges into the Union-Find; if the final number of connected components is greater than 1, it means not all nodes can be connected, and we return -1.

Next, we perform binary search in the range [1, mn]. We define a function check(lim) to check whether there exists a spanning tree with stability at least lim. In the check function, we first add all edges with strength no less than lim into the Union-Find. Then we try to use the upgrade count to connect the remaining edges, with the condition that the edge strength is at least lim/2 (since upgrading doubles the strength). If the final number of connected components in the Union-Find is 1, a spanning tree satisfying the condition exists.

The time complexity is $O((m \times \alpha(n) + n) \times \log M)$, and the space complexity is $O(n)$. Here, m is the number of edges, n is the number of nodes, and M is the maximum edge strength.

Python 3

```python
class UnionFind:
    def __init__(self, n):
        self.p = list(range(n))
        self.size = [1] * n
        self.cnt = n

    def find(self, x):
        if self.p[x] != x:
            self.p[x] = self.find(self.p[x])
        return self.p[x]

    def union(self, a, b):
        pa, pb = self.find(a), self.find(b)
        if pa == pb:
            return False
        if self.size[pa] > self.size[pb]:
            self.p[pb] = pa
            self.size[pa] += self.size[pb]
        else:
            self.p[pa] = pb
            self.size[pb] += self.size[pa]
        self.cnt -= 1
        return True

class Solution:
    def maxStability(self, n: int, edges: List[List[int]], k: int) -> int:
        def check(lim: int) -> bool:
            uf = UnionFind(n)
            for u, v, s, _ in edges:
                if s >= lim:
                    uf.union(u, v)
            rem = k
            for u, v, s, _ in edges:
                if s * 2 >= lim and rem > 0:
                    if uf.union(u, v):
                        rem -= 1
            return uf.cnt == 1

        uf = UnionFind(n)
        mn = 10**6
        for u, v, s, must in edges:
            if must:
                mn = min(mn, s)
                if not uf.union(u, v):
                    return -1
        for u, v, _, _ in edges:
            uf.union(u, v)
        if uf.cnt > 1:
            return -1
        l, r = 1, mn
        while l < r:
            mid = (l + r + 1) >> 1
            if check(mid):
                l = mid
            else:
                r = mid - 1
        return l
```

★ **TOP 10 PROBLEM** in Shortest Path: master this one first

PROBLEM

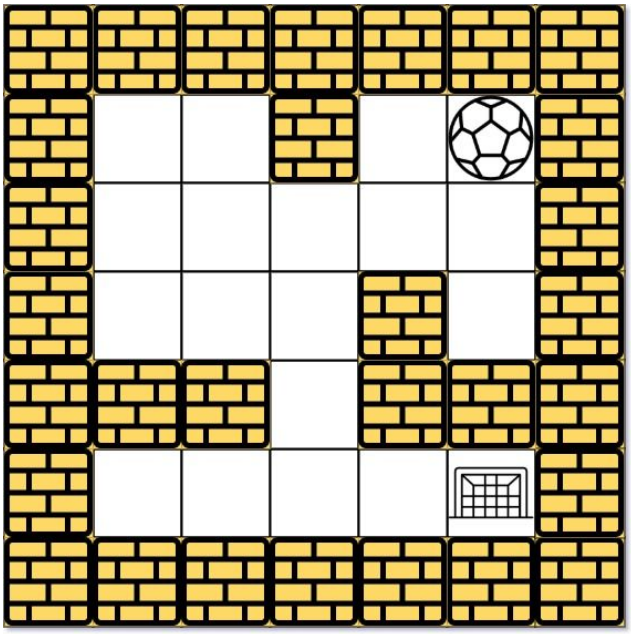
There is a ball in a `maze` with empty spaces (represented as `0`) and walls (represented as `1`). The ball can go through the empty spaces by rolling **up, down, left or right**, but it won't stop rolling until hitting a wall. When the ball stops, it could choose the next direction.

Given the `m x n maze`, the ball's `start` position and the `destination`, where `start = [start_row, start_col]` and `destination = [destination_row, destination_col]`, return *the shortest **distance** for the ball to stop at the destination*. If the ball cannot stop at `destination`, return `-1`.

The **distance** is the number of **empty spaces** traveled by the ball from the start position (excluded) to the destination (included).

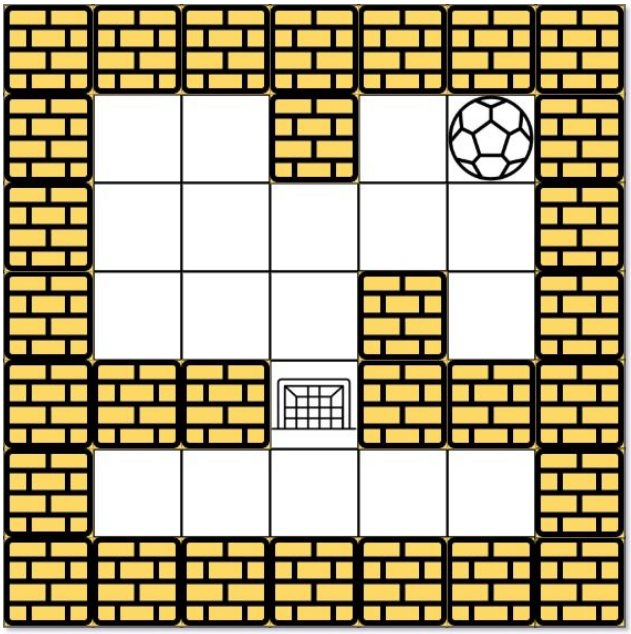
You may assume that **the borders of the maze are all walls** (see examples).

Example 1:



```
Input: maze = [[0,0,1,0,0],[0,0,0,0,0],[0,0,0,1,0],[1,1,0,1,1],[0,0,0,0,0]], start = [0,4],
destination = [4,4]
Output: 12
Explanation: One possible way is : left -> down -> left -> down -> right -> down -> right.
The length of the path is 1 + 1 + 3 + 1 + 2 + 2 + 2 = 12.
```

Example 2:



```
Input: maze = [[0,0,1,0,0],[0,0,0,0,0],[0,0,0,1,0],[1,1,0,1,1],[0,0,0,0,0]], start = [0,4],
destination = [3,2]
Output: -1
Explanation: There is no way for the ball to stop at the destination. Notice that you can pass through
the destination but you cannot stop there.
```

Example 3:

```
Input: maze = [[0,0,0,0,0],[1,1,0,0,1],[0,0,0,0,0],[0,1,0,0,1],[0,1,0,0,0]], start = [4,3],
destination = [0,1]
Output: -1
```

Constraints:

- `m == maze.length`
- `n == maze[i].length`
- `1 <= m, n <= 100`
- `maze[i][j]` is `0` or `1`.
- `start.length == 2`
- `destination.length == 2`
- $0 <= start_{row}, destination_{row} < m$
- $0 <= start_{col}, destination_{col} < n$
- Both the ball and the destination exist in an empty space, and they will not be in the same position initially.
- The maze contains **at least 2 empty spaces**.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

The ball rolls until it hits a wall, so an edge is a full roll rather than a single cell. Stepping cell by cell re-expands the same roll many times. States are stopping cells. From each stop, roll in four directions to the end and relax that cell if the path is shorter. Distances per roll vary, so this is shortest-path relaxation on stop points, not unweighted BFS. The recorded distance at the destination is the answer, or -1 if it stays infinite.

Python 3

```python
class Solution:
    def shortestDistance(
        self, maze: List[List[int]], start: List[int], destination: List[int]
    ) -> int:
        m, n = len(maze), len(maze[0])
        dirs = (-1, 0, 1, 0, -1)
        si, sj = start
        di, dj = destination
        q = deque([(si, sj)])
        dist = [[inf] * n for _ in range(m)]
        dist[si][sj] = 0
        while q:
            i, j = q.popleft()
            for a, b in pairwise(dirs):
                x, y, k = i, j, dist[i][j]
                while 0 <= x + a < m and 0 <= y + b < n and maze[x + a][y + b] == 0:
                    x, y, k = x + a, y + b, k + 1
                if k < dist[x][y]:
                    dist[x][y] = k
                    q.append((x, y))
        return -1 if dist[di][dj] == inf else dist[di][dj]
```

Complexity. Time: O(m * n * (m + n)) in the worst case (a cell can be improved several times). Space: O(m * n).

743. Network Delay Time

Medium · Depth-First Search, Breadth-First Search, Graph, Shortest Path, Dijkstra, Heap (Priority Queue)

leetcode.com/problems/network-delay-time

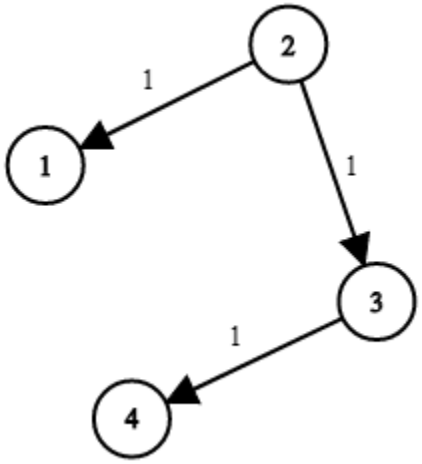
★ **TOP 10 PROBLEM** in Shortest Path: master this one first

PROBLEM

You are given a network of `n` nodes, labeled from `1` to `n`. You are also given `times`, a list of travel times as directed edges `times[i] = (u_i, v_i, w_i)`, where `u_i` is the source node, `v_i` is the target node, and `w_i` is the time it takes for a signal to travel from source to target.

We will send a signal from a given node `k`. Return *the **minimum** time it takes for all the `n` nodes to receive the signal*. If it is impossible for all the `n` nodes to receive the signal, return `-1`.

Example 1:



```
Input: times = [[2,1,1],[2,3,1],[3,4,1]], n = 4, k = 2
Output: 2
```

Example 2:

```
Input: times = [[1,2,1]], n = 2, k = 1
Output: 1
```

Example 3:

```
Input: times = [[1,2,1]], n = 2, k = 2
Output: -1
```

Constraints:

- `1 <= k <= n <= 100`
- `1 <= times.length <= 6000`
- `times[i].length == 3`
- `1 <= u_i, v_i <= n`
- `u_i != v_i`
- `0 <= w_i <= 100`
- All the pairs `(u_i, v_i)` are **unique**. (i.e., no multiple edges.)

SOLUTIONS (PYTHON 3)

Solution 1: Naive Dijkstra Algorithm

> **How to think about it**
>
> The time for every node to hear a signal from k is the longest shortest-path distance. n≤ 100 admits naive Dijkstra in $O(n^2)$. Repeatedly pick the unused node with smallest tentative distance and relax its outgoing edges. An adjacency matrix stores weights, missing edges as +∞. The answer is max(dist), or -1 if that value is still infinite.

We define g[u][v] to represent the edge weight from node u to node v. If there is no edge between node u and node v, then g[u][v] = +∞.

We maintain an array dist, where dist[i] represents the shortest path length from node k to node i. Initially, we set all dist[i] to +∞, except for dist[k - 1] = 0. We define an array vis, where vis[i] indicates whether node i has been visited. Initially, we set all vis[i] to false.

Each time, we find the unvisited node t with the smallest distance, and then perform relaxation operations centered on node t. For each node j, if dist[j] > dist[t] + g[t][j], we update dist[j] = dist[t] + g[t][j].

Finally, we return the maximum value in dist as the answer. If the answer is +∞, it means there are unreachable nodes, and we return -1.

The time complexity is $O(n^2 + m)$, and the space complexity is $O(n^2)$. Here, n and m are the number of nodes and edges, respectively.

Python 3

```
class Solution:
    def networkDelayTime(self, times: List[List[int]], n: int, k: int) -> int:
        g = [[inf] * n for _ in range(n)]
        for u, v, w in times:
            g[u - 1][v - 1] = w
        dist = [inf] * n
        dist[k - 1] = 0
        vis = [False] * n
        for _ in range(n):
            t = -1
            for j in range(n):
                if not vis[j] and (t == -1 or dist[t] > dist[j]):
                    t = j
            vis[t] = True
            for j in range(n):
                dist[j] = min(dist[j], dist[t] + g[t][j])
        ans = max(dist)
        return -1 if ans == inf else ans
```

Solution 2: Heap-Optimized Dijkstra Algorithm

> **How to think about it**
>
> Solution 1 scans all nodes to pick the next vertex; that is wasteful on a sparse graph. A heap pops the current best in O(mlog m). Store an adjacency list. Pop (d,u); skip stale distances; otherwise relax neighbors onto the heap. The answer is still the max finite distance.

We can use a priority queue (heap) to optimize the naive Dijkstra algorithm.

We define g[u] to represent all adjacent edges of node u, and dist[u] to represent the shortest path length from node k to node u. Initially, we set all dist[u] to +∞, except for dist[k - 1] = 0.

We define a priority queue pq, where each element is (d, u), representing the distance d from node u to node k. Each time, we take out the node (d, u) with the smallest distance from pq. If d >\textit{dist}[u], we skip this node. Otherwise, we traverse all adjacent edges of nodeu. For each adjacent edge(v, w), if\textit{dist}[v] > \textit{dist}[u] + w, we update\textit{dist}[v] = \textit{dist}[u] + wand add(\textit{dist}[v], v)to\textit{pq}$.

Finally, we return the maximum value in dist as the answer. If the answer is +∞, it means there are unreachable nodes, and we return -1.

The time complexity is O(m × log m + n), and the space complexity is O(n + m). Here, n and m are the number of nodes and edges, respectively.

Python 3

```python
class Solution:
    def networkDelayTime(self, times: List[List[int]], n: int, k: int) -> int:
        g = [[] for _ in range(n)]
        for u, v, w in times:
            g[u - 1].append((v - 1, w))
        dist = [inf] * n
        dist[k - 1] = 0
        pq = [(0, k - 1)]
        while pq:
            d, u = heappop(pq)
            if d > dist[u]:
                continue
            for v, w in g[u]:
                if (nd := d + w) < dist[v]:
                    dist[v] = nd
                    heappush(pq, (nd, v))
        ans = max(dist)
        return -1 if ans == inf else ans
```

1631. Path With Minimum Effort

Medium · Depth-First Search, Breadth-First Search, Union Find, Array, Binary Search, Matrix, Dijkstra, Heap (Priority Queue)

leetcode.com/problems/path-with-minimum-effort

★ **TOP 10 PROBLEM** in Shortest Path: master this one first

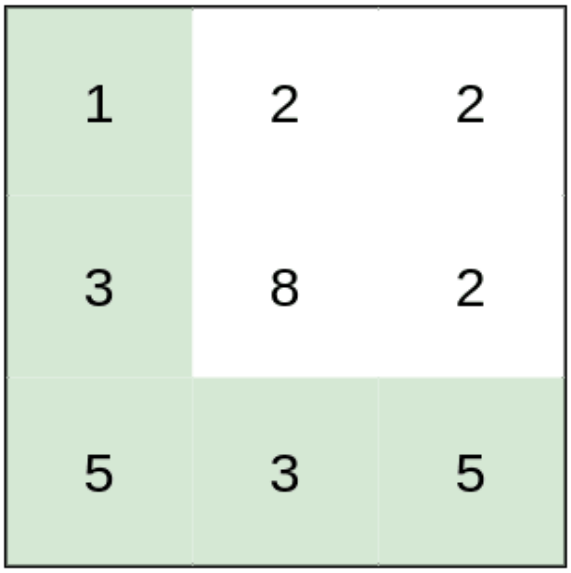
PROBLEM

You are a hiker preparing for an upcoming hike. You are given `heights`, a 2D array of size `rows x columns`, where `heights[row][col]` represents the height of cell `(row, col)`. You are situated in the top-left cell, `(0, 0)`, and you hope to travel to the bottom-right cell, `(rows-1, columns-1)` (i.e., **0-indexed**). You can move **up**, **down**, **left**, or **right**, and you wish to find a route that requires the minimum **effort**.

A route's **effort** is the **maximum absolute difference** in heights between two consecutive cells of the route.

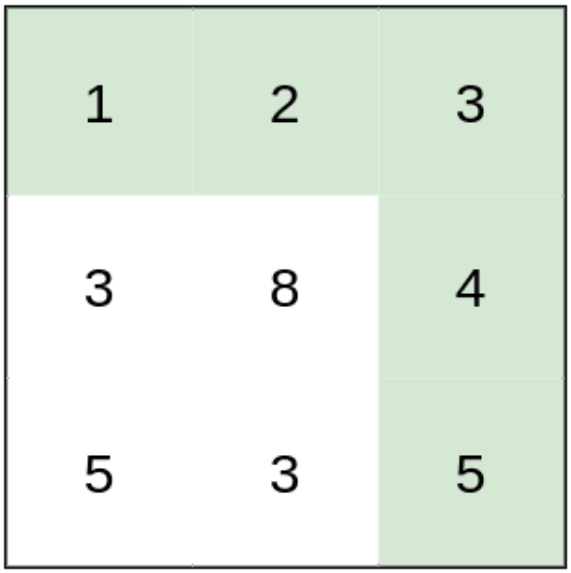
Return *the minimum **effort** required to travel from the top-left cell to the bottom-right cell.*

Example 1:



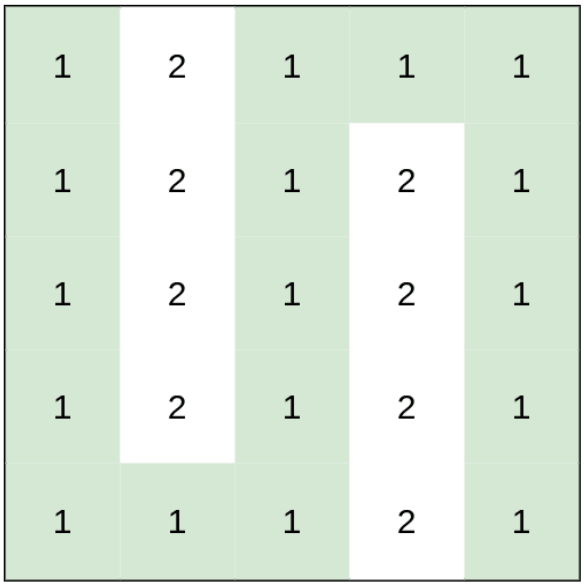
```
Input: heights = [[1,2,2],[3,8,2],[5,3,5]]
Output: 2
Explanation: The route of [1,3,5,3,5] has a maximum absolute difference of 2 in consecutive cells.
This is better than the route of [1,2,2,2,5], where the maximum absolute difference is 3.
```

Example 2:



```
Input: heights = [[1,2,3],[3,8,4],[5,3,5]]
Output: 1
Explanation: The route of [1,2,3,4,5] has a maximum absolute difference of 1 in consecutive cells,
which is better than route [1,3,5,3,5].
```

Example 3:



```
Input: heights = [[1,2,1,1,1],[1,2,1,2,1],[1,2,1,2,1],[1,2,1,2,1],[1,1,1,2,1]]
Output: 0
Explanation: This route does not require any effort.
```

Constraints:

- `rows == heights.length`
- `columns == heights[i].length`
- `1 <= rows, columns <= 100`
- `1 <= heights[i][j] <= 10^6`

Solution 1: Union-Find

How to think about it

A path's cost is the maximum adjacent height difference; we want the minimum such bottleneck. Binary search would still need a connectivity check; equivalently, treat cells as vertices and differences as edge weights and add edges in increasing order. A disjoint-set unions edges by weight; the first time start and end meet, that weight is the min-max effort. Collect 4-neighbor edges, sort them, and union until connected(0,mn-1).

For this problem, we can treat each cell as a node in a graph, and the absolute difference in height between two adjacent cells as the weight of the edge. Therefore, this problem is to solve the connectivity problem from the top-left node to the bottom-right node.

We first construct a set of edges, then sort them in ascending order of edge weight, and add edges one by one until the top-left node and the bottom-right node are connected. At this point, the weight of the edge is the minimum physical consumption value required by the problem.

The time complexity is $O(m \times n \times \log(m \times n))$, and the space complexity is $O(m \times n)$. Here, m and n are the number of rows and columns in the two-dimensional array, respectively.

Python 3

```python
class UnionFind:
    def __init__(self, n):
        self.p = list(range(n))
        self.size = [1] * n

    def find(self, x):
        if self.p[x] != x:
            self.p[x] = self.find(self.p[x])
        return self.p[x]

    def union(self, a, b):
        pa, pb = self.find(a), self.find(b)
        if pa == pb:
            return False
        if self.size[pa] > self.size[pb]:
            self.p[pb] = pa
            self.size[pa] += self.size[pb]
        else:
            self.p[pa] = pb
            self.size[pb] += self.size[pa]
        return True

    def connected(self, a, b):
        return self.find(a) == self.find(b)

class Solution:
    def minimumEffortPath(self, heights: List[List[int]]) -> int:
        m, n = len(heights), len(heights[0])
        uf = UnionFind(m * n)
        e = []
        dirs = (0, 1, 0)
        for i in range(m):
            for j in range(n):
                for a, b in pairwise(dirs):
                    x, y = i + a, j + b
                    if 0 <= x < m and 0 <= y < n:
                        e.append(
                            (abs(heights[i][j] - heights[x][y]), i * n + j, x * n + y)
                        )
        e.sort()
        for h, a, b in e:
            uf.union(a, b)
            if uf.connected(0, m * n - 1):
                return h
        return 0
```

Solution 2: Binary Search + BFS

> **How to think about it**
>
> Solution 1 sorts every edge. A candidate h works iff start reaches end using only differences ≤ h, and that predicate is monotone in h. Binary-search h in $[0,10^6]$ and BFS each mid, without a disjoint-set.

We notice that if the maximum physical consumption value of a path is x, then for any y > x, this path also meets the conditions. This shows monotonicity, so we can use the binary search method to find the minimum physical consumption value that meets the conditions.

We define the left boundary of the binary search as l=0, and the right boundary as $r=10^6$. Each time we take mid=(l+r)/2, then use BFS to determine whether there is a path from the top-left corner to the bottom-right corner, so that the absolute difference in height between adjacent nodes on the path is not greater than mid. If it exists, it means that mid may still be the minimum physical consumption value that meets the conditions, so we set r=mid, otherwise we set l=mid+1.

The time complexity is O(m × n × log M), and the space complexity is O(m × n). Here, m and n are the number of rows and columns in the two-dimensional array, respectively, and M is the maximum value in the two-dimensional array. In this

problem, M=10^6.

Python 3

```python
class Solution:
    def minimumEffortPath(self, heights: List[List[int]]) -> int:
        def check(h: int) -> bool:
            q = deque([(0, 0)])
            vis = {(0, 0)}
            dirs = (-1, 0, 1, 0, -1)
            while q:
                for _ in range(len(q)):
                    i, j = q.popleft()
                    if i == m - 1 and j == n - 1:
                        return True
                    for a, b in pairwise(dirs):
                        x, y = i + a, j + b
                        if (
                            0 <= x < m
                            and 0 <= y < n
                            and (x, y) not in vis
                            and abs(heights[i][j] - heights[x][y]) <= h
                        ):
                            q.append((x, y))
                            vis.add((x, y))
            return False

        m, n = len(heights), len(heights[0])
        return bisect_left(range(10**6), True, key=check)
```

Solution 3: Heap-optimized Dijkstra Algorithm

> **How to think about it**
>
> The first two methods sort globally or search repeatedly. Treating a move as the new bottleneck max(so far, | Δ h |) is a shortest-path problem with max instead of +. Dijkstra with a heap stores the best bottleneck dist to each cell and relaxes four neighbors; the bottom-right entry is the answer.

We can treat each cell as a node in a graph, and the absolute difference in height between two adjacent cells as the weight of the edge. Therefore, this problem is to solve the shortest path problem from the top-left node to the bottom-right node.

We can use the Dijkstra algorithm to solve the shortest path problem, and use a priority queue (heap) to optimize the time complexity. Specifically, we maintain a two-dimensional array dist of size m × n, where dist[i][j] represents the maximum weight of the shortest path from the top-left corner to the node (i,j). Initially, dist[0][0]=0, and all other elements are positive infinity.

We use a priority queue (heap) to store nodes, and each time we take out the node with the smallest weight from the priority queue (heap), then update the weights of its adjacent nodes. If the weight of an adjacent node changes, then we add this node to the priority queue (heap). When the priority queue (heap) is empty, it means that we have found the shortest path.

The time complexity is O(m × n × log(m × n)), and the space complexity is O(m × n). Here, m and n are the number of rows and columns in the two-dimensional array, respectively.

Python 3

```
class Solution:
    def minimumEffortPath(self, heights: List[List[int]]) -> int:
        m, n = len(heights), len(heights[0])
        dist = [[inf] * n for _ in range(m)]
        dist[0][0] = 0
        dirs = (-1, 0, 1, 0, -1)
        q = [(0, 0, 0)]
        while q:
            t, i, j = heappop(q)
            for a, b in pairwise(dirs):
                x, y = i + a, j + b
                if (
                    0 <= x < m
                    and 0 <= y < n
                    and (d := max(t, abs(heights[i][j] - heights[x][y]))) < dist[x][y]
                ):
                    dist[x][y] = d
                    heappush(q, (d, x, y))
        return int(dist[-1][-1])
```

2976. Minimum Cost to Convert String I

Medium · Graph, Array, String, Shortest Path

leetcode.com/problems/minimum-cost-to-convert-string-i

★ **TOP 10 PROBLEM** in Shortest Path: master this one first

PROBLEM

You are given two **0-indexed** strings `source` and `target`, both of length `n` and consisting of **lowercase** English letters. You are also given two **0-indexed** character arrays `original` and `changed`, and an integer array `cost`, where `cost[i]` represents the cost of changing the character `original[i]` to the character `changed[i]`.

You start with the string `source`. In one operation, you can pick a character `x` from the string and change it to the character `y` at a cost of `z` **if** there exists **any** index `j` such that `cost[j] == z`, `original[j] == x`, and `changed[j] == y`.

Return *the **minimum** cost to convert the string* `source` *to the string* `target` *using **any** number of operations. If it is impossible to convert* `source` *to* `target`, *return* `-1`.

Note that there may exist indices `i`, `j` such that `original[j] == original[i]` and `changed[j] == changed[i]`.

Example 1:

```
Input: source = "abcd", target = "acbe", original = ["a","b","c","c","e","d"], changed =
["b","c","b","e","b","e"], cost = [2,5,5,1,2,20]
Output: 28
Explanation: To convert the string "abcd" to string "acbe":
- Change value at index 1 from 'b' to 'c' at a cost of 5.
- Change value at index 2 from 'c' to 'e' at a cost of 1.
- Change value at index 2 from 'e' to 'b' at a cost of 2.
- Change value at index 3 from 'd' to 'e' at a cost of 20.
The total cost incurred is 5 + 1 + 2 + 20 = 28.
It can be shown that this is the minimum possible cost.
```

Example 2:

```
Input: source = "aaaa", target = "bbbb", original = ["a","c"], changed = ["c","b"], cost = [1,2]
Output: 12
Explanation: To change the character 'a' to 'b' change the character 'a' to 'c' at a cost of 1,
followed by changing the character 'c' to 'b' at a cost of 2, for a total cost of 1 + 2 = 3. To change
all occurrences of 'a' to 'b', a total cost of 3 * 4 = 12 is incurred.
```

Example 3:

```
Input: source = "abcd", target = "abce", original = ["a"], changed = ["e"], cost = [10000]
Output: -1
Explanation: It is impossible to convert source to target because the value at index 3 cannot be
changed from 'd' to 'e'.
```

Constraints:

- `1 <= source.length == target.length <= 10^5`
- `source`, `target` consist of lowercase English letters.
- `1 <= cost.length == original.length == changed.length <= 2000`
- `original[i]`, `changed[i]` are lowercase English letters.
- `1 <= cost[i] <= 10^6`
- `original[i] != changed[i]`

SOLUTION (PYTHON 3)

Solution 1: Floyd Algorithm

How to think about it

A letter may be rewritten into another at a given cost; we want the cheapest map from source to target. There are 26 letters and rewrites compose, so we need all-pairs shortest paths. Floyd finishes g[x][y] in 26^3. Sum per position; an unreachable pair fails the instance. Parallel edges keep the lighter cost. The string length is 10^5, so preprocessing is separate from the scan.

According to the problem description, we can consider each letter as a node, and the conversion cost between each pair of letters as a directed edge. We first initialize a 26 × 26 two-dimensional array g, where g[i][j] represents the minimum cost of converting letter i to letter j. Initially, g[i][j] = ∞, and if i = j, then g[i][j] = 0.

Next, we traverse the arrays original, changed, and cost. For each index i, we update the cost cost[i] of converting original[i] to changed[i] to g[original[i]][changed[i]], taking the minimum value.

Then, we use the Floyd algorithm to calculate the minimum cost between any two nodes in g. Finally, we traverse the strings source and target. If source[i] ≠ target[i] and g[source[i]][target[i]] ≥ ∞, it means that the conversion cannot be completed, so we return -1. Otherwise, we add g[source[i]][target[i]] to the answer.

After the traversal ends, we return the answer.

The time complexity is $O(m + n + |\Sigma|^3)$, and the space complexity is $O(|\Sigma|^2)$. Where m and n are the lengths of the arrays original and source respectively; and |Σ| is the size of the alphabet, that is, |Σ| = 26.

Python 3

```python
class Solution:
    def minimumCost(
        self,
        source: str,
        target: str,
        original: List[str],
        changed: List[str],
        cost: List[int],
    ) -> int:
        g = [[inf] * 26 for _ in range(26)]
        for i in range(26):
            g[i][i] = 0
        for x, y, z in zip(original, changed, cost):
            x = ord(x) - ord('a')
            y = ord(y) - ord('a')
            g[x][y] = min(g[x][y], z)
        for k in range(26):
            for i in range(26):
                for j in range(26):
                    g[i][j] = min(g[i][j], g[i][k] + g[k][j])
        ans = 0
        for a, b in zip(source, target):
            if a != b:
                x, y = ord(a) - ord('a'), ord(b) - ord('a')
                if g[x][y] >= inf:
                    return -1
                ans += g[x][y]
        return ans
```

3341. Find Minimum Time to Reach Last Room I

Medium · Graph, Array, Matrix, Shortest Path, Heap (Priority Queue)

leetcode.com/problems/find-minimum-time-to-reach-last-room-i

★ **TOP 10 PROBLEM** in Shortest Path: master this one first

PROBLEM

There is a dungeon with `n x m` rooms arranged as a grid.

You are given a 2D array `moveTime` of size `n x m`, where `moveTime[i][j]` represents the **minimum** time in seconds **after** which the room opens and can be moved to. You start from the room `(0, 0)` at time `t = 0` and can move to an **adjacent** room. Moving between adjacent rooms takes *exactly* one second.

Return the **minimum** time to reach the room `(n - 1, m - 1)`.

Two rooms are **adjacent** if they share a common wall, either *horizontally* or *vertically*.

Example 1:

Input: moveTime = [[0,4],[4,4]]

Output: 6

Explanation:

The minimum time required is 6 seconds.

- At time `t == 4`, move from room `(0, 0)` to room `(1, 0)` in one second.
- At time `t == 5`, move from room `(1, 0)` to room `(1, 1)` in one second.

Example 2:

Input: moveTime = [[0,0,0],[0,0,0]]

Output: 3

Explanation:

The minimum time required is 3 seconds.

- At time `t == 0`, move from room `(0, 0)` to room `(1, 0)` in one second.
- At time `t == 1`, move from room `(1, 0)` to room `(1, 1)` in one second.
- At time `t == 2`, move from room `(1, 1)` to room `(1, 2)` in one second.

Example 3:

Input: moveTime = [[0,1],[1,2]]

Output: 3

Constraints:

- `2 <= n == moveTime.length <= 50`
- `2 <= m == moveTime[i].length <= 50`
- `0 <= moveTime[i][j] <= 10^9`

SOLUTION (PYTHON 3)

Solution 1: Dijkstra's Algorithm

How to think about it

A move into (x,y) cannot happen before moveTime[x][y], and every step costs 1. Weights are nonnegative but depend on arrival time, so BFS is wrong. With n,m ≤ 50, Dijkstra on time is enough. The relaxation is t=max(moveTime[x][y],dist[i][j])+1. The first time the priority queue pops the destination is the answer.

We define a two-dimensional array dist, where dist[i][j] represents the minimum time required to reach room (i, j) from the starting point. Initially, we set all elements in the dist array to infinity, and then set the dist value of the starting point (0, 0) to 0.

We use a priority queue pq to store each state, where each state consists of three values (d, i, j), representing the time d required to reach room (i, j) from the starting point. Initially, we add the starting point (0, 0, 0) to pq.

In each iteration, we take the front element (d, i, j) from pq. If (i, j) is the endpoint, we return d. If d is greater than dist[i][j], we skip this state. Otherwise, we enumerate the four adjacent positions (x, y) of (i, j). If (x, y) is within the map, we calculate the final time t from (i, j) to (x, y) as t = max(moveTime[x][y], dist[i][j]) + 1. If t is less than dist[x][y], we update the value of dist[x][y] and add (t, x, y) to pq.

The time complexity is O(n × m × log (n × m)), and the space complexity is O(n × m). Here, n and m are the number of rows and columns of the map, respectively.

Python 3

```python
class Solution:
    def minTimeToReach(self, moveTime: List[List[int]]) -> int:
        n, m = len(moveTime), len(moveTime[0])
        dist = [[inf] * m for _ in range(n)]
        dist[0][0] = 0
        pq = [(0, 0, 0)]
        dirs = (-1, 0, 1, 0, -1)
        while 1:
            d, i, j = heappop(pq)
            if i == n - 1 and j == m - 1:
                return d
            if d > dist[i][j]:
                continue
            for a, b in pairwise(dirs):
                x, y = i + a, j + b
                if 0 <= x < n and 0 <= y < m:
                    t = max(moveTime[x][y], dist[i][j]) + 1
                    if dist[x][y] > t:
                        dist[x][y] = t
                        heappush(pq, (t, x, y))
```

3650. Minimum Cost Path with Edge Reversals

Medium · Graph, Shortest Path, Heap (Priority Queue)

leetcode.com/problems/minimum-cost-path-with-edge-reversals

★ **TOP 10 PROBLEM** in Shortest Path: master this one first

PROBLEM

You are given a directed, weighted graph with `n` nodes labeled from 0 to `n - 1`, and an array `edges` where `edges[i] = [u_i, v_i, w_i]` represents a directed edge from node `u_i` to node `v_i` with cost `w_i`.

Each node `u_i` has a switch that can be used **at most once**: when you arrive at `u_i` and have not yet used its switch, you may activate it on one of its incoming edges `v_i → u_i` reverse that edge to `u_i → v_i` and **immediately** traverse it.

The reversal is only valid for that single move, and using a reversed edge costs `2 * w_i`.

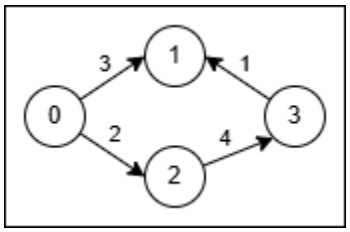
Return the **minimum** total cost to travel from node 0 to node `n - 1`. If it is not possible, return -1.

Example 1:

Input: n = 4, edges = [[0,1,3],[3,1,1],[2,3,4],[0,2,2]]

Output: 5

Explanation:



- Use the path `0 → 1` (cost 3).
- At node 1 reverse the original edge `3 → 1` into `1 → 3` and traverse it at cost `2 * 1 = 2`.
- Total cost is `3 + 2 = 5`.

Example 2:

Input: n = 4, edges = [[0,2,1],[2,1,1],[1,3,1],[2,3,3]]

Output: 3

Explanation:

- No reversal is needed. Take the path `0 → 2` (cost 1), then `2 → 1` (cost 1), then `1 → 3` (cost 1).
- Total cost is `1 + 1 + 1 = 3`.

Constraints:

- `2 <= n <= 5 * 10^4`
- `1 <= edges.length <= 10^5`
- `edges[i] = [u_i, v_i, w_i]`
- `0 <= u_i, v_i <= n - 1`
- `1 <= w_i <= 1000`

SOLUTION (PYTHON 3)

Solution 1: Dijkstra's Algorithm

How to think about it

A forward traversal costs w and a reversal costs 2w. We want the cheapest walk from 0 to n-1. Enumerating which edges to reverse is exponential. Materialize the reverse as an extra arc: keep (u,v,w) and add (v,u,2w). The instance becomes an ordinary nonnegative shortest-path problem. Heap Dijkstra from 0 returns the first time n-1 is popped; an empty heap means unreachable. Each original edge yields two directed arcs, so the complexity tracks mlog m.

According to the problem description, we can construct a directed graph g where each edge (u, v) allows for two types of traversal:

- Direct traversal with cost w, corresponding to edge (u, v).
- Reverse traversal with cost 2w, corresponding to edge (v, u).

Then, we can use Dijkstra's algorithm on graph g to find the shortest path from node 0 to node n-1, which corresponds to the minimum total cost required.

Specifically, we define a priority queue pq, where each element is a tuple (d, u), indicating that the current minimum cost to reach node u is d. We also define an array dist, where dist[u] represents the minimum cost from node 0 to node u. Initially, we set dist[0] = 0, and the costs for all other nodes to infinity, then push (0, 0) into the queue.

In each iteration, we extract the node (d, u) with the minimum cost from the priority queue. If d is greater than dist[u], we skip this node. Otherwise, we traverse all neighbors v of node u, calculating the new cost nd = d + w to reach node v via node u. If nd is less than dist[v], we update dist[v] = nd and push (nd, v) into the queue.

When we extract node n-1, the current d is the minimum total cost from node 0 to node n-1. If the priority queue becomes empty and node n-1 has not been extracted, it implies that node n-1 is unreachable, so we return -1.

The time complexity is O(n + m × log m), and the space complexity is O(n + m). Here, n and m refer to the number of nodes and edges, respectively.

Python 3

```python
class Solution:
    def minCost(self, n: int, edges: List[List[int]]) -> int:
        g = [[] for _ in range(n)]
        for u, v, w in edges:
            g[u].append((v, w))
            g[v].append((u, w * 2))
        pq = [(0, 0)]
        dist = [inf] * n
        dist[0] = 0
        while pq:
            d, u = heappop(pq)
            if d > dist[u]:
                continue
            if u == n - 1:
                return d
            for v, w in g[u]:
                nd = d + w
                if nd < dist[v]:
                    dist[v] = nd
                    heappush(pq, (nd, v))
        return -1
```

778. Swim in Rising Water

Hard · Depth-First Search, Breadth-First Search, Union Find, Minimax, Array, Binary Search, Matrix, Dijkstra, Heap (Priority Queue)

leetcode.com/problems/swim-in-rising-water

★ **TOP 10 PROBLEM** in Shortest Path: master this one first

PROBLEM

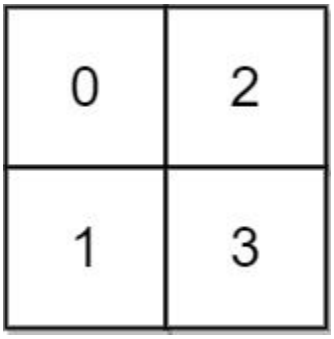
You are given an `n x n` integer matrix `grid` where each value `grid[i][j]` represents the elevation at that point `(i, j)`.

It starts raining, and water gradually rises over time. At time `t`, the water level is `t`, meaning **any** cell with elevation less than equal to `t` is submerged or reachable.

You can swim from a square to another 4-directionally adjacent square if and only if the elevation of both squares individually are at most `t`. You can swim infinite distances in zero time. Of course, you must stay within the boundaries of the grid during your swim.

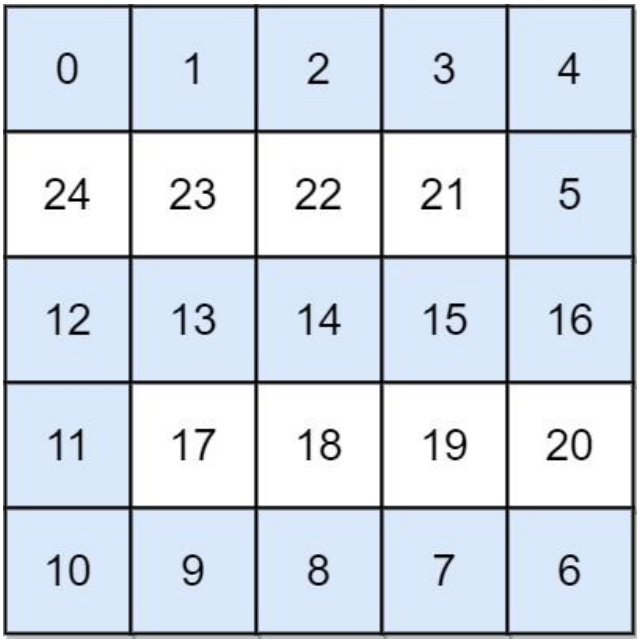
Return *the minimum time until you can reach the bottom right square* `(n - 1, n - 1)` *if you start at the top left square* `(0, 0)`.

Example 1:



```
Input: grid = [[0,2],[1,3]]
Output: 3
Explanation:
At time 0, you are in grid location (0, 0).
You cannot go anywhere else because 4-directionally adjacent neighbors have a higher elevation than t
= 0.
You cannot reach point (1, 1) until time 3.
When the depth of water is 3, we can swim anywhere inside the grid.
```

Example 2:



```
Input: grid = [[0,1,2,3,4],[24,23,22,21,5],[12,13,14,15,16],[11,17,18,19,20],[10,9,8,7,6]]
Output: 16
Explanation: The final route is shown.
We need to wait until time 16 so that (0, 0) and (4, 4) are connected.
```

Constraints:

- `n == grid.length`
- `n == grid[i].length`
- `1 <= n <= 50`
- `0 <= grid[i][j] < n^2`
- Each value `grid[i][j]` is **unique**.

SOLUTION (PYTHON 3)

Solution 1: Union Find

How to think about it

At time t we may walk cells ≤ t. Heights are a permutation of 0..n^2-1, so add cells in height order. When the cell of height t is unioned with already-present neighbors, the first time start meets end is the answer. Map height to id, then union as t grows. O(n^2α).

We can map each position (i, j) to an ID id = i × n + j, and use a union-find data structure to maintain connected components.

First, we use a one-dimensional array hi to record the position ID corresponding to each height, i.e., hi[h] represents the position ID with height h.

Then we traverse from height 0 to height n^2 - 1. For each height t, we merge position hi[t] with its four adjacent positions that have heights not exceeding t. If after merging, position 0 and position n^2 - 1 are connected, then we have found the minimum time t, and we return t.

The time complexity is O(n^2 × log n) and the space complexity is O(n^2), where n is the side length of the matrix.

Python 3

```python
class Solution:
    def swimInWater(self, grid: List[List[int]]) -> int:
        def find(x: int) -> int:
            if p[x] != x:
                p[x] = find(p[x])
            return p[x]

        n = len(grid)
        m = n * n
        p = list(range(m))
        hi = [0] * m
        for i, row in enumerate(grid):
            for j, h in enumerate(row):
                hi[h] = i * n + j
        dirs = (-1, 0, 1, 0, -1)
        for t in range(m):
            x, y = divmod(hi[t], n)
            for dx, dy in pairwise(dirs):
                nx, ny = x + dx, y + dy
                if 0 <= nx < n and 0 <= ny < n and grid[nx][ny] <= t:
                    p[find(x * n + y)] = find(nx * n + ny)
            if find(0) == find(m - 1):
                return t
        return 0
```

1368. Minimum Cost to Make at Least One Valid Path in a Grid

Hard · Breadth-First Search, Graph, Array, Matrix, Shortest Path, Dijkstra, Heap (Priority Queue), 0-1 BFS

leetcode.com/problems/minimum-cost-to-make-at-least-one-valid-path-in-a-grid

★ **TOP 10 PROBLEM** in Shortest Path: master this one first

PROBLEM

Given an `m x n` grid. Each cell of the grid has a sign pointing to the next cell you should visit if you are currently in this cell. The sign of `grid[i][j]` can be:

- `1` which means go to the cell to the right. (i.e go from `grid[i][j]` to `grid[i][j + 1]`)
- `2` which means go to the cell to the left. (i.e go from `grid[i][j]` to `grid[i][j - 1]`)
- `3` which means go to the lower cell. (i.e go from `grid[i][j]` to `grid[i + 1][j]`)
- `4` which means go to the upper cell. (i.e go from `grid[i][j]` to `grid[i - 1][j]`)

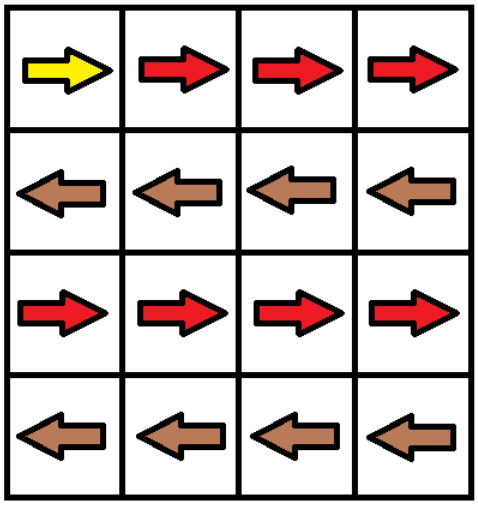
Notice that there could be some signs on the cells of the grid that point outside the grid.

You will initially start at the upper left cell `(0, 0)`. A valid path in the grid is a path that starts from the upper left cell `(0, 0)` and ends at the bottom-right cell `(m - 1, n - 1)` following the signs on the grid. The valid path does not have to be the shortest.

You can modify the sign on a cell with `cost = 1`. You can modify the sign on a cell **one time only**.

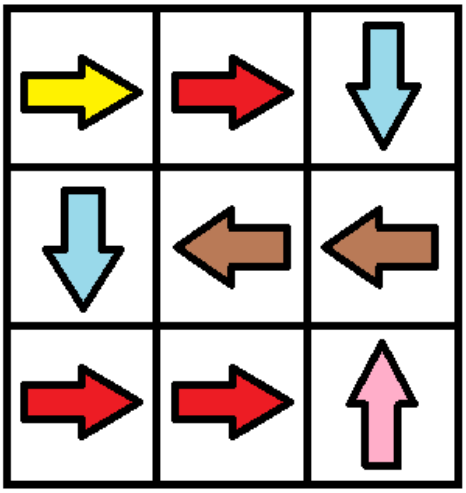
Return *the minimum cost to make the grid have at least one valid path*.

Example 1:



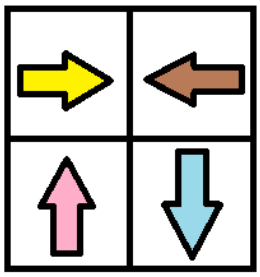
```
Input: grid = [[1,1,1,1],[2,2,2,2],[1,1,1,1],[2,2,2,2]]
Output: 3
Explanation: You will start at point (0, 0).
The path to (3, 3) is as follows. (0, 0) --> (0, 1) --> (0, 2) --> (0, 3) change the arrow to down with cost = 1 --> (1, 3) --> (1, 2) --> (1, 1) --> (1, 0) change the arrow to down with cost = 1 --> (2, 0) --> (2, 1) --> (2, 2) --> (2, 3) change the arrow to down with cost = 1 --> (3, 3)
The total cost = 3.
```

Example 2:



```
Input: grid = [[1,1,3],[3,2,2],[1,1,4]]
Output: 0
Explanation: You can follow the path from (0, 0) to (2, 2).
```

Example 3:



```
Input: grid = [[1,2],[4,3]]
Output: 1
```

Constraints:

- `m == grid.length`
- `n == grid[i].length`
- `1 <= m, n <= 100`
- `1 <= grid[i][j] <= 4`

SOLUTION (PYTHON 3)

Solution 1: Double-ended Queue BFS

How to think about it

Each cell points to a neighbor; changing an arrow costs 1. We want the fewest changes to the bottom-right. Dijkstra is O(mnlog). Weights are only 0 (follow the arrow) and 1 (change it), so 0-1 BFS applies: an aligned neighbor goes to the front at the same cost, a changed one to the back at cost plus one. The first visit to the target is optimal.

This problem is essentially a shortest path model, but what we are looking for is the minimum number of direction changes.

In an undirected graph where the edge weights are only 0 and 1, we can use a double-ended queue for BFS. The principle is that when the weight of the point that can be expanded currently is 0, it is added to the front of the queue; when the weight is 1, it is added to the end of the queue.

If the weight of an edge is 0, then the weight of the newly expanded node is the same as the weight of the current queue head node. Obviously, it can be used as the starting point for the next expansion.

Python 3

```python
class Solution:
    def minCost(self, grid: List[List[int]]) -> int:
        m, n = len(grid), len(grid[0])
        dirs = [[0, 0], [0, 1], [0, -1], [1, 0], [-1, 0]]
        q = deque([(0, 0, 0)])
        vis = set()
        while q:
            i, j, d = q.popleft()
            if (i, j) in vis:
                continue
            vis.add((i, j))
            if i == m - 1 and j == n - 1:
                return d
            for k in range(1, 5):
                x, y = i + dirs[k][0], j + dirs[k][1]
                if 0 <= x < m and 0 <= y < n:
                    if grid[i][j] == k:
                        q.appendleft((x, y, d))
                    else:
                        q.append((x, y, d + 1))
        return -1
```

2203. Minimum Weighted Subgraph With the Required Paths

Hard · Graph, Shortest Path, Heap (Priority Queue)

leetcode.com/problems/minimum-weighted-subgraph-with-the-required-paths

★ **TOP 10 PROBLEM** in Shortest Path: master this one first

PROBLEM

You are given an integer `n` denoting the number of nodes of a **weighted directed** graph. The nodes are numbered from `0` to `n - 1`.

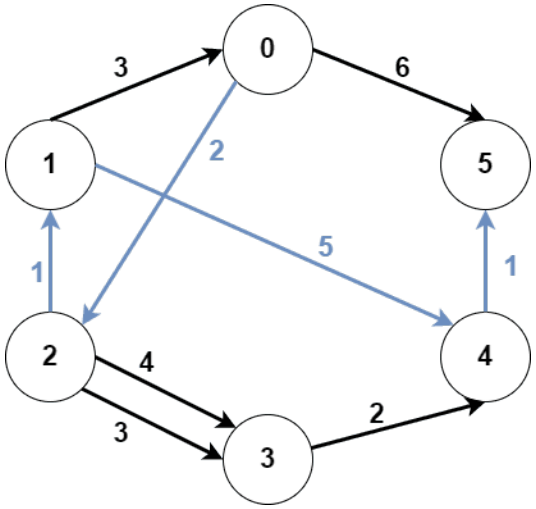
You are also given a 2D integer array `edges` where `edges[i] = [from_i, to_i, weight_i]` denotes that there exists a **directed** edge from `from_i` to `to_i` with weight `weight_i`.

Lastly, you are given three **distinct** integers `src1`, `src2`, and `dest` denoting three distinct nodes of the graph.

Return *the **minimum weight** of a subgraph of the graph such that it is **possible** to reach* `dest` *from both* `src1` *and* `src2` *via a set of edges of this subgraph*. In case such a subgraph does not exist, return `-1`.

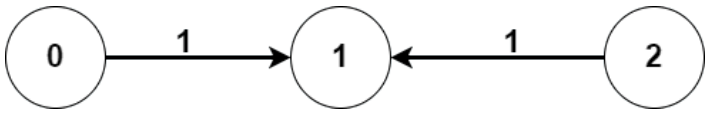
A **subgraph** is a graph whose vertices and edges are subsets of the original graph. The **weight** of a subgraph is the sum of weights of its constituent edges.

Example 1:



```
Input: n = 6, edges = [[0,2,2],[0,5,6],[1,0,3],[1,4,5],[2,1,1],[2,3,3],[2,3,4],[3,4,2],[4,5,1]], src1
= 0, src2 = 1, dest = 5
Output: 9
Explanation:
The above figure represents the input graph.
The blue edges represent one of the subgraphs that yield the optimal answer.
Note that the subgraph [[1,0,3],[0,5,6]] also yields the optimal answer. It is not possible to get a
subgraph with less weight satisfying all the constraints.
```

Example 2:



```
Input: n = 3, edges = [[0,1,1],[2,1,1]], src1 = 0, src2 = 1, dest = 2
Output: -1
Explanation:
The above figure represents the input graph.
It can be seen that there does not exist any path from node 1 to node 2, hence there are no subgraphs
satisfying all the constraints.
```

Constraints:

- `3 <= n <= 10^5`
- `0 <= edges.length <= 10^5`
- `edges[i].length == 3`
- `0 <= from_i, to_i, src1, src2, dest <= n - 1`
- `from_i != to_i`
- `src1`, `src2`, and `dest` are pairwise distinct.
- `1 <= weight[i] <= 10^5`

SOLUTION (PYTHON 3)

Solution 1

How to think about it

We need a minimum-weight subgraph that contains both $src_1 \to dest$ and $src_2 \to dest$. Taking two shortest paths independently double-counts the shared suffix and is not always optimal. n, m ≤ 10^5, so enumerating subgraphs is impossible. Both paths end at dest, so they meet at some vertex p (possibly dest itself). The optimum is the sum of three shortest paths: $src_1 \to p$, $src_2 \to p$, and $p \to dest$. Run Dijkstra from src_1 and src_2 on the original graph, and from dest on the reversed graph. Enumerate p and take $\min(d_1[p]+d_2[p]+d_3[p])$, or -1 if the value stays infinite.

Python 3

```python
class Solution:
    def minimumWeight(
        self, n: int, edges: List[List[int]], src1: int, src2: int, dest: int
    ) -> int:
        def dijkstra(g, u):
            dist = [inf] * n
            dist[u] = 0
            q = [(0, u)]
            while q:
                d, u = heappop(q)
                if d > dist[u]:
                    continue
                for v, w in g[u]:
                    if dist[v] > dist[u] + w:
                        dist[v] = dist[u] + w
                        heappush(q, (dist[v], v))
            return dist

        g = defaultdict(list)
        rg = defaultdict(list)
        for f, t, w in edges:
            g[f].append((t, w))
            rg[t].append((f, w))
        d1 = dijkstra(g, src1)
        d2 = dijkstra(g, src2)
        d3 = dijkstra(rg, dest)
        ans = min(sum(v) for v in zip(d1, d2, d3))
        return -1 if ans >= inf else ans
```

Complexity. Time: O(E log E) (three Dijkstra runs). Space: O(n + E).

332. Reconstruct Itinerary

Hard · Depth-First Search, Graph, Array, String, Sorting, Eulerian Path, Eulerian Circuit, Heap (Priority Queue), Semi-Eulerian Graph

leetcode.com/problems/reconstruct-itinerary

★ **TOP 10 PROBLEM** in Eulerian Circuit: master this one first

PROBLEM

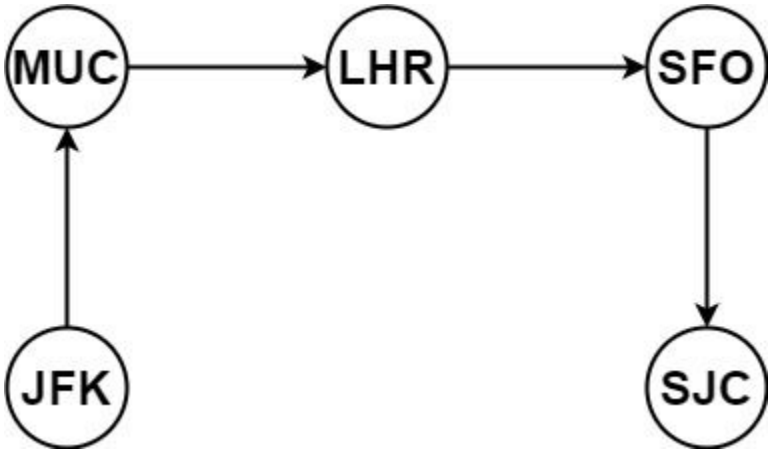
You are given a list of airline `tickets` where `tickets[i] = [from`$_i$`, to`$_i$`]` represent the departure and the arrival airports of one flight. Reconstruct the itinerary in order and return it.

All of the tickets belong to a man who departs from `"JFK"`, thus, the itinerary must begin with `"JFK"`. If there are multiple valid itineraries, you should return the itinerary that has the smallest lexical order when read as a single string.

- For example, the itinerary `["JFK", "LGA"]` has a smaller lexical order than `["JFK", "LGB"]`.

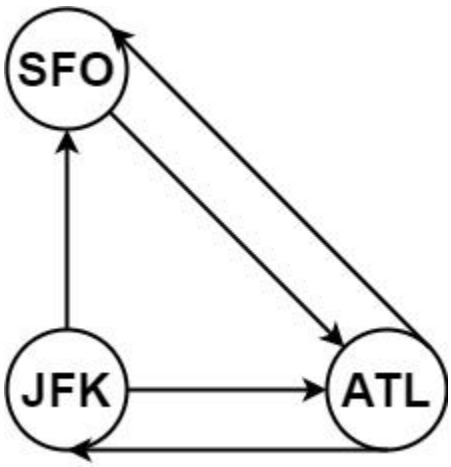
You may assume all tickets form at least one valid itinerary. You must use all the tickets once and only once.

Example 1:



```
Input: tickets = [["MUC","LHR"],["JFK","MUC"],["SFO","SJC"],["LHR","SFO"]]
Output: ["JFK","MUC","LHR","SFO","SJC"]
```

Example 2:



```
Input: tickets = [["JFK","SFO"],["JFK","ATL"],["SFO","ATL"],["ATL","JFK"],["ATL","SFO"]]
Output: ["JFK","ATL","JFK","SFO","ATL","SFO"]
Explanation: Another possible reconstruction is ["JFK","SFO","ATL","JFK","ATL","SFO"] but it is larger in lexical order.
```

Constraints:

- `1 <= tickets.length <= 300`
- `tickets[i].length == 2`
- `from`$_i$`.length == 3`
- `to`$_i$`.length == 3`
- `from`$_i$ and `to`$_i$ consist of uppercase English letters.
- `from`$_i$ `!= to`$_i$

SOLUTION (PYTHON 3)

Solution 1: Eulerian Path

> **How to think about it**
>
> Use every ticket once and produce the lexicographically smallest itinerary: an Eulerian path starting at `JFK`. Store destinations in reverse order so the last pop is the smallest next hop. Append nodes in postorder and reverse; dead ends are recorded first. A tour is guaranteed.

The problem is essentially about finding a path that starts from a specified starting point, passes through all the edges exactly once, and has the smallest lexicographical order among all such paths, given n vertices and m edges. This is a classic Eulerian path problem.

Since the problem guarantees that there is at least one feasible itinerary, we can directly use the Hierholzer algorithm to output the Eulerian path starting from the starting point.

The time complexity is O(m × log m), and the space complexity is O(m). Here, m is the number of edges.

Python 3

```python
class Solution:
    def findItinerary(self, tickets: List[List[str]]) -> List[str]:
        def dfs(f: str):
            while g[f]:
                dfs(g[f].pop())
            ans.append(f)

        g = defaultdict(list)
        for f, t in sorted(tickets, reverse=True):
            g[f].append(t)
        ans = []
        dfs("JFK")
        return ans[::-1]
```

753. Cracking the Safe

Hard · Depth-First Search, Graph, String, Eulerian Path, Eulerian Circuit, Eulerian Graph

leetcode.com/problems/cracking-the-safe

★ **TOP 10 PROBLEM** in Eulerian Circuit: master this one first

PROBLEM

There is a safe protected by a password. The password is a sequence of `n` digits where each digit can be in the range `[0, k - 1]`.

The safe has a peculiar way of checking the password. When you enter in a sequence, it checks the **most recent** `n` **digits** that were entered each time you type a digit.

- For example, the correct password is `"345"` and you enter in `"012345"`:
  - After typing `0`, the most recent `3` digits is `"0"`, which is incorrect.
  - After typing `1`, the most recent `3` digits is `"01"`, which is incorrect.
  - After typing `2`, the most recent `3` digits is `"012"`, which is incorrect.
  - After typing `3`, the most recent `3` digits is `"123"`, which is incorrect.
  - After typing `4`, the most recent `3` digits is `"234"`, which is incorrect.
  - After typing `5`, the most recent `3` digits is `"345"`, which is correct and the safe unlocks.

Return *any string of* ***minimum length*** *that will unlock the safe* ***at some point*** *of entering it*.

Example 1:

```
Input: n = 1, k = 2
Output: "10"
Explanation: The password is a single digit, so enter each digit. "01" would also unlock the safe.
```

Example 2:

```
Input: n = 2, k = 2
Output: "01100"
Explanation: For each possible password:
- "00" is typed in starting from the 4th digit.
- "01" is typed in starting from the 1st digit.
- "10" is typed in starting from the 3rd digit.
- "11" is typed in starting from the 2nd digit.
Thus "01100" will unlock the safe. "10011", and "11001" would also unlock the safe.
```

Constraints:

- `1 <= n <= 4`
- `1 <= k <= 10`
- `1 <= k^n <= 4096`

SOLUTION (PYTHON 3)

Solution 1: Eulerian Circuit

How to think about it

A shortest string that contains every length-n password over k digits is a de Bruijn sequence, length k^n+n-1. Nodes are (n-1)-mers; an extra digit is an edge, i.e. one password. Every degree is k, so an Eulerian circuit exists and spells the answer. Hierholzer from 0: mark edge u· 10+x, recurse, then append the digit (post-order), and finally add the n-1 zeros of the start.

We can construct a directed graph based on the description in the problem: each point is considered as a length n-1 k-string, and each edge carries a character from 0 to k-1. If there is a directed edge e from point u to point v, and the character carried by e is c, then the last k-1 characters of u+c form the string v. At this point, the edge u+c represents a password of length n.

In this directed graph, there are k^{n-1} points, each point has k outgoing edges and k incoming edges. Therefore, this directed graph has an Eulerian circuit, and the path traversed by the Eulerian circuit is the answer to the problem.

The time complexity is $O(k^n)$, and the space complexity is $O(k^n)$.

Python 3

```
class Solution:
    def crackSafe(self, n: int, k: int) -> str:
        def dfs(u):
            for x in range(k):
                e = u * 10 + x
                if e not in vis:
                    vis.add(e)
                    v = e % mod
                    dfs(v)
                    ans.append(str(x))

        mod = 10 ** (n - 1)
        vis = set()
        ans = []
        dfs(0)
        ans.append("0" * (n - 1))
        return "".join(ans)
```

PART 2 · EULERIAN CIRCUIT · PROBLEM 3 OF 3

2097. Valid Arrangement of Pairs

Hard · Depth-First Search, Graph, Array, Eulerian Path, Eulerian Circuit, Semi-Eulerian Graph

leetcode.com/problems/valid-arrangement-of-pairs

★ **TOP 10 PROBLEM** in Eulerian Circuit: master this one first

PROBLEM

You are given a **0-indexed** 2D integer array `pairs` where `pairs[i] = [start`$_i$`, end`$_i$`]`. An arrangement of `pairs` is **valid** if for every index `i` where `1 <= i < pairs.length`, we have `end`$_{i-1}$ `== start`$_i$.

Return ***any** valid arrangement of* `pairs`.

Note: The inputs will be generated such that there exists a valid arrangement of `pairs`.

Example 1:

```
Input: pairs = [[5,1],[4,5],[11,9],[9,4]]
Output: [[11,9],[9,4],[4,5],[5,1]]
Explanation:
This is a valid arrangement since endi-1 always equals starti.
end0 = 9 == 9 = start1
end1 = 4 == 4 = start2
end2 = 5 == 5 = start3
```

Example 2:

```
Input: pairs = [[1,3],[3,2],[2,1]]
Output: [[1,3],[3,2],[2,1]]
Explanation:
This is a valid arrangement since endi-1 always equals starti.
end0 = 3 == 3 = start1
end1 = 2 == 2 = start2
The arrangements [[2,1],[1,3],[3,2]] and [[3,2],[2,1],[1,3]] are also valid.
```

Example 3:

```
Input: pairs = [[1,2],[1,3],[2,1]]
Output: [[1,2],[2,1],[1,3]]
Explanation:
This is a valid arrangement since endi-1 always equals starti.
end0 = 2 == 2 = start1
end1 = 1 == 1 = start2
```

Constraints:

- `1 <= pairs.length <= 10`^{5}
- `pairs[i].length == 2`
- `0 <= start`$_i$`, end`$_i$ `<= 10`^{9}
- `start`$_i$ `!= end`$_i$
- No two pairs are exactly the same.
- There **exists** a valid arrangement of `pairs`.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Pairs must chain, i.e. an Eulerian path in the directed graph of edges start → end. Hierholzer runs in linear time for m ≤ 10^5. Start at a vertex with out-degree one higher than in-degree, else anywhere. Push edges in postorder and reverse to obtain the arrangement. The code tabs are empty; the reasoning is the Eulerian-path construction.

Python 3 (written for this guide: the doocs page has an empty Python tab)

```python
class Solution:
    def validArrangement(self, pairs: List[List[int]]) -> List[List[int]]:
        # every pair is a directed edge a -> b: the answer is an Eulerian path (Hierholzer's algorithm)
        graph = defaultdict(list)
        out_minus_in = defaultdict(int)
        for a, b in pairs:
            graph[a].append(b)
            out_minus_in[a] += 1
            out_minus_in[b] -= 1
        start = pairs[0][0]
        for node, d in out_minus_in.items():
            if d == 1:                      # the path must begin where one more edge leaves than enters
                start = node
                break
        stack = [start]
        path = []
        while stack:
            node = stack[-1]
            if graph[node]:
                stack.append(graph[node].pop())
            else:
                path.append(stack.pop())
        path.reverse()
        return [[path[i], path[i + 1]] for i in range(len(path) - 1)]
```

Complexity. Time: O(E), E = number of pairs. Space: O(E).

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

Built on the solutions above: helper functions, then the function for each follow-up. No tests and no restating of the question.

509. Fibonacci Number

Easy · Recursion, Memoization, Math, Dynamic Programming

leetcode.com/problems/fibonacci-number

★ **TOP 10 PROBLEM** in 1-D DP: master this one first

PROBLEM

The **Fibonacci numbers**, commonly denoted `F(n)` form a sequence, called the **Fibonacci sequence**, such that each number is the sum of the two preceding ones, starting from `0` and `1`. That is,

```
F(0) = 0, F(1) = 1
F(n) = F(n - 1) + F(n - 2), for n > 1.
```

Given `n`, calculate `F(n)`.

Example 1:

```
Input: n = 2
Output: 1
Explanation: F(2) = F(1) + F(0) = 1 + 0 = 1.
```

Example 2:

```
Input: n = 3
Output: 2
Explanation: F(3) = F(2) + F(1) = 1 + 1 = 2.
```

Example 3:

```
Input: n = 4
Output: 3
Explanation: F(4) = F(3) + F(2) = 2 + 1 = 3.
```

Constraints:

- `0 <= n <= 30`

SOLUTIONS (PYTHON 3)

Solution 1: Recurrence

How to think about it

Fibonacci obeys $F_n = F_{n-1} + F_{n-2}$. Naive recursion recomputes the same subproblems. Even though n ≤ 30, an iterative recurrence is enough. Roll two variables for consecutive terms and iterate n times. Time is linear and extra space is constant.

We define two variables a and b, initially a = 0 and b = 1.

Next, we perform n iterations. In each iteration, we update the values of a and b to b and a + b, respectively.

Finally, we return a.

The time complexity is O(n), where n is the given integer. The space complexity is O(1).

Python 3

```python
class Solution:
    def fib(self, n: int) -> int:
        a, b = 0, 1
        for _ in range(n):
            a, b = b, a + b
        return a
```

Solution 2: Matrix Exponentiation

> **How to think about it**
>
> Solution 1 is already O(n) and enough here, but the same linear recurrence can be sped up for larger n. F_n is a product of a fixed 2 × 2 transition matrix. Fast exponentiation reduces n multiplications to O(log n). The constant is larger; use it when the same recurrence must scale.

We define Fib(n) as a 1 × 2 matrix bmatrix F_n & F_{n-1} bmatrix, where F_n and F_{n-1} are the n-th and (n - 1)-th Fibonacci numbers, respectively.

We want to derive Fib(n) from Fib(n - 1) = bmatrix F_{n-1} & F_{n-2} bmatrix. In other words, we need a matrix base such that Fib(n - 1) × base = Fib(n), i.e.:

$$\text{bmatrix } F_{n-1} \text{ \& } F_{n-2} \text{ bmatrix} \times \text{base} = \text{bmatrix } F_n \text{ \& } F_{n-1} \text{ bmatrix}$$

Since $F_n = F_{n-1} + F_{n-2}$, the first column of the matrix base is:

$$\text{bmatrix } 1 \text{ \textbackslash } 1 \text{ bmatrix}$$

The second column is:

$$\text{bmatrix } 1 \text{ \textbackslash } 0 \text{ bmatrix}$$

Thus, we have:

$$\text{bmatrix } F_{n-1} \text{ \& } F_{n-2} \text{ bmatrix} \times \text{bmatrix1 \& 1 \textbackslash 1 \& 0bmatrix} = \text{bmatrix } F_n \text{ \& } F_{n-1} \text{ bmatrix}$$

We define the initial matrix res = bmatrix 1 & 0 bmatrix, then F_n is equal to the second element of the first row of the result matrix obtained by multiplying res with base^n. We can solve this using matrix exponentiation.

The time complexity is O(log n), and the space complexity is O(1).

Python 3

```python
import numpy as np

class Solution:
    def fib(self, n: int) -> int:
        factor = np.asmatrix([(1, 1), (1, 0)], np.dtype("O"))
        res = np.asmatrix([(1, 0)], np.dtype("O"))
        while n:
            if n & 1:
                res = res * factor
            factor = factor * factor
            n >>= 1
        return res[0, 1]
```

PART 2 · 1-D DP · PROBLEM 2 OF 6

746. Min Cost Climbing Stairs

Easy · Array, Dynamic Programming

leetcode.com/problems/min-cost-climbing-stairs

★ **TOP 10 PROBLEM** in 1-D DP: master this one first

PROBLEM

You are given an integer array `cost` where `cost[i]` is the cost of i^{th} step on a staircase.

Once you pay the cost, you can either climb **one** or **two** steps.

You can either start from the step with index 0, or the step with index 1.

Return the **minimum** cost to reach the top of the staircase, which is the position just past the last step (index `cost.length`).

Example 1:

```
Input: cost = [10,15,20]
Output: 15
Explanation: You will start at index 1.
- Pay 15 and climb two steps to reach the top.
The total cost is 15.
```

Example 2:

```
Input: cost = [1,100,1,1,1,100,1,1,100,1]
Output: 6
Explanation: You will start at index 0.
- Pay 1 and climb two steps to reach index 2.
- Pay 1 and climb two steps to reach index 4.
- Pay 1 and climb two steps to reach index 6.
- Pay 1 and climb one step to reach index 7.
- Pay 1 and climb two steps to reach index 9.
- Pay 1 and climb one step to reach the top.
The total cost is 6.
```

Constraints:

- `2 <= cost.length <= 1000`
- `0 <= cost[i] <= 999`

SOLUTIONS (PYTHON 3)

Solution 1: Memoization Search

How to think about it

Start at index 0 or 1, pay the current stair, and climb one or two steps. n≤ 1000; plain recursion repeats stairs. The cost from i depends only on i+1 and i+2; past the top it is 0. Memoization computes each index once. The answer is min(dfs(0), dfs(1)). Time and space O(n).

We design a function dfs(i), which represents the minimum cost required to climb the stairs starting from the i-th step. Therefore, the answer is min(dfs(0), dfs(1)).

The execution process of the function dfs(i) is as follows:

- If i ≥ len(cost), it means the current position has exceeded the top of the stairs, and there is no need to climb further, so return 0;

- Otherwise, we can choose to climb 1 step with a cost of cost[i], then recursively call dfs(i + 1); or we can choose to climb 2 steps with a cost of cost[i], then recursively call dfs(i + 2);
- Return the minimum cost between these two options.

To avoid repeated calculations, we use memoization search, saving the results that have already been calculated in an array or hash table.

The time complexity is O(n), and the space complexity is O(n), where n is the length of the array cost.

Python 3

```
class Solution:
    def minCostClimbingStairs(self, cost: List[int]) -> int:
        @cache
        def dfs(i: int) -> int:
            if i >= len(cost):
                return 0
            return cost[i] + min(dfs(i + 1), dfs(i + 2))

        return min(dfs(0), dfs(1))
```

Solution 2: Dynamic Programming

> **How to think about it**
>
> Solution 1 already fills the cost of leaving each stair from the top downward. Here f[i] is the cost of reaching index i, which depends only on i-1 and i-2, so the table is filled upward and f[n] is the top.

We define f[i] as the minimum cost needed to reach the i-th stair. Initially, f[0] = f[1] = 0, and the answer is f[n].

When i ≥ 2, we can reach the i-th stair directly from the (i - 1)-th stair with one step, or from the (i - 2)-th stair with two steps. Therefore, we have the state transition equation:

$$f[i] = \min(f[i - 1] + cost[i - 1], f[i - 2] + cost[i - 2])$$

The final answer is f[n].

The time complexity is O(n), and the space complexity is O(n), where n is the length of the array cost.

Python 3

```
class Solution:
    def minCostClimbingStairs(self, cost: List[int]) -> int:
        n = len(cost)
        f = [0] * (n + 1)
        for i in range(2, n + 1):
            f[i] = min(f[i - 2] + cost[i - 2], f[i - 1] + cost[i - 1])
        return f[n]
```

Solution 3: Dynamic Programming (Space Optimization)

> **How to think about it**
>
> f[i] reads only the previous two values, so two scalars suffice. Space O(1).

We notice that the state transition equation for f[i] only depends on f[i - 1] and f[i - 2]. Therefore, we can use two variables f and g to alternately record the values of f[i - 2] and f[i - 1], thus optimizing the space complexity to O(1).

Python 3

```
class Solution:
    def minCostClimbingStairs(self, cost: List[int]) -> int:
        f = g = 0
        for i in range(2, len(cost) + 1):
            f, g = g, min(f + cost[i - 2], g + cost[i - 1])
        return g
```

Solution 4: Dynamic Programming

How to think about it

Expanding every one-step and two-step choice is exponential. There can be 1000 stairs, and the first call always moves to the next stair, so the chain has depth n. The cost of leaving stair i depends only on i+1 and i+2, and past the top the cost is 0. Set f[i] = cost[i] + min(f[i+1], f[i+2]) and fill i from n-1 down to 0. The answer is min(f[0], f[1]).

We let f[i] be the minimum cost of climbing from stair i to the top. When i ≥ n, f[i] = 0. For i < n,

$$f[i] = cost[i] + \min(f[i + 1], f[i + 2])$$

Compute this for i from n - 1 down to 0. The answer is min(f[0], f[1]).

The time complexity is O(n), and the space complexity is O(n), where n is the length of cost.

Python 3

```python
class Solution:
    def minCostClimbingStairs(self, cost: List[int]) -> int:
        n = len(cost)
        f = [0] * (n + 2)
        for i in range(n - 1, -1, -1):
            f[i] = cost[i] + min(f[i + 1], f[i + 2])
        return min(f[0], f[1])
```

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

Built on the solutions above: helper functions, then the function for each follow-up. No tests and no restating of the question.

```python
# FOLLOW-UPS (answered below, in this order):

    n = len(cost)
    best = [float("inf")] * (n + 1)
    best[0] = best[1] = 0
    for i in range(2, n + 1):
        for k in (1, 2, 3):
            if i - k >= 0:
                best[i] = min(best[i], best[i - k] + cost[i - k])
    return best[n]
```

343. Integer Break

Medium · Math, Dynamic Programming

leetcode.com/problems/integer-break

★ **TOP 10 PROBLEM** in 1-D DP: master this one first

PROBLEM

Given an integer `n`, break it into the sum of `k` **positive integers**, where `k >= 2`, and maximize the product of those integers.

Return *the maximum product you can get*.

Example 1:

```
Input: n = 2
Output: 1
Explanation: 2 = 1 + 1, 1 × 1 = 1.
```

Example 2:

```
Input: n = 10
Output: 36
Explanation: 10 = 3 + 3 + 4, 3 × 3 × 4 = 36.
```

Constraints:

- `2 <= n <= 58`

SOLUTIONS (PYTHON 3)

Solution 1: Dynamic Programming

How to think about it

Split n into at least two positives maximizing the product. Listing partitions is large. If the last part is j, the rest is either kept whole or already optimal. f[i]=max$_j$ max(f[i-j]· j, (i-j)· j) with f[1]=1. Fill by increasing i; the answer is f[n]. n≤ 58 allows O(n^2).

We define f[i] as the maximum product that can be obtained by splitting the positive integer i, with an initial condition of f[1] = 1. The answer is f[n].

Consider the last number j split from i, where j ∈ [1, i). For the number j split from i, there are two cases:

1. Split i into the sum of i - j and j, without further splitting, where the product is (i - j) × j;
2. Split i into the sum of i - j and j, and continue splitting, where the product is f[i - j] × j.

Therefore, we can derive the state transition equation:

$$f[i] = \max(f[i], f[i - j] \times j, (i - j) \times j) \ (j \in [0, i))$$

Finally, returning f[n] will suffice.

The time complexity is O(n^2), and the space complexity is O(n). Here, n is the given positive integer.

Python 3

```python
class Solution:
    def integerBreak(self, n: int) -> int:
        f = [1] * (n + 1)
        for i in range(2, n + 1):
            for j in range(1, i):
                f[i] = max(f[i], f[i - j] * j, (i - j) * j)
        return f[n]
```

Solution 2: Mathematics

> **How to think about it**
>
> Method 1 does not name the optimal parts. For n≥ 4 use as many 3s as possible; a remainder 1 becomes 2+2, a remainder 2 keeps an extra 2. For n<4 the product is n-1. Closed form in O(1).

When n < 4, since the problem requires splitting into at least two integers, n - 1 yields the maximum product. When n ≥ 4, we split into as many 3s as possible. If the last segment remaining is 4, we split it into 2 + 2 for the maximum product.

The time complexity is O(1), and the space complexity is O(1).

Python 3

```
class Solution:
    def integerBreak(self, n: int) -> int:
        if n < 4:
            return n - 1
        if n % 3 == 0:
            return pow(3, n // 3)
        if n % 3 == 1:
            return pow(3, n // 3 - 1) * 4
        return pow(3, n // 3) * 2
```

```

PART 2 · 1-D DP · PROBLEM 4 OF 6

646. Maximum Length of Pair Chain

Medium · Greedy, Array, Dynamic Programming, Sorting, Longest Increasing Subsequence

leetcode.com/problems/maximum-length-of-pair-chain

★ **TOP 10 PROBLEM** in 1-D DP: master this one first

PROBLEM

You are given an array of `n` pairs `pairs` where `pairs[i] = [left_i, right_i]` and `left_i < right_i`.

A pair `p2 = [c, d]` **follows** a pair `p1 = [a, b]` if `b < c`. A **chain** of pairs can be formed in this fashion.

Return *the length longest chain which can be formed*.

You do not need to use up all the given intervals. You can select pairs in any order.

Example 1:

```
Input: pairs = [[1,2],[2,3],[3,4]]
Output: 2
Explanation: The longest chain is [1,2] -> [3,4].
```

Example 2:

```
Input: pairs = [[1,2],[7,8],[4,5]]
Output: 3
Explanation: The longest chain is [1,2] -> [4,5] -> [7,8].
```

Constraints:

- `n == pairs.length`
- `1 <= n <= 1000`
- `-1000 <= left_i < right_i <= 1000`

SOLUTION (PYTHON 3)

Solution 1: Sorting + Greedy

How to think about it

A chain is a strictly increasing sequence of pairs. LIS-style DP is $O(n^2)$. Sort by the right end and take a pair whenever it fits. Smaller right ends leave more room, so one greedy pass is optimal.

We sort all pairs in ascending order by the second number, and use a variable pre to maintain the maximum value of the second number of the selected pairs.

We traverse the sorted pairs. If the first number of the current pair is greater than pre, we can greedily select the current pair, increment the answer by one, and update pre to the second number of the current pair.

After the traversal, we return the answer.

The time complexity is O(n × log n), and the space complexity is O(log n). Here, n is the number of pairs.

Python 3

```python
class Solution:
    def findLongestChain(self, pairs: List[List[int]]) -> int:
        pairs.sort(key=lambda x: x[1])
        ans, pre = 0, -inf
        for a, b in pairs:
            if pre < a:
                ans += 1
                pre = b
        return ans
```

1262. Greatest Sum Divisible by Three

Medium · Greedy, Array, Dynamic Programming, Sorting

leetcode.com/problems/greatest-sum-divisible-by-three

★ **TOP 10 PROBLEM** in 1-D DP: master this one first

PROBLEM

Given an integer array `nums`, return *the **maximum possible sum** of elements of the array such that it is divisible by three*.

Example 1:

```
Input: nums = [3,6,5,1,8]
Output: 18
Explanation: Pick numbers 3, 6, 1 and 8 their sum is 18 (maximum sum divisible by 3).
```

Example 2:

```
Input: nums = [4]
Output: 0
Explanation: Since 4 is not divisible by 3, do not pick any number.
```

Example 3:

```
Input: nums = [1,2,3,4,4]
Output: 12
Explanation: Pick numbers 1, 3, 4 and 4 their sum is 12 (maximum sum divisible by 3).
```

Constraints:

- `1 <= nums.length <= 4 * 10^4`
- `1 <= nums[i] <= 10^4`

SOLUTIONS (PYTHON 3)

Solution 1: Dynamic Programming

How to think about it

We want the maximum subsequence sum divisible by 3. n ≤ 4× 10^4 forbids subsets. A sum has only three remainders modulo 3, and taking or skipping the current value moves among those three. f[i][j] is the best sum of the first i numbers with remainder j. Skip inherits; take adds x from remainder j-x. The answer is f[n][0]. Remainders collapse the constraint to a constant number of states.

We define f[i][j] as the maximum sum of several numbers selected from the first i numbers, such that the sum modulo 3 equals j. Initially, f[0][0]=0, and the rest are -∞.

For f[i][j], we can consider the state of the ith number x:

- If we do not select x, then f[i][j]=f[i-1][j];
- If we select x, then f[i][j]=f[i-1][(j-x mod 3 + 3) mod 3]+x.

Therefore, we can get the state transition equation:

$$f[i][j]=\max\{f[i-1][j],f[i-1][(j-x \bmod 3 + 3) \bmod 3]+x\}$$

The final answer is f[n][0].

The time complexity is O(n), and the space complexity is O(n). Where n is the length of the array nums.

Python 3

```python
class Solution:
    def maxSumDivThree(self, nums: List[int]) -> int:
        n = len(nums)
        f = [[-inf] * 3 for _ in range(n + 1)]
        f[0][0] = 0
        for i, x in enumerate(nums, 1):
            for j in range(3):
                f[i][j] = max(f[i - 1][j], f[i - 1][(j - x) % 3] + x)
        return f[n][0]
```

Solution 2: Dynamic Programming (Rolling Array)

> **How to think about it**
>
> Solution 1 stores O(n) rows. Row i reads only three previous values, so a length-3 rolling array suffices. Extra space is constant; the transition is unchanged.

f[i][j] depends only on the previous row's three residues, so an array of length 3 is enough. The space complexity is O(1).

Python 3

```python
class Solution:
    def maxSumDivThree(self, nums: List[int]) -> int:
        f = [0, -inf, -inf]
        for x in nums:
            g = f[:]
            for j in range(3):
                g[j] = max(f[j], f[(j - x) % 3] + x)
            f = g
        return f[0]
```

    return sorted(rest)
```

1411. Number of Ways to Paint N × 3 Grid

Hard · Dynamic Programming, Graph Coloring

leetcode.com/problems/number-of-ways-to-paint-n-3-grid

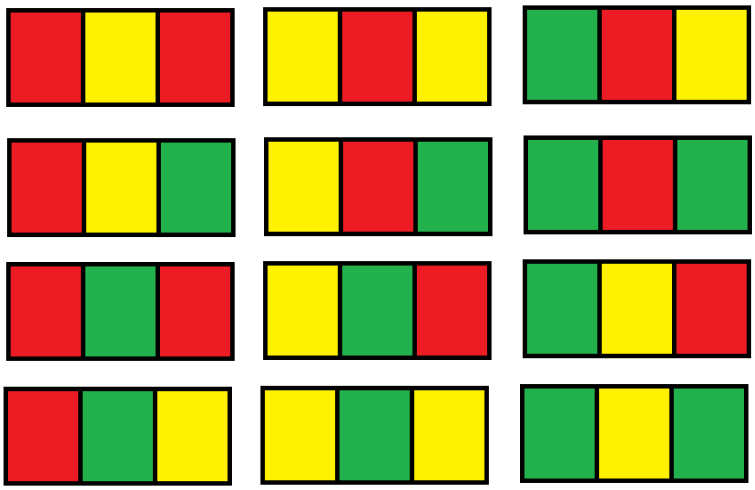
★ **TOP 10 PROBLEM** in 1-D DP: master this one first

PROBLEM

You have a `grid` of size `n x 3` and you want to paint each cell of the grid with exactly one of the three colors: **Red**, **Yellow,** or **Green** while making sure that no two adjacent cells have the same color (i.e., no two cells that share vertical or horizontal sides have the same color).

Given `n` the number of rows of the grid, return *the number of ways* you can paint this `grid`. As the answer may grow large, the answer **must be** computed modulo $10^9 + 7$.

Example 1:



```
Input: n = 1
Output: 12
Explanation: There are 12 possible way to paint the grid as shown.
```

Example 2:

```
Input: n = 5000
Output: 30228214
```

Constraints:

- `n == grid.length`
- `1 <= n <= 5000`

SOLUTIONS (PYTHON 3)

Solution 1: Recursion

How to think about it

Three colors with adjacent cells different and n≤ 5000 make coloring the whole grid infeasible. A row of three cells falls into two symmetry classes: type 010 (two colors) and type 012 (three colors). Counting successors yields $g_0=3f_0+2f_1$ and $g_1=2f_0+2f_1$. Both classes start at 6; after n-1 transitions their sum is the answer.

We classify all possible states for each row. According to the principle of symmetry, when a row only has 3 elements, all legal states are classified as: 010 type, 012 type.

- When the state is 010 type: The possible states for the next row are: 101, 102, 121, 201, 202. These 5 states can be summarized as 3 010 types and 2 012 types.
- When the state is 012 type: The possible states for the next row are: 101, 120, 121, 201. These 4 states can be summarized as 2 010 types and 2 012 types.

In summary, we can get: newf0 = 3 × f0 + 2 × f1, newf1 = 2 × f0 + 2 × f1.

The time complexity is O(n), where n is the number of rows in the grid. The space complexity is O(1).

Python 3

```python
class Solution:
    def numOfWays(self, n: int) -> int:
        mod = 10**9 + 7
        f0 = f1 = 6
        for _ in range(n - 1):
            g0 = (3 * f0 + 2 * f1) % mod
            g1 = (2 * f0 + 2 * f1) % mod
            f0, f1 = g0, g1
        return (f0 + f1) % mod
```

Solution 2: State Compression + Dynamic Programming

> **How to think about it**
>
> Method 1 needs hand-derived transition coefficients. With only three columns there are at most 27 colorings per row, so we can list valid masks and compatible pairs. f[i][j] is the number of ways to paint row i with mask j, summed from compatible previous masks. A rolling array keeps one layer, without closed-form coefficients.

We notice that the grid only has 3 columns, so there are at most 3^3=27 different coloring schemes in a row.

Therefore, we define f[i][j] to represent the number of schemes in the first i rows, where the coloring state of the ith row is j. The state f[i][j] is transferred from f[i - 1][k], where k is the coloring state of the i - 1th row, and k and j meet the requirement of different colors being adjacent. That is:

$$f[i][j] = \sum_{k \in valid(j)} f[i - 1][k]$$

where valid(j) represents all legal predecessor states of state j.

The final answer is the sum of f[n][j], where j is any legal state.

We notice that f[i][j] is only related to f[i - 1][k], so we can use a rolling array to optimize the space complexity.

The time complexity is $O((m + n) \times 3^{2m})$, and the space complexity is $O(3^m)$. Here, m and n are the number of rows and columns of the grid, respectively.

Python 3

```python
class Solution:
    def numOfWays(self, n: int) -> int:
        def f1(x: int) -> bool:
            last = -1
            for _ in range(3):
                if x % 3 == last:
                    return False
                last = x % 3
                x //= 3
            return True

        def f2(x: int, y: int) -> bool:
            for _ in range(3):
                if x % 3 == y % 3:
                    return False
                x //= 3
                y //= 3
            return True

        mod = 10**9 + 7
        m = 27
        valid = {i for i in range(m) if f1(i)}
        d = defaultdict(list)
        for i in valid:
            for j in valid:
                if f2(i, j):
                    d[i].append(j)
        f = [int(i in valid) for i in range(m)]
        for _ in range(n - 1):
            g = [0] * m
            for i in valid:
                for j in d[i]:
                    g[j] = (g[j] + f[i]) % mod
            f = g
        return sum(f) % mod
```

1027. Longest Arithmetic Subsequence

Medium · Array, Hash Table, Binary Search, Dynamic Programming

leetcode.com/problems/longest-arithmetic-subsequence

★ **TOP 10 PROBLEM** in Longest Increasing Subsequence (LIS): master this one first

PROBLEM

Given an array `nums` of integers, return *the length of the longest arithmetic subsequence in* `nums`.

Note that:

- A **subsequence** is an array that can be derived from another array by deleting some or no elements without changing the order of the remaining elements.
- A sequence `seq` is arithmetic if `seq[i + 1] - seq[i]` are all the same value (for `0 <= i < seq.length - 1`).

Example 1:

Input: nums = [3, 6, 9, 12]

Output: 4

Explanation: The whole array is already an arithmetic sequence with a common difference of 3, so the longest arithmetic subsequence is `[3, 6, 9, 12]`, of length 4.

Example 2:

Input: nums = [9, 4, 7, 2, 10]

Output: 3

Explanation: The longest arithmetic subsequence is `[4, 7, 10]` (indices `1`, `2`, `4`), with a common difference of 3. There is no arithmetic subsequence of length 4.

Example 3:

Input: nums = [20, 1, 15, 3, 10, 5, 8]

Output: 4

Explanation: The longest arithmetic subsequence is `[20, 15, 10, 5]` (indices `0`, `2`, `4`, `5`), with a common difference of -5.

Constraints:

- `2 <= nums.length <= 1500`
- `0 <= nums[i] <= 500`

SOLUTION (PYTHON 3)

Solution 1: Dynamic Programming

How to think about it

Trying every difference and scanning for a subsequence is viable: n≤ 1000 and values lie in [0,500], so differences are a few thousand. The subsequence need not be contiguous, so the state should be “ending at index i with difference j”. f[i][j] is that length. Shifting j by 500 maps differences into [0,1000]. A transition enumerates k<i and sets f[i][j]=max(f[i][j],f[k][j]+1). Every pair of indices updates once; the answer is the maximum over the table.

We define f[i][j] as the maximum length of the arithmetic sequence ending with nums[i] and having a common difference of j. Initially, f[i][j]=1, that is, each element itself is an arithmetic sequence of length 1.

Since the common difference may be negative, and the maximum difference is 500, we can uniformly add 500 to the common difference, so the range of the common difference becomes [0, 1000].

Considering f[i], we can enumerate the previous element nums[k] of nums[i], then the common difference j=nums[i]-nums[k]+500, at this time f[i][j]=max(f[i][j], f[k][j]+1), then we update the answer ans=max(ans, f[i][j]).

Finally, return the answer.

If initially f[i][j]=0, then we need to add 1 to the answer when returning the answer.

The time complexity is O(n × (d + n)), and the space complexity is O(n × d). Where n and d are the length of the array nums and the difference between the maximum and minimum values in the array nums, respectively.

Python 3

```
class Solution:
    def longestArithSeqLength(self, nums: List[int]) -> int:
        n = len(nums)
        f = [[1] * 1001 for _ in range(n)]
        ans = 0
        for i in range(1, n):
            for k in range(i):
                j = nums[i] - nums[k] + 500
                f[i][j] = max(f[i][j], f[k][j] + 1)
                ans = max(ans, f[i][j])
        return ans
```

1048. Longest String Chain

Medium · Array, Hash Table, Two Pointers, String, Dynamic Programming, Sorting

leetcode.com/problems/longest-string-chain

★ **TOP 10 PROBLEM** in Longest Increasing Subsequence (LIS): master this one first

PROBLEM

You are given an array of `words` where each word consists of lowercase English letters.

$word_A$ is a **predecessor** of $word_B$ if and only if we can insert **exactly one** letter anywhere in $word_A$ **without changing the order of the other characters** to make it equal to $word_B$.

- For example, `"abc"` is a **predecessor** of `"abac"`, while `"cba"` is not a **predecessor** of `"bcad"`.

A **word chain** is a sequence of words $[word_1, word_2, ..., word_k]$ with $k >= 1$, where $word_1$ is a **predecessor** of $word_2$, $word_2$ is a **predecessor** of $word_3$, and so on. A single word is trivially a **word chain** with $k == 1$.

Return *the **length** of the **longest possible word chain** with words chosen from the given list of* `words`.

Example 1:

```
Input: words = ["a","b","ba","bca","bda","bdca"]
Output: 4
Explanation: One of the longest word chains is ["a","ba","bda","bdca"].
```

Example 2:

```
Input: words = ["xbc","pcxbcf","xb","cxbc","pcxbc"]
Output: 5
Explanation: All the words can be put in a word chain ["xb", "xbc", "cxbc", "pcxbc", "pcxbcf"].
```

Example 3:

```
Input: words = ["abcd","dbqca"]
Output: 1
Explanation: The trivial word chain ["abcd"] is one of the longest word chains.
["abcd","dbqca"] is not a valid word chain because the ordering of the letters is changed.
```

Constraints:

- `1 <= words.length <= 1000`
- `1 <= words[i].length <= 16`
- `words[i]` only consists of lowercase English letters.

SOLUTIONS (PYTHON 3)

Solution 1: Dynamic Programming

How to think about it

A chain grows by one character. n≤ 1000 and length ≤ 16 allow DP after sorting by length. The best chain ending at i comes from some predecessor j whose length is one smaller. Two pointers test whether a becomes b by inserting one letter. Each i tries earlier j and sets f[i]=max(f[i],f[j]+1) on a hit. The answer is the maximum of f.

First, sort words by string length in ascending order. Define f[i] as the length of the longest word chain ending with words[i]. Initially, f[i] = 1.

For each i, enumerate j ∈ [0, i). If words[j] is a predecessor of words[i], update f[i] = max(f[i], f[j] + 1). Two strings form a predecessor pair if their lengths differ by 1 and the shorter one can be obtained by deleting exactly one character from the longer one.

The answer is max(f).

The time complexity is $O(n^2 \times L)$ and the space complexity is $O(n)$, where n is the length of the array and L is the maximum length of a string.

Python 3

```python
class Solution:
    def longestStrChain(self, words: List[str]) -> int:
        def check(a: str, b: str) -> bool:
            if len(a) + 1 != len(b):
                return False
            i = 0
            for c in b:
                if i < len(a) and a[i] == c:
                    i += 1
            return i == len(a)

        words.sort(key=len)
        n = len(words)
        f = [1] * n
        for i in range(n):
            for j in range(i):
                if check(words[j], words[i]):
                    f[i] = max(f[i], f[j] + 1)
        return max(f)
```

Solution 2: Dynamic Programming + Hash Table

> **How to think about it**
>
> Solution 1 scans every shorter word even when the length gap is not 1. A predecessor is w with one character deleted, so there are at most L candidates and a hash map can store scores by word. Still sorting by length, we delete each index of w and take f[p]+1. The time becomes $O(nL^2)$.

Sort words by length as well. Use a hash table f to record the longest word chain length ending at each word.

For the current word w, enumerate each predecessor p obtained by deleting one character. If p is already in the hash table, update f[w] with f[p] + 1.

The answer is the maximum value among all f[w].

The time complexity is $O(n \times L^2)$ and the space complexity is $O(n \times L)$.

Python 3

```python
class Solution:
    def longestStrChain(self, words: List[str]) -> int:
        words.sort(key=len)
        f = {}
        ans = 0
        for w in words:
            x = 1
            for i in range(len(w)):
                pred = w[:i] + w[i + 1 :]
                x = max(x, f.get(pred, 0) + 1)
            f[w] = x
            ans = max(ans, x)
        return ans
```

PART 2 · 2D GRID DP · PROBLEM 1 OF 10

256. Paint House

Medium · Array, Dynamic Programming

leetcode.com/problems/paint-house

★ **TOP 10 PROBLEM** in 2D Grid DP: master this one first

PROBLEM

There is a row of `n` houses, where each house can be painted one of three colors: red, blue, or green. The cost of painting each house with a certain color is different. You have to paint all the houses such that no two adjacent houses have the same color.

The cost of painting each house with a certain color is represented by an `n x 3` cost matrix `costs`.

- For example, `costs[0][0]` is the cost of painting house `0` with the color red; `costs[1][2]` is the cost of painting house 1 with color green, and so on...

Return *the minimum cost to paint all houses*.

Example 1:

```
Input: costs = [[17,2,17],[16,16,5],[14,3,19]]
Output: 10
Explanation: Paint house 0 into blue, paint house 1 into green, paint house 2 into blue.
Minimum cost: 2 + 5 + 3 = 10.
```

Example 2:

```
Input: costs = [[7,6,2]]
Output: 2
```

Constraints:

- `costs.length == n`
- `costs[i].length == 3`
- `1 <= n <= 100`
- `1 <= costs[i][j] <= 20`

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Adjacent houses cannot share a color, so listing paintings is too large. The best cost of color c on house i depends only on the other two colors on house i-1. Three rolling variables store the best totals for the three colors; the answer is their minimum.

Python 3

```python
class Solution:
    def minCost(self, costs: List[List[int]]) -> int:
        a = b = c = 0
        for ca, cb, cc in costs:
            a, b, c = min(b, c) + ca, min(a, c) + cb, min(a, b) + cc
        return min(a, b, c)
```

Complexity. Time: O(n). Space: O(1).

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

PART 2 · 2D GRID DP · PROBLEM 2 OF 10

1937. Maximum Number of Points with Cost

Medium · Array, Dynamic Programming, Matrix

leetcode.com/problems/maximum-number-of-points-with-cost

★ **TOP 10 PROBLEM** in 2D Grid DP: master this one first

PROBLEM

You are given an `m x n` integer matrix `points` (**0-indexed**). Starting with `0` points, you want to **maximize** the number of points you can get from the matrix.

To gain points, you must pick one cell in **each row**. Picking the cell at coordinates `(r, c)` will **add** `points[r][c]` to your score.

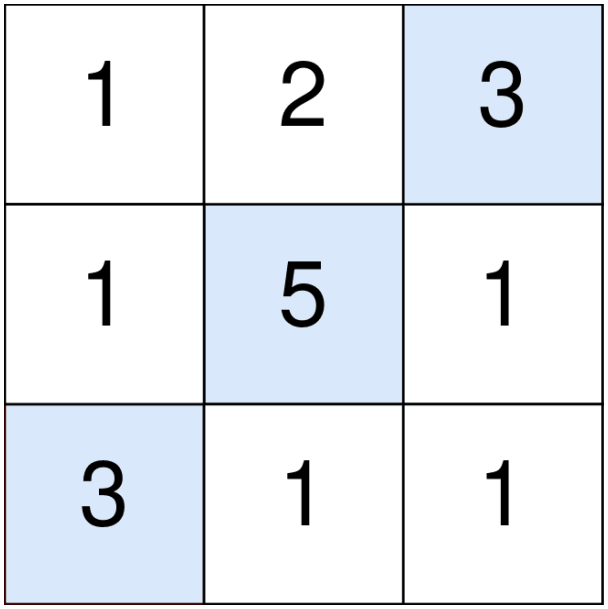
However, you will lose points if you pick a cell too far from the cell that you picked in the previous row. For every two adjacent rows `r` and `r + 1` (where `0 <= r < m - 1`), picking cells at coordinates (r, c_1) and $(r + 1, c_2)$ will **subtract** $\texttt{abs}(c_1 - c_2)$ from your score.

Return *the **maximum** number of points you can achieve*.

`abs(x)` is defined as:

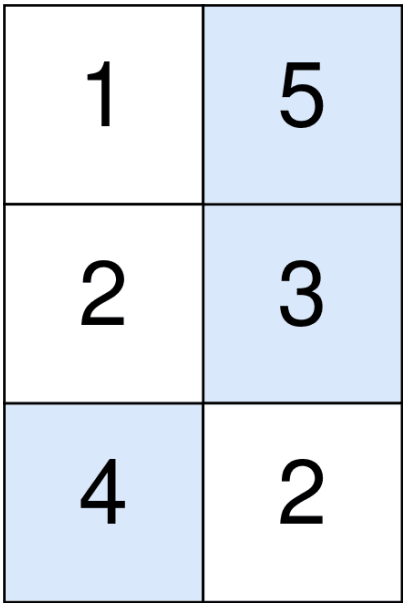
- `x` for `x >= 0`.
- `-x` for `x < 0`.

Example 1:



```
Input: points = [[1,2,3],[1,5,1],[3,1,1]]
Output: 9
Explanation:
The blue cells denote the optimal cells to pick, which have coordinates (0, 2), (1, 1), and (2, 0).
You add 3 + 5 + 3 = 11 to your score.
However, you must subtract abs(2 - 1) + abs(1 - 0) = 2 from your score.
Your final score is 11 - 2 = 9.
```

Example 2:



```
Input: points = [[1,5],[2,3],[4,2]]
Output: 11
Explanation:
The blue cells denote the optimal cells to pick, which have coordinates (0, 1), (1, 1), and (2, 0).
You add 5 + 3 + 4 = 12 to your score.
However, you must subtract abs(1 - 1) + abs(1 - 0) = 1 from your score.
Your final score is 12 - 1 = 11.
```

Constraints:

- `m == points.length`
- `n == points[r].length`
- `1 <= m, n <= 10^5`
- `1 <= m * n <= 10^5`
- `0 <= points[r][c] <= 10^5`

SOLUTION (PYTHON 3)

Solution 1

How to think about it

One cell per row with an absolute-column penalty. Trying every previous column is $O(n^2)$ per row and fails when $mn \le 10^5$. The $k \le j$ part depends on $\max(f[k]+k)$ and the $k \ge j$ part on $\max(f[k]-k)$. A left-to-right prefix max and a right-to-left suffix max evaluate each cell in $O(1)$. Rolling one row of DP uses $O(n)$ extra space and linear time in the number of cells.

Python 3

```python
class Solution:
    def maxPoints(self, points: List[List[int]]) -> int:
        n = len(points[0])
        f = points[0][:]
        for p in points[1:]:
            g = [0] * n
            lmx = -inf
            for j in range(n):
                lmx = max(lmx, f[j] + j)
                g[j] = max(g[j], p[j] + lmx - j)
            rmx = -inf
            for j in range(n - 1, -1, -1):
                rmx = max(rmx, f[j] - j)
                g[j] = max(g[j], p[j] + rmx + j)
            f = g
        return max(f)
```

        best = [points[r][c] + max(best[p] - (p - c) ** 2 for p in range(n)) for c in range(n)]
    return max(best)
```

PART 2 · 2D GRID DP · PROBLEM 3 OF 10

403. Frog Jump

Hard · Array, Dynamic Programming

leetcode.com/problems/frog-jump

★ **TOP 10 PROBLEM** in 2D Grid DP: master this one first

PROBLEM

A frog is crossing a river. The river is divided into some number of units, and at each unit, there may or may not exist a stone. The frog can jump on a stone, but it must not jump into the water.

Given a list of `stones` positions (in units) in sorted **ascending order**, determine if the frog can cross the river by landing on the last stone. Initially, the frog is on the first stone and assumes the first jump must be `1` unit.

If the frog's last jump was `k` units, its next jump must be either `k - 1`, `k`, or `k + 1` units. The frog can only jump in the forward direction.

Example 1:

```
Input: stones = [0,1,3,5,6,8,12,17]
Output: true
Explanation: The frog can jump to the last stone by jumping 1 unit to the 2nd stone, then 2 units to the 3rd stone, then 2 units to the 4th stone, then 3 units to the 6th stone, 4 units to the 7th stone, and 5 units to the 8th stone.
```

Example 2:

```
Input: stones = [0,1,2,3,4,8,9,11]
Output: false
Explanation: There is no way to jump to the last stone as the gap between the 5th and 6th stone is too large.
```

Constraints:

- `2 <= stones.length <= 2000`
- `0 <= stones[i] <= 2^31 - 1`
- `stones[0] == 0`
- `stones` is sorted in a strictly increasing order.

SOLUTIONS (PYTHON 3)

Solution 1: Hash Table + Memoization

How to think about it

Trying jumps of k-1,k,k+1 from every stone revisits the same (stone, last jump). With n≤ 1100 the pair (i,k) has at most $O(n^2)$ states. Map positions to indices, memoize dfs(i,k), and expand only onto stones that exist. The hash table makes the landing test O(1).

We use a hash table pos to record the index of each stone. Next, we design a function dfs(i, k), which means that the frog jumps from the i-th stone and the last jump distance is k. If the frog can reach the end, the function returns `true`, otherwise it returns `false`.

The calculation process of function dfs(i, k) is as follows:

If i is the index of the last stone, the frog has reached the end, and return `true`;

Otherwise, we need to enumerate the frog's next jump distance j, where j ∈ [k-1, k, k+1]. If j is a positive integer and the hash table pos exists the position stones[i] + j, then the frog can choose to jump j units on the i-th stone, if dfs(pos[stones[i] + j], j) returns `true`, the frog can successfully jump to the end from the i-th stone, and we can return `true`.

The enumeration is over, indicating that the frog cannot choose the appropriate jump distance on the i-th stone to jump to the end, so we return `false`.

In order to prevent repeated calculations in the function dfs(i, k), we can use memoization, record the result of dfs(i, k) in an array f, and assign f[i][k] each time the function dfs(i, k) returns result, and return f[i][k] directly when encountering dfs(i, k) next time.

The time complexity is $O(n^2)$, and the space complexity is $O(n^2)$. Where n is the number of stones.

Python 3

```python
class Solution:
    def canCross(self, stones: List[int]) -> bool:
        @cache
        def dfs(i, k):
            if i == n - 1:
                return True
            for j in range(k - 1, k + 2):
                if j > 0 and stones[i] + j in pos and dfs(pos[stones[i] + j], j):
                    return True
            return False

        n = len(stones)
        pos = {s: i for i, s in enumerate(stones)}
        return dfs(0, 0)
```

Solution 2: Dynamic Programming

> **How to think about it**
>
> The recursive search can grow a deep stack. Let f[i][k] mean we can reach stone i with last jump k, transferring from an earlier j with k=stones[i]-stones[j]. If k-1>j, farther stones cannot supply that jump, so the inner loop may stop. Filling the table bottom-up removes the recursion.

We define f[i][k] to be true if and only if it is possible to reach stone i with last jump of size k. Initially f[0][0] = true, and all other elements of f are false.

We can determine the value of f[i][k] for all i and k using a double loop. For each possible jump size k, we look at the stones we could have jumped from: i-k, i-k+1, i-k+2. If any of these stones exist and if we can reach them with a last jump of size k-1, k, or k+1, then we can reach stone i with a last jump of size k.

If we can reach the last stone, the answer is true. Otherwise, the answer is false.

The time complexity is $O(n^2)$, and the space complexity is $O(n^2)$. Where n is the number of stones.

Python 3

```python
class Solution:
    def canCross(self, stones: List[int]) -> bool:
        n = len(stones)
        f = [[False] * n for _ in range(n)]
        f[0][0] = True
        for i in range(1, n):
            for j in range(i - 1, -1, -1):
                k = stones[i] - stones[j]
                if k - 1 > j:
                    break
                f[i][k] = f[j][k - 1] or f[j][k] or f[j][k + 1]
                if i == n - 1 and f[i][k]:
                    return True
        return False
```

465. Optimal Account Balancing

Hard · Bit Manipulation, Array, Dynamic Programming, Backtracking, Bitmask

leetcode.com/problems/optimal-account-balancing

★ **TOP 10 PROBLEM** in 2D Grid DP: master this one first

PROBLEM

You are given an array of transactions `transactions` where `transactions[i] = [from_i, to_i, amount_i]` indicates that the person with `ID = from_i` gave `amount_i $` to the person with `ID = to_i`.

Return *the minimum number of transactions required to settle the debt*.

Example 1:

```
Input: transactions = [[0,1,10],[2,0,5]]
Output: 2
Explanation:
Person #0 gave person #1 $10.
Person #2 gave person #0 $5.
Two transactions are needed. One way to settle the debt is person #1 pays person #0 and #2 $5 each.
```

Example 2:

```
Input: transactions = [[0,1,10],[1,0,1],[1,2,5],[2,0,5]]
Output: 1
Explanation:
Person #0 gave person #1 $10.
Person #1 gave person #0 $1.
Person #1 gave person #2 $5.
Person #2 gave person #0 $5.
Therefore, person #1 only need to give person #0 $4, and all debt is settled.
```

Constraints:

- `1 <= transactions.length <= 8`
- `transactions[i].length == 3`
- `0 <= from_i, to_i < 12`
- `from_i != to_i`
- `1 <= amount_i <= 100`

SOLUTION (PYTHON 3)

Solution 1

How to think about it

We want the fewest transfers that zero every balance. People already at 0 drop out. Searching transfer orders among the remaining m≤ 12 people is still large; subset DP is the right grain. A subset whose balances sum to 0 needs at most |S|-1 transfers. f[i] is that minimum for mask i: only a zero-sum mask is feasible, starting from |i|-1 and trying f[j]+f[ixor j] over nonempty proper subsets. Subset enumeration is $O(3^m)$. Collapse transactions into nonzero balances first, and transfer only on zero-sum masks.

Python 3

```python
class Solution:
    def minTransfers(self, transactions: List[List[int]]) -> int:
        g = defaultdict(int)
        for f, t, x in transactions:
            g[f] -= x
            g[t] += x
        nums = [x for x in g.values() if x]
        m = len(nums)
        f = [inf] * (1 << m)
        f[0] = 0
        for i in range(1, 1 << m):
            s = 0
            for j, x in enumerate(nums):
                if i >> j & 1:
                    s += x
            if s == 0:
                f[i] = i.bit_count() - 1
                j = (i - 1) & i
                while j > 0:
                    f[i] = min(f[i], f[j] + f[i ^ j])
                    j = (j - 1) & i
        return f[-1]
```

546. Remove Boxes

Hard · Memoization, Array, Dynamic Programming

leetcode.com/problems/remove-boxes

★ **TOP 10 PROBLEM** in 2D Grid DP: master this one first

PROBLEM

You are given several `boxes` with different colors represented by different positive numbers.

You may experience several rounds to remove boxes until there is no box left. Each time you can choose some continuous boxes with the same color (i.e., composed of `k` boxes, `k >= 1`), remove them and get `k * k` points.

Return *the maximum points you can get*.

Example 1:

```
Input: boxes = [1,3,2,2,2,3,4,3,1]
Output: 23
Explanation:
[1, 3, 2, 2, 2, 3, 4, 3, 1]
----> [1, 3, 3, 4, 3, 1] (3*3=9 points)
----> [1, 3, 3, 3, 1] (1*1=1 points)
----> [1, 1] (3*3=9 points)
----> [] (2*2=4 points)
```

Example 2:

```
Input: boxes = [1,1,1]
Output: 9
```

Example 3:

```
Input: boxes = [1]
Output: 1
```

Constraints:

- `1 <= boxes.length <= 100`
- `1 <= boxes[i] <= 100`

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Removing a run scores the square of its length, and order changes later merges. A plain interval DP cannot express "clear the middle, then join the right run". dfs(i,j,k) is the interval [i,j] with k extra boxes already equal to boxes[j]. Absorb the run ending at j into k, then either remove j now or find an earlier h of the same color, clear (h,j), and merge. Memoization caches each triple.

Python 3

```python
class Solution:
    def removeBoxes(self, boxes: List[int]) -> int:
        @cache
        def dfs(i, j, k):
            if i > j:
                return 0
            while i < j and boxes[j] == boxes[j - 1]:
                j, k = j - 1, k + 1
            ans = dfs(i, j - 1, 0) + (k + 1) * (k + 1)
            for h in range(i, j):
                if boxes[h] == boxes[j]:
                    ans = max(ans, dfs(h + 1, j - 1, 0) + dfs(i, h, k + 1))
            return ans

        n = len(boxes)
        ans = dfs(0, n - 1, 0)
        dfs.cache_clear()
        return ans
```

Complexity. Time: O(n^4). Space: O(n^3).

PART 2 · 2D GRID DP · PROBLEM 6 OF 10

1235. Maximum Profit in Job Scheduling

Hard · Array, Binary Search, Dynamic Programming, Sorting

leetcode.com/problems/maximum-profit-in-job-scheduling

★ **TOP 10 PROBLEM** in 2D Grid DP: master this one first

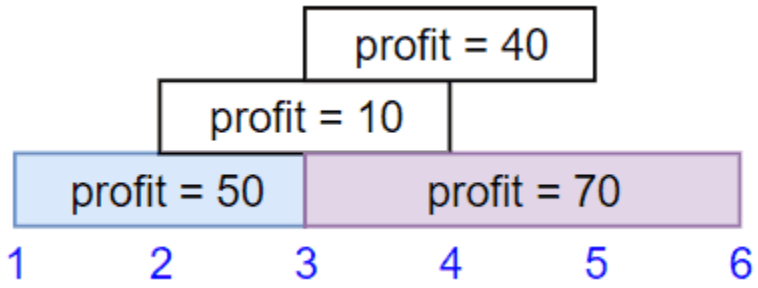
PROBLEM

We have `n` jobs, where every job is scheduled to be done from `startTime[i]` to `endTime[i]`, obtaining a profit of `profit[i]`.

You're given the `startTime`, `endTime` and `profit` arrays, return the maximum profit you can take such that there are no two jobs in the subset with overlapping time range.

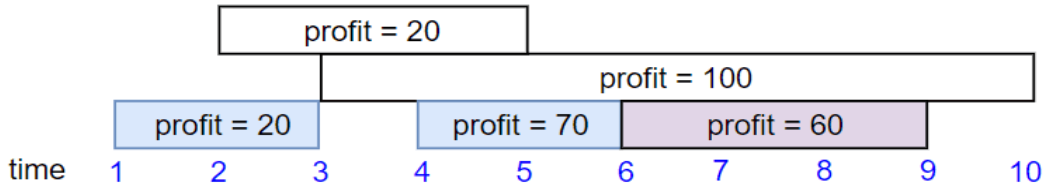
If you choose a job that ends at time `X` you will be able to start another job that starts at time `X`.

Example 1:



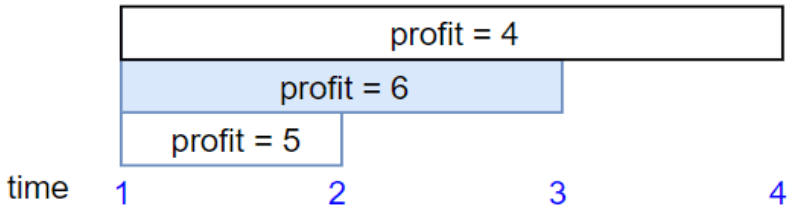
```
Input: startTime = [1,2,3,3], endTime = [3,4,5,6], profit = [50,10,40,70]
Output: 120
Explanation: The subset chosen is the first and fourth job.
Time range [1-3]+[3-6] , we get profit of 120 = 50 + 70.
```

Example 2:



```
Input: startTime = [1,2,3,4,6], endTime = [3,5,10,6,9], profit = [20,20,100,70,60]
Output: 150
Explanation: The subset chosen is the first, fourth and fifth job.
Profit obtained 150 = 20 + 70 + 60.
```

Example 3:



```
Input: startTime = [1,1,1], endTime = [2,3,4], profit = [5,6,4]
Output: 6
```

Constraints:

- `1 <= startTime.length == endTime.length == profit.length <= 5 * 10^4`
- `1 <= startTime[i] < endTime[i] <= 10^9`
- `1 <= profit[i] <= 10^4`

SOLUTIONS (PYTHON 3)

Solution 1: Memoization Search + Binary Search

How to think about it

Jobs must not overlap. $n \le 5\times 10^4$ rules out subset search. Whether we take job i only affects jobs that start no earlier than its end. After sorting by start, dfs(i) takes the better of skipping i and taking i then jumping to the first job with start≥ end_i. That index is a binary search on the sorted starts. Memoization evaluates each i once.

First, we sort the jobs by start time in ascending order, then design a function dfs(i) to represent the maximum profit that can be obtained starting from the i-th job. The answer is dfs(0).

The calculation process of function dfs(i) is as follows:

For the i-th job, we can choose to do it or not. If we don't do it, the maximum profit is dfs(i + 1); if we do it, we can use binary search to find the first job that starts after the end time of the i-th job, denoted as j, then the maximum profit is profit[i] + dfs(j). We take the larger of the two. That is:

$$dfs(i)=max(dfs(i+1),profit[i]+dfs(j))$$

Where j is the smallest index that satisfies startTime[j] ≥ endTime[i].

In this process, we can use memoization search to save the answer of each state to avoid repeated calculations.

The time complexity is O(n × log n), where n is the number of jobs.

Python 3

```python
class Solution:
    def jobScheduling(
        self, startTime: List[int], endTime: List[int], profit: List[int]
    ) -> int:
        @cache
        def dfs(i):
            if i >= n:
                return 0
            _, e, p = jobs[i]
            j = bisect_left(jobs, e, lo=i + 1, key=lambda x: x[0])
            return max(dfs(i + 1), p + dfs(j))

        jobs = sorted(zip(startTime, endTime, profit))
        n = len(profit)
        return dfs(0)
```

Solution 2: Dynamic Programming + Binary Search

How to think about it

Solution 1 sorts by start and fills one suffix table. Sorting by end instead, dp[i] is the best profit among the first i jobs: skip inherits dp[i-1]; take adds dp[j] for the last job that ends before this start, with j still from binary search.

Solution 1 sorts by start and fills a suffix table. Here we sort by end and define a prefix table.

First, sort the jobs, this time we sort by end time in ascending order, then define dp[i], which represents the maximum profit that can be obtained from the first i jobs. The answer is dp[n]. Initialize dp[0]=0.

For the i-th job, we can choose to do it or not. If we don't do it, the maximum profit is dp[i]; if we do it, we can use binary search to find the last job that ends before the start time of the i-th job, denoted as j, then the maximum profit is profit[i] + dp[j]. We take the larger of the two. That is:

$$dp[i+1] = \max(dp[i], profit[i] + dp[j])$$

Where j is the largest index that satisfies endTime[j] ≤ startTime[i].

The time complexity is O(n × log n), where n is the number of jobs.

Similar problems:

- 2008. Maximum Earnings From Taxi
- 1751. Maximum Number of Events That Can Be Attended II

Python 3

```
class Solution:
    def jobScheduling(
        self, startTime: List[int], endTime: List[int], profit: List[int]
    ) -> int:
        jobs = sorted(zip(endTime, startTime, profit))
        n = len(profit)
        dp = [0] * (n + 1)
        for i, (_, s, p) in enumerate(jobs):
            j = bisect_right(jobs, s, hi=i, key=lambda x: x[0])
            dp[i + 1] = max(dp[i], dp[j] + p)
        return dp[n]
```

Solution 3: Dynamic Programming + Binary Search

> **How to think about it**
>
> Jobs must not overlap. n ≤ 5× 10^4 rules out subset search. Whether we take job i only affects jobs that start no earlier than its end. After sorting by start, skipping calls i+1 before it returns, so the chain has length n and overflows the stack. Later indices are known if we walk from the end. Let f[i] be the best profit from job i, with f[n]=0, and binary-search the next compatible job while filling i from n-1 down to 0.

First, we sort the jobs by start time in ascending order. Let f[i] be the maximum profit that can be obtained starting from the i-th job. The answer is f[0], and f[n] = 0.

Fill i from n - 1 down to 0. For the i-th job we can skip it, which keeps f[i + 1], or take it. Binary search finds the first job j that starts at or after end_i. Taking it earns profit[i] + f[j]. Take the larger of the two:

$$f[i]=\max(f[i+1],profit[i]+f[j])$$

Where j is the smallest index that satisfies startTime[j] ≥ endTime[i]. Because j > i, f[j] is already filled.

The time complexity is O(n × log n), where n is the number of jobs.

Python 3

```
class Solution:
    def jobScheduling(
        self, startTime: List[int], endTime: List[int], profit: List[int]
    ) -> int:
        jobs = sorted(zip(startTime, endTime, profit))
        n = len(profit)
        f = [0] * (n + 1)
        for i in range(n - 1, -1, -1):
            _, e, p = jobs[i]
            j = bisect_left(jobs, e, lo=i + 1, key=lambda x: x[0])
            f[i] = max(f[i + 1], p + f[j])
        return f[0]
```

1335. Minimum Difficulty of a Job Schedule

Hard · Array, Dynamic Programming

leetcode.com/problems/minimum-difficulty-of-a-job-schedule

★ **TOP 10 PROBLEM** in 2D Grid DP: master this one first

PROBLEM

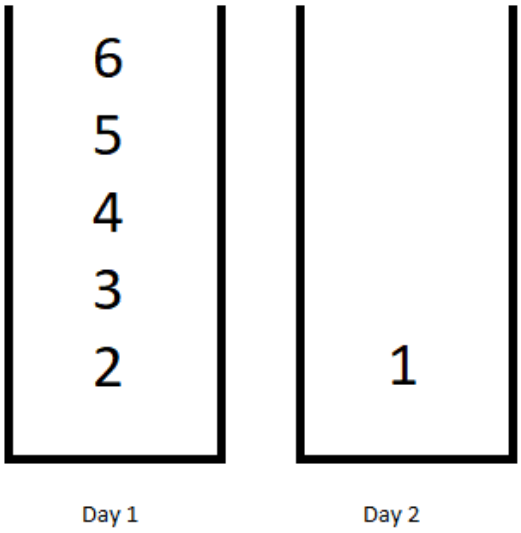
You want to schedule a list of jobs in `d` days. Jobs are dependent (i.e To work on the i^{th} job, you have to finish all the jobs `j` where `0 <= j < i`).

You have to finish **at least** one task every day. The difficulty of a job schedule is the sum of difficulties of each day of the `d` days. The difficulty of a day is the maximum difficulty of a job done on that day.

You are given an integer array `jobDifficulty` and an integer `d`. The difficulty of the i^{th} job is `jobDifficulty[i]`.

Return *the minimum difficulty of a job schedule*. If you cannot find a schedule for the jobs return `-1`.

Example 1:



```
Input: jobDifficulty = [6,5,4,3,2,1], d = 2
Output: 7
Explanation: First day you can finish the first 5 jobs, total difficulty = 6.
Second day you can finish the last job, total difficulty = 1.
The difficulty of the schedule = 6 + 1 = 7
```

Example 2:

```
Input: jobDifficulty = [9,9,9], d = 4
Output: -1
Explanation: If you finish a job per day you will still have a free day. you cannot find a schedule for the given jobs.
```

Example 3:

```
Input: jobDifficulty = [1,1,1], d = 3
Output: 3
Explanation: The schedule is one job per day. total difficulty will be 3.
```

Constraints:

- `1 <= jobDifficulty.length <= 300`
- `0 <= jobDifficulty[i] <= 1000`
- `1 <= d <= 10`

SOLUTION (PYTHON 3)

Solution 1: Dynamic Programming

> **How to think about it**
>
> Split the job sequence into d contiguous days; a day's difficulty is its max job, and the total should be minimal. Jobs stay in order. n ≤ 300, d ≤ 10 still forbids enumerating all cuts. The best way to finish i jobs in j days depends only on the last day covering [k..i]. f[i][j] stores that optimum. Enumerating k backward maintains the segment max and transitions from f[k-1][j-1]. Fewer jobs than days is impossible.

We define f[i][j] as the minimum difficulty to finish the first i jobs within j days. Initially f[0][0] = 0, and all other f[i][j] are ∞.

For the j-th day, we can choose to finish jobs [k,..i] on this day. Therefore, we have the following state transition equation:

$$f[i][j] = \min_{k \in [1,i]} \{f[k-1][j-1] + \max_{k \le t \le i} \{jobDifficulty[t]\}\}$$

The final answer is f[n][d].

The time complexity is $O(n^2 \times d)$, and the space complexity is $O(n \times d)$. Here n and d are the number of jobs and the number of days respectively.

Python 3

```python
class Solution:
    def minDifficulty(self, jobDifficulty: List[int], d: int) -> int:
        n = len(jobDifficulty)
        f = [[inf] * (d + 1) for _ in range(n + 1)]
        f[0][0] = 0
        for i in range(1, n + 1):
            for j in range(1, min(d + 1, i + 1)):
                mx = 0
                for k in range(i, 0, -1):
                    mx = max(mx, jobDifficulty[k - 1])
                    f[i][j] = min(f[i][j], f[k - 1][j - 1] + mx)
        return -1 if f[n][d] >= inf else f[n][d]
```

```

1547. Minimum Cost to Cut a Stick

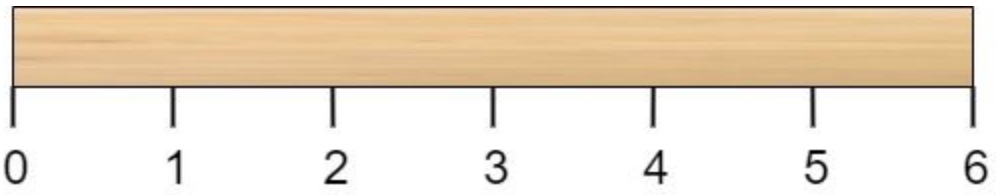
Hard · Array, Dynamic Programming, Sorting

leetcode.com/problems/minimum-cost-to-cut-a-stick

★ **TOP 10 PROBLEM** in 2D Grid DP: master this one first

PROBLEM

Given a wooden stick of length `n` units. The stick is labelled from `0` to `n`. For example, a stick of length **6** is labelled as follows:



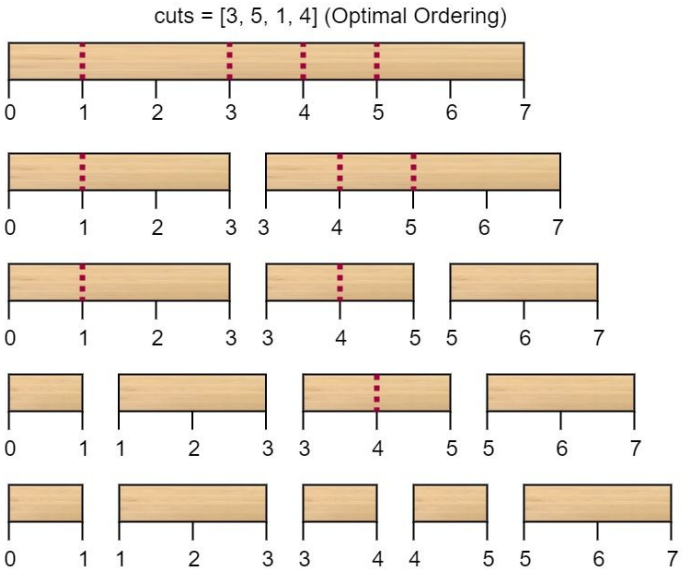
Given an integer array `cuts` where `cuts[i]` denotes a position you should perform a cut at.

You should perform the cuts in order, you can change the order of the cuts as you wish.

The cost of one cut is the length of the stick to be cut, the total cost is the sum of costs of all cuts. When you cut a stick, it will be split into two smaller sticks (i.e. the sum of their lengths is the length of the stick before the cut). Please refer to the first example for a better explanation.

Return *the minimum total cost* of the cuts.

Example 1:



```
Input: n = 7, cuts = [1,3,4,5]
Output: 16
Explanation: Using cuts order = [1, 3, 4, 5] as in the input leads to the following scenario:

The first cut is done to a rod of length 7 so the cost is 7. The second cut is done to a rod of length
6 (i.e. the second part of the first cut), the third is done to a rod of length 4 and the last cut is
to a rod of length 3. The total cost is 7 + 6 + 4 + 3 = 20.
Rearranging the cuts to be [3, 5, 1, 4] for example will lead to a scenario with total cost = 16 (as
shown in the example photo 7 + 4 + 3 + 2 = 16).
```

Example 2:

```
Input: n = 9, cuts = [5,6,1,4,2]
Output: 22
Explanation: If you try the given cuts ordering the cost will be 25.
There are much ordering with total cost <= 25, for example, the order [4, 6, 5, 2, 1] has total cost =
22 which is the minimum possible.
```

Constraints:

- `2 <= n <= 10^6`
- `1 <= cuts.length <= min(n - 1, 100)`
- `1 <= cuts[i] <= n - 1`
- All the integers in `cuts` array are **distinct**.

SOLUTIONS (PYTHON 3)

Solution 1: Dynamic Programming (Interval DP)

How to think about it

Cut a stick of length n at given points; each cut costs the current piece's length. n can be 10^6 but there are at most 100 cuts, so DP belongs on the cut list, not on stick coordinates. Insert 0 and n and sort. f[i][j] is the min cost to finish every cut strictly inside (cuts[i],cuts[j]). The last cut at cuts[k] costs f[i][k]+f[k][j]+cuts[j]-cuts[i]. Filling by increasing interval length makes every subinterval ready.

We can add two elements to the array cuts, namely 0 and n, representing the two ends of the stick. Then we sort the cuts array, so we can divide the entire stick into several intervals, each with two cut points. Let the length of the cuts array be m.

Next, we define f[i][j] to represent the minimum cost to cut the interval [cuts[i], cuts[j]].

If an interval has only two cut points, meaning we do not need to cut this interval, then f[i][j] = 0.

Otherwise, we enumerate the length l of the interval, where l is equal to the number of cut points minus 1. Then we enumerate the left endpoint i of the interval, and the right endpoint j can be obtained by i + l. For each interval, we enumerate its cut point k, where i < k < j. We can then divide the interval [i, j] into [i, k] and [k, j]. The cost at this point is f[i][k] + f[k][j] + cuts[j] - cuts[i]. We take the minimum value among all possible k, which is the value of f[i][j].

Finally, we return f[0][m - 1].

The time complexity is $O(m^3)$, and the space complexity is $O(m^2)$. Here, m is the length of the modified cuts array.

Python 3

```python
class Solution:
    def minCost(self, n: int, cuts: List[int]) -> int:
        cuts.extend([0, n])
        cuts.sort()
        m = len(cuts)
        f = [[0] * m for _ in range(m)]
        for l in range(2, m):
            for i in range(m - l):
                j = i + l
                f[i][j] = inf
                for k in range(i + 1, j):
                    f[i][j] = min(f[i][j], f[i][k] + f[k][j] + cuts[j] - cuts[i])
        return f[0][-1]
```

Solution 2: Dynamic Programming (Another Enumeration Method)

How to think about it

Solution 1 enumerates by length only to compute short intervals first. The same recurrence works if i runs downward and j runs upward, which also evaluates every i<k<j beforehand. The asymptotics are unchanged; only the loop order differs.

We can also enumerate i from large to small and j from small to large. This ensures that when calculating f[i][j], the states f[i][k] and f[k][j] have already been computed, where i < k < j.

The time complexity is $O(m^3)$, and the space complexity is $O(m^2)$. Here, m is the length of the modified cuts array.

Python 3

```
class Solution:
    def minCost(self, n: int, cuts: List[int]) -> int:
        cuts.extend([0, n])
        cuts.sort()
        m = len(cuts)
        f = [[0] * m for _ in range(m)]
        for i in range(m - 1, -1, -1):
            for j in range(i + 2, m):
                f[i][j] = inf
                for k in range(i + 1, j):
                    f[i][j] = min(f[i][j], f[i][k] + f[k][j] + cuts[j] - cuts[i])
        return f[0][-1]
```

1931. Painting a Grid With Three Different Colors

Hard · Dynamic Programming, Graph Coloring

leetcode.com/problems/painting-a-grid-with-three-different-colors

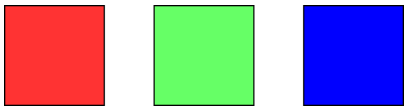
★ **TOP 10 PROBLEM** in 2D Grid DP: master this one first

PROBLEM

You are given two integers `m` and `n`. Consider an `m x n` grid where each cell is initially white. You can paint each cell **red**, **green**, or **blue**. All cells **must** be painted.

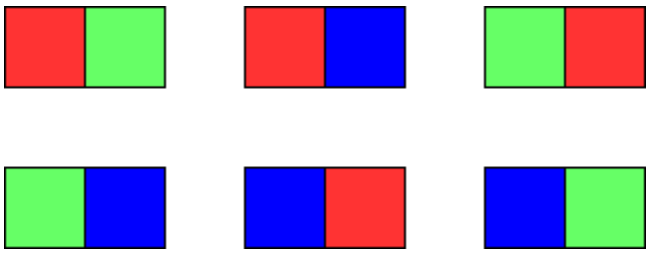
Return *the number of ways to color the grid with* ***no two adjacent cells having the same color***. Since the answer can be very large, return it **modulo** $10^9 + 7$.

Example 1:



```
Input: m = 1, n = 1
Output: 3
Explanation: The three possible colorings are shown in the image above.
```

Example 2:



```
Input: m = 1, n = 2
Output: 6
Explanation: The six possible colorings are shown in the image above.
```

Example 3:

```
Input: m = 5, n = 5
Output: 580986
```

Constraints:

- `1 <= m <= 5`
- `1 <= n <= 1000`

SOLUTION (PYTHON 3)

Solution 1: State Compression + Dynamic Programming

How to think about it

Adjacent cells need different colors. Cell-by-cell coloring is too large, but m≤ 5 so a column has only 3^m colorings. We keep masks whose vertical neighbors differ, then precompute pairs of masks that also differ horizontally. f[j] is the number of ways the previous column equals j, rolled forward. The first column counts valid masks; n-1 transitions follow, and the answer is the sum modulo 10^9+7.

We notice that the number of rows in the grid does not exceed 5, so there are at most 3^5=243 different color schemes in a column.

Therefore, we define f[i][j] to represent the number of schemes in the first i columns, where the coloring state of the ith column is j. The state f[i][j] is transferred from f[i - 1][k], where k is the coloring state of the i - 1th column, and k and j meet the requirement of different colors being adjacent. That is:

$$f[i][j] = \sum_{k \in valid(j)} f[i - 1][k]$$

where valid(j) represents all legal predecessor states of state j.

The final answer is the sum of f[n][j], where j is any legal state.

We notice that f[i][j] is only related to f[i - 1][k], so we can use a rolling array to optimize the space complexity.

The time complexity is $O((m + n) \times 3^{2m})$, and the space complexity is $O(3^m)$. Here, m and n are the number of rows and columns of the grid, respectively.

Python 3

```python
class Solution:
    def colorTheGrid(self, m: int, n: int) -> int:
        def f1(x: int) -> bool:
            last = -1
            for _ in range(m):
                if x % 3 == last:
                    return False
                last = x % 3
                x //= 3
            return True

        def f2(x: int, y: int) -> bool:
            for _ in range(m):
                if x % 3 == y % 3:
                    return False
                x, y = x // 3, y // 3
            return True

        mod = 10**9 + 7
        mx = 3**m

3651. Minimum Cost Path with Teleportations

Hard · Array, Dynamic Programming, Matrix

leetcode.com/problems/minimum-cost-path-with-teleportations

★ **TOP 10 PROBLEM** in 2D Grid DP: master this one first

PROBLEM

You are given a `m x n` 2D integer array `grid` and an integer `k`. You start at the top-left cell `(0, 0)` and your goal is to reach the bottom-right cell `(m - 1, n - 1)`.

There are two types of moves available:

- **Normal move**: You can move right or down from your current cell `(i, j)`, i.e. you can move to `(i, j + 1)` (right) or `(i + 1, j)` (down). The cost is the value of the destination cell.
- **Teleportation**: You can teleport from any cell `(i, j)`, to any cell `(x, y)` such that `grid[x][y] <= grid[i][j]`; the cost of this move is 0. You may teleport at most `k` times.

Return the **minimum** total cost to reach cell `(m - 1, n - 1)` from `(0, 0)`.

Example 1:

Input: grid = [[1,3,3],[2,5,4],[4,3,5]], k = 2

Output: 7

Explanation:

Initially we are at (0, 0) and cost is 0.

Current Position	Move	New Position	Total Cost
`(0, 0)`	Move Down	`(1, 0)`	`0 + 2 = 2`
`(1, 0)`	Move Right	`(1, 1)`	`2 + 5 = 7`
`(1, 1)`	Teleport to `(2, 2)`	`(2, 2)`	`7 + 0 = 7`

The minimum cost to reach bottom-right cell is 7.

Example 2:

Input: grid = [[1,2],[2,3],[3,4]], k = 1

Output: 9

Explanation:

Initially we are at (0, 0) and cost is 0.

Current Position	Move	New Position	Total Cost
`(0, 0)`	Move Down	`(1, 0)`	`0 + 2 = 2`
`(1, 0)`	Move Right	`(1, 1)`	`2 + 3 = 5`
`(1, 1)`	Move Down	`(2, 1)`	`5 + 4 = 9`

The minimum cost to reach bottom-right cell is 9.

Constraints:

- `2 <= m, n <= 80`
- `m == grid.length`
- `n == grid[i].length`
- `0 <= grid[i][j] <= 10^4`
- `0 <= k <= 10`

SOLUTION (PYTHON 3)

Solution 1: Dynamic Programming

How to think about it

Besides paying a cell when moving right or down, we may teleport from a larger value to a smaller one at most k times. The leftover teleport count is part of the state. f[t][i][j] is the cheapest way to reach (i,j) with t teleports. Layer t=0 uses only grid moves. Teleports require a nonincreasing value, so cells are scanned from large to small and the best previous-layer cost among those cells is written onto the current layer. A second right/down sweep after the assignment lets the walk continue. The answer is the minimum destination cost over all t.

We define f[t][i][j] as the minimum cost to reach cell (i, j) using exactly t teleportations. Initially, f[0][0][0] = 0, and all other states are infinity.

First, we need to initialize f[0][i][j]. Without using teleportation, we can only reach cell (i, j) by moving right or down.

If i > 0, we can move from the cell above (i-1, j), updating the state as:

$$f[0][i][j] = \min(f[0][i][j], f[0][i-1][j] + grid[i][j])$$

If j > 0, we can move from the cell to the left (i, j-1), updating the state as:

$$f[0][i][j] = \min(f[0][i][j], f[0][i][j-1] + grid[i][j])$$

To handle teleportation, we need to group the cells in the grid by their values. We use a hash map g, where the key is the cell value and the value is a list of coordinates of cells with that value.

For each teleportation count t from 1 to k, we process each group in descending order of cell values. For each cell (i, j) in a group, we first update a global minimum mn, representing the minimum cost to reach these cells using t-1 teleportations:

$$mn = \min(mn, f[t-1][i][j])$$

Then, we update the state of all cells in the group to mn, representing the minimum cost to reach these cells via teleportation.

Next, we traverse the entire grid again to update f[t][i][j], considering moves from the top or left cells:

If i > 0, then:

$$f[t][i][j] = \min(f[t][i][j], f[t][i-1][j] + grid[i][j])$$

If j > 0, then:

$$f[t][i][j] = \min(f[t][i][j], f[t][i][j-1] + grid[i][j])$$

Finally, our answer is min(f[t][m-1][n-1]), where t ranges from 0 to k.

The time complexity is $O((k + \log mn) \times mn)$, and the space complexity is $O(k \times mn)$. Here, m and n are the number of rows and columns of the grid, respectively, and k is the maximum allowed number of teleportations.

Python 3

```python
class Solution:
    def minCost(self, grid: List[List[int]], k: int) -> int:
        m, n = len(grid), len(grid[0])
        f = [[[inf] * n for _ in range(m)] for _ in range(k + 1)]
        f[0][0][0] = 0
        for i in range(m):
            for j in range(n):
                if i:
                    f[0][i][j] = min(f[0][i][j], f[0][i - 1][j] + grid[i][j])
                if j:
                    f[0][i][j] = min(f[0][i][j], f[0][i][j - 1] + grid[i][j])
        g = defaultdict(list)
        for i, row in enumerate(grid):
            for j, x in enumerate(row):
                g[x].append((i, j))
        keys = sorted(g, reverse=True)
        for t in range(1, k + 1):
            mn = inf
            for key in keys:
                pos = g[key]
                for i, j in pos:
                    mn = min(mn, f[t - 1][i][j])
                for i, j in pos:
                    f[t][i][j] = mn
            for i in range(m):
                for j in range(n):
                    if i:
                        f[t][i][j] = min(f[t][i][j], f[t][i - 1][j] + grid[i][j])
                    if j:
                        f[t][i][j] = min(f[t][i][j], f[t][i][j - 1] + grid[i][j])
        return min(f[t][m - 1][n - 1] for t in range(k + 1))
```

516. Longest Palindromic Subsequence

Medium · String, Dynamic Programming

leetcode.com/problems/longest-palindromic-subsequence

★ **TOP 10 PROBLEM** in String DP: master this one first

PROBLEM

Given a string `s`, find *the longest palindromic **subsequence**'s length in* `s`.

A **subsequence** is a sequence that can be derived from another sequence by deleting some or no elements without changing the order of the remaining elements.

Example 1:

```
Input: s = "bbbab"
Output: 4
Explanation: One possible longest palindromic subsequence is "bbbb".
```

Example 2:

```
Input: s = "cbbd"
Output: 2
Explanation: One possible longest palindromic subsequence is "bb".
```

Constraints:

- `1 <= s.length <= 1000`
- `s` consists only of lowercase English letters.

SOLUTION (PYTHON 3)

Solution 1: Dynamic Programming

How to think about it

A palindromic subsequence need not be contiguous, so center expansion is not enough, and listing all subsequences is too many. Let f[i][j] be the LPS length of s[i..j]. Equal ends add 2 to the inner interval; otherwise drop one end. Fill by increasing interval length (i right to left, j to the right) so dependencies are ready. f[0][n-1] is the answer.

We define f[i][j] as the length of the longest palindromic subsequence from the i-th character to the j-th character in string s. Initially, f[i][i] = 1, and the values of other positions are all 0.

If s[i] = s[j], then f[i][j] = f[i + 1][j - 1] + 2; otherwise, f[i][j] = max(f[i + 1][j], f[i][j - 1]).

Since the value of f[i][j] is related to f[i + 1][j - 1], f[i + 1][j], and f[i][j - 1], we should enumerate i from large to small, and enumerate j from small to large.

The answer is f[0][n - 1].

The time complexity is $O(n^2)$, and the space complexity is $O(n^2)$. Where n is the length of the string s.

Python 3

```python
class Solution:
    def longestPalindromeSubseq(self, s: str) -> int:
        n = len(s)
        f = [[0] * n for _ in range(n)]
        for i in range(n):
            f[i][i] = 1
        for i in range(n - 1, -1, -1):
            for j in range(i + 1, n):
                if s[i] == s[j]:
                    f[i][j] = f[i + 1][j - 1] + 2
                else:
                    f[i][j] = max(f[i + 1][j], f[i][j - 1])
        return f[0][-1]
```

PART 2 · STRING DP · PROBLEM 2 OF 5

1653. Minimum Deletions to Make String Balanced

Medium · Stack, String, Dynamic Programming

leetcode.com/problems/minimum-deletions-to-make-string-balanced

★ **TOP 10 PROBLEM** in String DP: master this one first

PROBLEM

You are given a string `s` consisting only of characters `'a'` and `'b'`.

You can delete any number of characters in `s` to make `s` **balanced**. `s` is **balanced** if there is no pair of indices `(i,j)` such that `i < j` and `s[i] = 'b'` and `s[j]= 'a'`.

Return *the **minimum** number of deletions needed to make* `s` ***balanced***.

Example 1:

```
Input: s = "aababbab"
Output: 2
Explanation: You can either:
Delete the characters at 0-indexed positions 2 and 6 ("aababbab" -> "aaabbb"), or
Delete the characters at 0-indexed positions 3 and 6 ("aababbab" -> "aabbbb").
```

Example 2:

```
Input: s = "bbaaaaabb"
Output: 2
Explanation: The only solution is to delete the first two characters.
```

Constraints:

- `1 <= s.length <= 10^5`
- `s[i]` is `'a'` or `'b'`.

SOLUTIONS (PYTHON 3)

Solution 1: Dynamic Programming

How to think about it

A balanced string is some `a`s followed by some `b`s. n can be 10^5, so we cannot try every deletion set. After a prefix, the number of `b`s seen is the cost of deleting them versus deleting the current `a`. f[i] is the min deletions to balance the first i characters: on `b` keep f[i-1] and increment b; on `a` take min(f[i-1]+1,b).

We define f[i] as the minimum number of characters to be deleted in the first i characters to make the string balanced. Initially, f[0]=0. The answer is f[n].

We traverse the string s, maintaining a variable b, which represents the number of character 'b' in the characters before the current position.

- If the current character is 'b', it does not affect the balance of the first i characters, so f[i]=f[i-1], then we update b ← b+1.
- If the current character is 'a', we can choose to delete the current character, so f[i]=f[i-1]+1; or we can choose to delete the previous character 'b', so f[i]=b. Therefore, we take the minimum of the two, that is, f[i]=min(f[i-1]+1,b).

In summary, we can get the state transition equation:

f[i]=cases f[i-1], & s[i-1]='b'\ min(f[i-1]+1,b), & s[i-1]='a' cases

The final answer is f[n].

We notice that the state transition equation is only related to the previous state and the variable b, so we can just use an answer variable ans to maintain the current f[i], and there is no need to allocate an array f.

The time complexity is O(n), where n is the length of the string s. The space complexity is O(1).

Python 3

```python
class Solution:
    def minimumDeletions(self, s: str) -> int:
        n = len(s)
        f = [0] * (n + 1)
        b = 0
        for i, c in enumerate(s, 1):
            if c == 'b':
                f[i] = f[i - 1]
                b += 1
            else:
                f[i] = min(f[i - 1] + 1, b)
        return f[n]
```

Solution 2: Enumeration + Prefix Sum

> **How to think about it**
>
> Solution 1 is a prefix DP. We can also pick a cut: delete every `b` on the left and every `a` on the right; their sum is the deletion cost. Track left-hand `b`s and right-hand `a`s and take the minimum sum in one pass, still O(1) extra space.

We can enumerate each position i in the string s, dividing the string s into two parts, namely s[0,..,i-1] and s[i+1,..n-1]. To make the string balanced, the number of characters we need to delete at the current position i is the number of character 'b' in s[0,..,i-1] plus the number of character 'a' in s[i+1,..n-1].

Therefore, we maintain two variables lb and ra to represent the number of character 'b' in s[0,..,i-1] and the number of character 'a' in s[i+1,..n-1] respectively. The number of characters we need to delete is lb+ra. During the enumeration process, we update the variables lb and ra.

The time complexity is O(n), and the space complexity is O(1). Here, n is the length of the string s.

Python 3

```python
class Solution:
    def minimumDeletions(self, s: str) -> int:
        lb, ra = 0, s.count('a')
        ans = len(s)
        for c in s:
            ra -= c == 'a'
            ans = min(ans, lb + ra)
            lb += c == 'b'
        return ans
```

PART 2 · STRING DP · PROBLEM 3 OF 5

132. Palindrome Partitioning II

Hard · String, Dynamic Programming

leetcode.com/problems/palindrome-partitioning-ii

★ **TOP 10 PROBLEM** in String DP: master this one first

PROBLEM

Given a string `s`, partition `s` such that every substring of the partition is a palindrome.

Return *the **minimum** cuts needed for a palindrome partitioning of* `s`.

Example 1:

```
Input: s = "aab"
Output: 1
Explanation: The palindrome partitioning ["aa","b"] could be produced using 1 cut.
```

Example 2:

```
Input: s = "a"
Output: 0
```

Example 3:

```
Input: s = "ab"
Output: 1
```

Constraints:

- `1 <= s.length <= 2000`
- `s` consists of lowercase English letters only.

SOLUTION (PYTHON 3)

Solution 1: Dynamic Programming

How to think about it

We only need the fewest cuts, not the partitions. n≤ 2000, so enumerating them is impossible. Precompute palindromic spans as before. f[i] is the min cuts of s[0..i]: try a last palindrome s[j..i] and take f[j-1]+1; if the whole prefix is a palindrome, the answer is 0.

First, we preprocess the string s to determine whether each substring s[i..j] is a palindrome, and record this in a 2D array g[i][j], where g[i][j] indicates whether the substring s[i..j] is a palindrome.

Next, we define f[i] to represent the minimum number of cuts needed for the substring s[0..i-1]. Initially, f[i] = i.

Next, we consider how to transition the state for f[i]. We can enumerate the previous cut point j. If the substring s[j..i] is a palindrome, then f[i] can be transitioned from f[j]. If j = 0, it means that s[0..i] itself is a palindrome, and no cuts are needed, i.e., f[i] = 0. Therefore, the state transition equation is as follows:

$$f[i] = \min_{0 \le j \le i} \text{cases } f[j-1] + 1, \text{ \& if } g[j][i] = \text{True } \backslash\ 0, \text{ \& if } g[0][i] = \text{True cases}$$

The answer is f[n], where n is the length of the string s.

The time complexity is $O(n^2)$, and the space complexity is $O(n^2)$. Here, n is the length of the string s.

Python 3

```python
class Solution:
    def minCut(self, s: str) -> int:
        n = len(s)
        g = [[True] * n for _ in range(n)]
        for i in range(n - 1, -1, -1):
            for j in range(i + 1, n):
                g[i][j] = s[i] == s[j] and g[i + 1][j - 1]
        f = list(range(n))
        for i in range(1, n):
            for j in range(i + 1):
                if g[j][i]:
                    f[i] = min(f[i], 1 + f[j - 1] if j else 0)
        return f[-1]
```

            count += 1
            i -= 1
            j += 1
    return count
```

PART 2 · STRING DP · PROBLEM 4 OF 5

140. Word Break II

Hard · Trie, Memoization, Array, Hash Table, String, Dynamic Programming, Backtracking

leetcode.com/problems/word-break-ii

★ **TOP 10 PROBLEM** in String DP: master this one first

PROBLEM

Given a string `s` and a dictionary of strings `wordDict`, add spaces in `s` to construct a sentence where each word is a valid dictionary word. Return all such possible sentences in **any order**.

Note that the same word in the dictionary may be reused multiple times in the segmentation.

Example 1:

```
Input: s = "catsanddog", wordDict = ["cat","cats","and","sand","dog"]
Output: ["cats and dog","cat sand dog"]
```

Example 2:

```
Input: s = "pineapplepenapple", wordDict = ["apple","pen","applepen","pine","pineapple"]
Output: ["pine apple pen apple","pineapple pen apple","pine applepen apple"]
Explanation: Note that you are allowed to reuse a dictionary word.
```

Example 3:

```
Input: s = "catsandog", wordDict = ["cats","dog","sand","and","cat"]
Output: []
```

Constraints:

- `1 <= s.length <= 20`
- `1 <= wordDict.length <= 1000`
- `1 <= wordDict[i].length <= 10`
- `s` and `wordDict[i]` consist of only lowercase English letters.
- All the strings of `wordDict` are **unique**.
- Input is generated in a way that the length of the answer doesn't exceed 10^5.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

We must list every sentence, not only decide feasibility. |s|≤ 20, so the number of partitions is manageable. After inserting words into a trie, try every next word ending in the current suffix; on a hit, recurse on the rest and join the pieces. The trie tests prefixes quickly.

Python 3

```python
class Trie:
    def __init__(self):
        self.children = [None] * 26
        self.is_end = False

    def insert(self, word):
        node = self
        for c in word:
            idx = ord(c) - ord('a')
            if node.children[idx] is None:
                node.children[idx] = Trie()
            node = node.children[idx]
        node.is_end = True

    def search(self, word):
        node = self
        for c in word:
            idx = ord(c) - ord('a')
            if node.children[idx] is None:
                return False
            node = node.children[idx]
        return node.is_end

class Solution:
    def wordBreak(self, s: str, wordDict: List[str]) -> List[str]:
        def dfs(s):
            if not s:
                return [[]]
            res = []
            for i in range(1, len(s) + 1):
                if trie.search(s[:i]):
                    for v in dfs(s[i:]):
                        res.append([s[:i]] + v)
            return res

        trie = Trie()
        for w in wordDict:
            trie.insert(w)
        ans = dfs(s)
        return [' '.join(v) for v in ans]
```

Complexity. Time: O(2^n) in the worst case (the number of sentences can be exponential). Space: O(2^n).

                if best[end] is None or len(candidate) < len(best[end]):
                    best[end] = candidate
    return " ".join(best[len(s)]) if best[len(s)] is not None else None
```

PART 2 · STRING DP · PROBLEM 5 OF 5

1092. Shortest Common Supersequence

Hard · String, Dynamic Programming, Longest Common Subsequence

leetcode.com/problems/shortest-common-supersequence

★ **TOP 10 PROBLEM** in String DP: master this one first

PROBLEM

Given two strings `str1` and `str2`, return *the shortest string that has both* `str1` *and* `str2` *as* ***subsequences***. If there are multiple valid strings, return **any** of them.

A string `s` is a **subsequence** of string `t` if deleting some number of characters from `t` (possibly `0`) results in the string `s`.

Example 1:

```
Input: str1 = "abac", str2 = "cab"
Output: "cabac"
Explanation:
str1 = "abac" is a subsequence of "cabac" because we can delete the first "c".
str2 = "cab" is a subsequence of "cabac" because we can delete the last "ac".
The answer provided is the shortest such string that satisfies these properties.
```

Example 2:

```
Input: str1 = "aaaaaaaa", str2 = "aaaaaaaa"
Output: "aaaaaaaa"
```

Constraints:

- `1 <= str1.length, str2.length <= 1000`
- `str1` and `str2` consist of lowercase English letters.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

The SCS length is $|s_1|+|s_2|$-LCS. m,n≤ 1000: build the LCS table, then walk the transitions backward, inserting the characters that are not shared. f[i][j] is the LCS of the two prefixes. From (m,n), a move from above or the left emits the discarded character; an equal pair emits the common character and steps diagonally. The walk collects the reverse of the SCS; leftover characters on one side are appended when the other index hits zero.

Python 3

```python
class Solution:
    def shortestCommonSupersequence(self, str1: str, str2: str) -> str:
        m, n = len(str1), len(str2)
        f = [[0] * (n + 1) for _ in range(m + 1)]
        for i in range(1, m + 1):
            for j in range(1, n + 1):
                if str1[i - 1] == str2[j - 1]:
                    f[i][j] = f[i - 1][j - 1] + 1
                else:
                    f[i][j] = max(f[i - 1][j], f[i][j - 1])
        ans = []
        i, j = m, n
        while i or j:
            if i == 0:
                j -= 1
                ans.append(str2[j])
            elif j == 0:
                i -= 1
                ans.append(str1[i])
            else:
                if f[i][j] == f[i - 1][j]:
                    i -= 1
                    ans.append(str1[i])
                elif f[i][j] == f[i][j - 1]:
                    j -= 1
                    ans.append(str2[j])
                else:
                    i, j = i - 1, j - 1
                    ans.append(str1[i])
        return ''.join(ans[::-1])
```

337. House Robber III

Medium · Tree, Depth-First Search, Dynamic Programming, Binary Tree, Tree DP

leetcode.com/problems/house-robber-iii

★ **TOP 10 PROBLEM** in Tree / Graph DP: master this one first

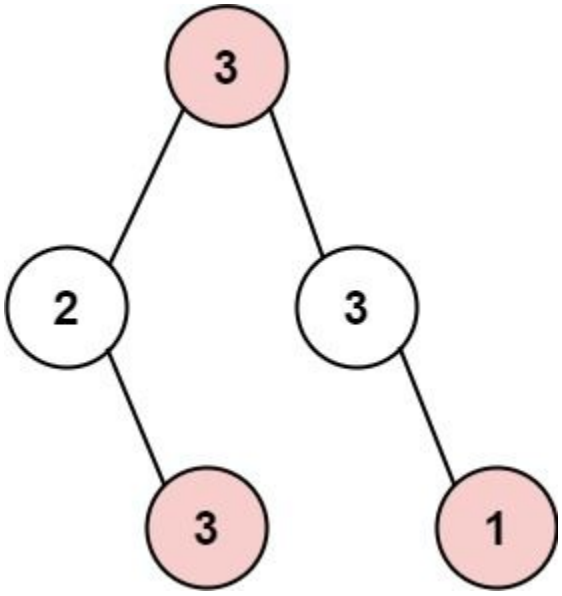
PROBLEM

The thief has found himself a new place for his thievery again. There is only one entrance to this area, called `root`.

Besides the `root`, each house has one and only one parent house. After a tour, the smart thief realized that all houses in this place form a binary tree. It will automatically contact the police if **two directly-linked houses were broken into on the same night**.

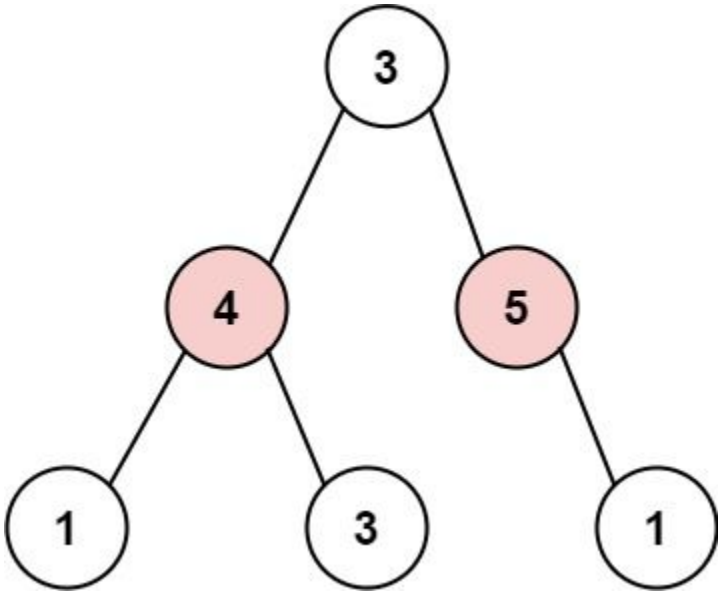
Given the `root` of the binary tree, return *the maximum amount of money the thief can rob* ***without alerting the police***.

Example 1:



```
Input: root = [3,2,3,null,3,null,1]
Output: 7
Explanation: Maximum amount of money the thief can rob = 3 + 3 + 1 = 7.
```

Example 2:



```
Input: root = [3,4,5,1,3,null,1]
Output: 9
Explanation: Maximum amount of money the thief can rob = 4 + 5 = 9.
```

Constraints:

- The number of nodes in the tree is in the range $[1, 10^4]$.
- $0 <= Node.val <= 10^4$

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Adjacent nodes cannot both be robbed. Computing steal/skip separately and walking each subtree twice repeats work. Postorder returns (rob root, skip root). Robbing the root forces both children to skip; skipping takes the better of each child. The answer is the max at the root. Each node is visited once.

Python 3

```python
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def rob(self, root: Optional[TreeNode]) -> int:
        def dfs(root: Optional[TreeNode]) -> (int, int):
            if root is None:
                return 0, 0
            la, lb = dfs(root.left)
            ra, rb = dfs(root.right)
            return root.val + lb + rb, max(la, lb) + max(ra, rb)

        return max(dfs(root))
```

Complexity. Time: O(n). Space: O(h).

834. Sum of Distances in Tree

Hard · Tree, Depth-First Search, Graph, Dynamic Programming, Tree DP

leetcode.com/problems/sum-of-distances-in-tree

★ **TOP 10 PROBLEM** in Tree / Graph DP: master this one first

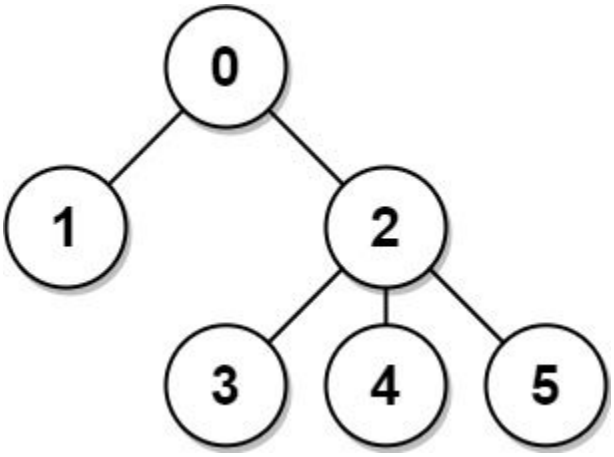
PROBLEM

There is an undirected connected tree with `n` nodes labeled from `0` to `n - 1` and `n - 1` edges.

You are given the integer `n` and the array `edges` where `edges[i] = [a_i, b_i]` indicates that there is an edge between nodes a_i and b_i in the tree.

Return an array `answer` of length `n` where `answer[i]` is the sum of the distances between the i^{th} node in the tree and all other nodes.

Example 1:

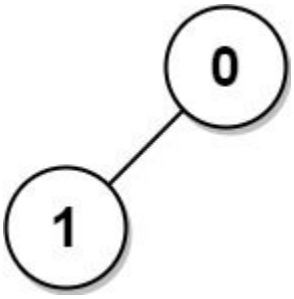


```
Input: n = 6, edges = [[0,1],[0,2],[2,3],[2,4],[2,5]]
Output: [8,12,6,10,10,10]
Explanation: The tree is shown above.
We can see that dist(0,1) + dist(0,2) + dist(0,3) + dist(0,4) + dist(0,5)
equals 1 + 1 + 2 + 2 + 2 = 8.
Hence, answer[0] = 8, and so on.
```

Example 2:

```
Input: n = 1, edges = []
Output: [0]
```

Example 3:



```
Input: n = 2, edges = [[1,0]]
Output: [1,1]
```

Constraints:

- $1 <= n <= 3 * 10^4$
- `edges.length == n - 1`
- `edges[i].length == 2`
- $0 <= a_i, b_i < n$
- $a_i != b_i$
- The given input represents a valid tree.

SOLUTIONS (PYTHON 3)

Solution 1: Tree DP (Re-rooting)

How to think about it

We need the sum of distances from every node. n≤ 3· 10^4, so a DFS from each root is quadratic. After rerooting, neighboring answers differ only by subtree size versus the rest of the tree. Root at 0 to get ans[0] and subtree sizes, then a second DFS pushes t-size[j]+n-size[j] to each child. Two traversals fill every answer.

First, we run a DFS to calculate the size of each node's subtree, recorded in the array size, and compute the sum of distances from node 0 to all other nodes, recorded in ans[0].

Next, we run another DFS to enumerate the sum of distances from each node when it is considered as the root. Suppose the answer for the current node i is t. When we move from node i to node j, the sum of distances changes to t - size[j] + n - size[j], meaning the sum of distances to node j and its subtree nodes decreases by size[j], while the sum of distances to other nodes increases by n - size[j].

The time complexity is O(n), and the space complexity is O(n), where n is the number of nodes in the tree.

Python 3

```python
class Solution:
    def sumOfDistancesInTree(self, n: int, edges: List[List[int]]) -> List[int]:
        def dfs1(i: int, fa: int, d: int):
            ans[0] += d
            size[i] = 1
            for j in g[i]:
                if j != fa:
                    dfs1(j, i, d + 1)
                    size[i] += size[j]

        def dfs2(i: int, fa: int, t: int):
            ans[i] = t
            for j in g[i]:
                if j != fa:
                    dfs2(j, i, t - size[j] + n - size[j])

        g = defaultdict(list)
        for a, b in edges:
            g[a].append(b)
            g[b].append(a)

        ans = [0] * n
        size = [0] * n
        dfs1(0, -1, 0)
        dfs2(0, -1, ans[0])
        return ans
```

Solution 2: Re-rooting DP + Explicit Stack

> **How to think about it**
>
> We need the sum of distances from every node. With $n \le 3 \cdot 10^4$, a walk from each root is quadratic. After rerooting, neighboring answers differ only by subtree size versus the rest of the tree. Recursion along a chain uses a call depth equal to n and overflows Python once the chain reaches length 1000. Subtree sizes are known only after the children finish, so the first walk is a post-order stack: state 0 adds the depth and pushes the children, and state 1 totals size. The second answer depends only on the parent's answer and the finished sizes, so a pre-order stack passes t-size[j]+n-size[j] to each child.

Root the tree at 0 and walk in post-order. The stack holds a node, its parent, a depth, and a state. In state 0, add the depth to ans[0], push the same node with state 1, and push every child. In state 1, every child size is already stored, and size[i] is 1 plus those sizes.

Then reroot with an explicit stack. It starts with (0,-1,ans[0]). When node i is popped, write the current sum t into ans[i]. Moving from i to a child j decreases the distances inside j's subtree by size[j] and increases the distances to every other node by n-size[j], so the pushed sum is t-size[j]+n-size[j].

The time complexity is O(n), and the space complexity is O(n), where n is the number of nodes in the tree.

Similar problems:

class Solution:
    def sumOfDistancesInTree(self, n: int, edges: List[List[int]]) -> List[int]:
        g = defaultdict(list)
        for a, b in edges:
            g[a].append(b)
            g[b].append(a)
        ans = [0] * n
        size = [0] * n
        stk = [(0, -1, 0, 0)]
        while stk:
            i, fa, d, state = stk.pop()
            if state == 0:
                ans[0] += d
                stk.append((i, fa, d, 1))
                for j in g[i]:
                    if j != fa:
                        stk.append((j, i, d + 1, 0))
            else:
                size[i] = 1
                for j in g[i]:
                    if j != fa:
                        size[i] += size[j]
        walk = [(0, -1, ans[0])]
        while walk:
            i, fa, t = walk.pop()
            ans[i] = t
            for j in g[i]:
                if j != fa:
                    walk.append((j, i, t - size[j] + n - size[j]))
        return ans
```

968. Binary Tree Cameras

Hard · Tree, Depth-First Search, Dynamic Programming, Binary Tree, Tree DP

leetcode.com/problems/binary-tree-cameras

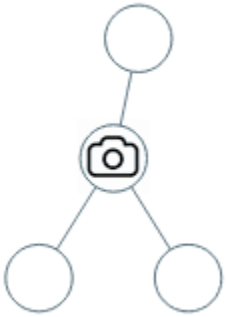
★ **TOP 10 PROBLEM** in Tree / Graph DP: master this one first

PROBLEM

You are given the `root` of a binary tree. We install cameras on the tree nodes where each camera at a node can monitor its parent, itself, and its immediate children.

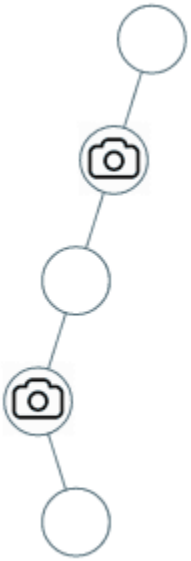
Return *the minimum number of cameras needed to monitor all nodes of the tree*.

Example 1:



```
Input: root = [0,0,null,0,0]
Output: 1
Explanation: One camera is enough to monitor all nodes if placed as shown.
```

Example 2:



```
Input: root = [0,0,null,0,null,0,null,null,0]
Output: 2
Explanation: At least two cameras are needed to monitor all nodes of the tree. The above image shows
one of the valid configurations of camera placement.
```

Constraints:

- The number of nodes in the tree is in the range `[1, 1000]`.
- `Node.val == 0`

SOLUTIONS (PYTHON 3)

Solution 1: Dynamic Programming (Tree DP)

> **How to think about it**
> A camera covers itself, its parent, and its children; we want as few as possible. The optimum at a node depends on the children, so we distinguish "has a camera / covered by a child / uncovered". Tree DP returns the three minima bottom-up; the root may not stay uncovered.

For each node, we define three states:

- `a`: The current node has a camera
- `b`: The current node does not have a camera, but is monitored by its children
- `c`: The current node does not have a camera and is not monitored by its children

Next, we design a function dfs(root), which will return an array of length 3, representing the minimum number of cameras in the subtree rooted at `root` for the three states. The answer is min(dfs(root)[0], dfs(root)[1]).

The calculation process of the function dfs(root) is as follows:

If `root` is null, return [inf, 0, 0], where `inf` represents a very large number, used to indicate an impossible situation.

Otherwise, we recursively calculate the left and right subtrees of `root`, obtaining [la, lb, lc] and [ra, rb, rc] respectively.

- If the current node has a camera, then its left and right children must be in a monitored state, i.e., a = min(la, lb, lc) + min(ra, rb, rc) + 1.
- If the current node does not have a camera but is monitored by its children, then one or both of the children must have a camera, i.e., b = min(la + rb, lb + ra, la + ra).
- If the current node does not have a camera and is not monitored by its children, then the children must be monitored by their children, i.e., c = lb + rb.

Finally, we return [a, b, c].

The time complexity is O(n), and the space complexity is O(n), where n is the number of nodes in the binary tree.

Python 3

```python
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def minCameraCover(self, root: Optional[TreeNode]) -> int:
        def dfs(root):
            if root is None:
                return inf, 0, 0
            la, lb, lc = dfs(root.left)
            ra, rb, rc = dfs(root.right)
            a = min(la, lb, lc) + min(ra, rb, rc) + 1
            b = min(la + rb, lb + ra, la + ra)
            c = lb + rb
            return a, b, c

        a, b, _ = dfs(root)
        return min(a, b)
```

Solution 2: Tree DP on an Explicit Stack

How to think about it

A camera covers itself, its parent, and its children, so the minimum depends on how each node is covered. Bottom-up, the three states are “has a camera”, “covered by a child”, and “uncovered”. On a short tree, returning those three minima is enough, and the root may not stay uncovered. The tree can contain 1000 nodes. A left chain makes this postorder walk recurse once per node and overflow the call stack. The three states of a node depend only on the three states of its children, so children must be finished before their parent. An explicit stack performs that postorder walk. On entry it pushes an exit marker and the two children; on exit it writes the node’s states with the original three formulas. The answer is the smaller of the root’s first two states.

For each node, we define three states:

- `a`: The current node has a camera
- `b`: The current node does not have a camera, but is monitored by its children
- `c`: The current node does not have a camera and is not monitored by its children

A null node corresponds to (inf, 0, 0), where inf is a very large number used for an impossible situation.

We walk the binary tree in postorder with an explicit stack. On entry we push an exit marker, then the right child and the left child. On exit the children’s states are already stored as [la, lb, lc] and [ra, rb, rc].

- If the current node has a camera, then its left and right children must be in a monitored state, i.e., a = min(la, lb, lc) + min(ra, rb, rc) + 1.
- If the current node does not have a camera but is monitored by its children, then one or both of the children must have a camera, i.e., b = min(la + rb, lb + ra, la + ra).
- If the current node does not have a camera and is not monitored by its children, then the children must be monitored by their children, i.e., c = lb + rb.

The root must not stay uncovered, so the answer is min(a, b).

The time complexity is O(n), and the space complexity is O(n), where n is the number of nodes in the binary tree.

Python 3

```python
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def minCameraCover(self, root: Optional[TreeNode]) -> int:
        if root is None:
            return 0
        stk = [(root, 0)]
        sub = {}
        while stk:
            node, state = stk.pop()
            if node is None:
                continue
            if state == 0:
                stk.append((node, 1))
                stk.append((node.right, 0))
                stk.append((node.left, 0))
                continue
            la, lb, lc = sub[id(node.left)] if node.left is not None else (inf, 0, 0)
            ra, rb, rc = sub[id(node.right)] if node.right is not None else (inf, 0, 0)
            a = min(la, lb, lc) + min(ra, rb, rc) + 1
            b = min(la + rb, lb + ra, la + ra)
            c = lb + rb
            sub[id(node)] = (a, b, c)
        a, b, _ = sub[id(root)]
        return min(a, b)
```

★ **TOP 10 PROBLEM** in Bitmask DP: master this one first

PROBLEM

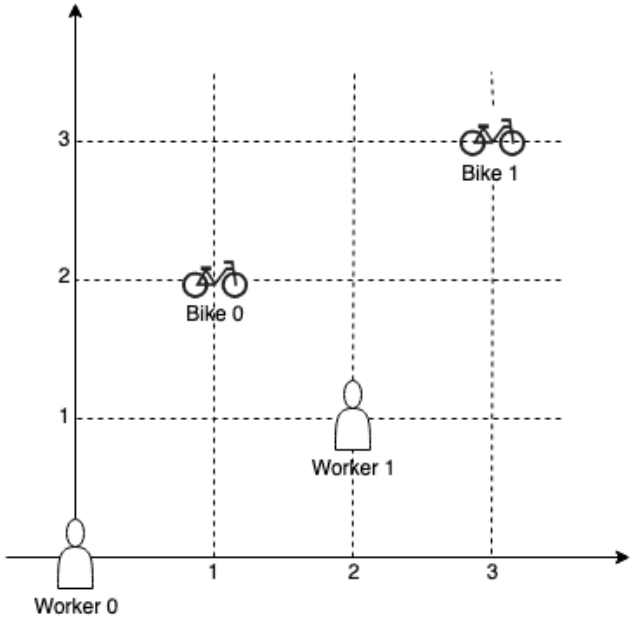
On a campus represented as a 2D grid, there are `n` workers and `m` bikes, with `n <= m`. Each worker and bike is a 2D coordinate on this grid.

We assign one unique bike to each worker so that the sum of the **Manhattan distances** between each worker and their assigned bike is minimized.

Return `the minimum possible sum of Manhattan distances between each worker and their assigned bike`.

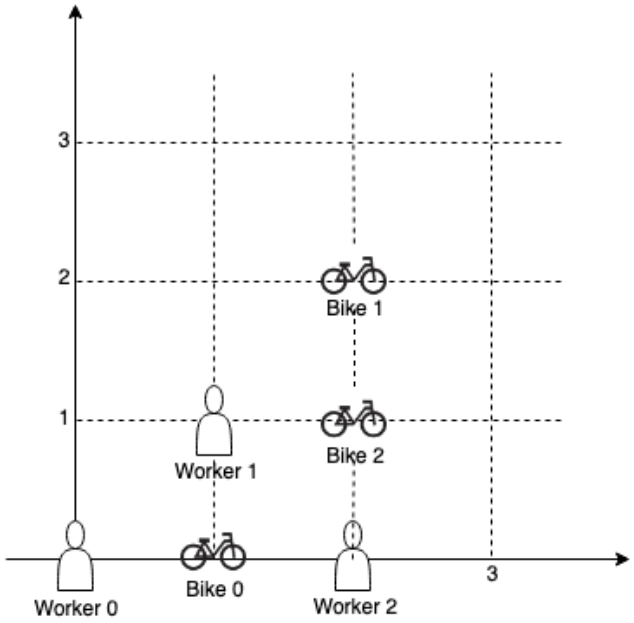
The **Manhattan distance** between two points `p1` and `p2` is `Manhattan(p1, p2) = |p1.x - p2.x| + |p1.y - p2.y|`.

Example 1:



```
Input: workers = [[0,0],[2,1]], bikes = [[1,2],[3,3]]
Output: 6
Explanation:
We assign bike 0 to worker 0, bike 1 to worker 1. The Manhattan distance of both assignments is 3, so the output is 6.
```

Example 2:



```
Input: workers = [[0,0],[1,1],[2,0]], bikes = [[1,0],[2,2],[2,1]]
Output: 4
Explanation:
We first assign bike 0 to worker 0, then assign bike 1 to worker 1 or worker 2, bike 2 to worker 2 or
worker 1. Both assignments lead to sum of the Manhattan distances as 4.
```

Example 3:

```
Input: workers = [[0,0],[1,0],[2,0],[3,0],[4,0]], bikes = [[0,999],[1,999],[2,999],[3,999],[4,999]]
Output: 4995
```

Constraints:

- `n == workers.length`
- `m == bikes.length`
- `1 <= n <= m <= 10`
- `workers[i].length == 2`
- `bikes[i].length == 2`
- `0 <= workers[i][0], workers[i][1], bikes[i][0], bikes[i][1] < 1000`
- All the workers and the bikes locations are **unique**.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

At most ten workers and bikes; listing assignments is P(m,n). The set of used bikes is an m-bit mask, so $n \cdot 2^m$ states fit. f[i][j] is the least total distance after i workers using mask j. For each bit k set in j we come from f[i-1][jxor 2^k] plus that pair's Manhattan distance. The answer is the minimum of row n.

Python 3

```
class Solution:
    def assignBikes(self, workers: List[List[int]], bikes: List[List[int]]) -> int:
        n, m = len(workers), len(bikes)
        f = [[inf] * (1 << m) for _ in range(n + 1)]
        f[0][0] = 0
        for i, (x1, y1) in enumerate(workers, 1):
            for j in range(1 << m):
                for k, (x2, y2) in enumerate(bikes):
                    if j >> k & 1:
                        f[i][j] = min(
                            f[i][j],
                            f[i - 1][j ^ (1 << k)] + abs(x1 - x2) + abs(y1 - y2),
                        )
        return min(f[n])
```

Complexity. Time: O(n * 2^m * m). Space: O(n * 2^m).

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

        memo[(w, mask)] = best
        return best

    return go(0, 0)
```

1986. Minimum Number of Work Sessions to Finish the Tasks

Medium · Bit Manipulation, Array, Dynamic Programming, Backtracking, Bitmask

leetcode.com/problems/minimum-number-of-work-sessions-to-finish-the-tasks

★ **TOP 10 PROBLEM** in Bitmask DP: master this one first

PROBLEM

There are `n` tasks assigned to you. The task times are represented as an integer array `tasks` of length `n`, where the i^{th} task takes `tasks[i]` hours to finish. A **work session** is when you work for **at most** `sessionTime` consecutive hours and then take a break.

You should finish the given tasks in a way that satisfies the following conditions:

- If you start a task in a work session, you must complete it in the **same** work session.
- You can start a new task **immediately** after finishing the previous one.
- You may complete the tasks in **any order**.

Given `tasks` and `sessionTime`, return *the **minimum** number of **work sessions** needed to finish all the tasks following the conditions above.*

The tests are generated such that `sessionTime` is **greater** than or **equal** to the **maximum** element in `tasks[i]`.

Example 1:

```
Input: tasks = [1,2,3], sessionTime = 3
Output: 2
Explanation: You can finish the tasks in two work sessions.
- First work session: finish the first and the second tasks in 1 + 2 = 3 hours.
- Second work session: finish the third task in 3 hours.
```

Example 2:

```
Input: tasks = [3,1,3,1,1], sessionTime = 8
Output: 2
Explanation: You can finish the tasks in two work sessions.
- First work session: finish all the tasks except the last one in 3 + 1 + 3 + 1 = 8 hours.
- Second work session: finish the last task in 1 hour.
```

Example 3:

```
Input: tasks = [1,2,3,4,5], sessionTime = 15
Output: 1
Explanation: You can finish all the tasks in one work session.
```

Constraints:

- `n == tasks.length`
- `1 <= n <= 14`
- `1 <= tasks[i] <= 10`
- `max(tasks[i]) <= sessionTime <= 15`

SOLUTION (PYTHON 3)

Solution 1: State Compression Dynamic Programming + Subset Enumeration

How to think about it

Tasks must fill sessions of capacity sessionTime, using as few sessions as possible. n≤ 14 admits subset DP. Mark subsets that fit in one session, then for each mask i try every submask j: if j is feasible, f[i]=min(f[ixor j]+1). f[2^n-1] is the session count.

We note that n does not exceed 14, so we can consider using state compression dynamic programming to solve this problem.

We use a binary number i of length n to represent the current task state, where the j-th bit of i is 1 if and only if the j-th task is completed. We use f[i] to represent the minimum number of work sessions needed to complete all tasks with state i.

We can enumerate all subsets j of i, where each bit of the binary representation of j is a subset of the corresponding bit of the binary representation of i, i.e., j ⊆ i. If the tasks corresponding to j can be completed in one work session, then we can update f[i] using f[i xor j] + 1, where i xor j represents the bitwise XOR of i and j.

The final answer is f[2^n - 1].

The time complexity is O(n × 3^n), and the space complexity is O(2^n). Here, n is the number of tasks.

Python 3

```python
class Solution:
    def minSessions(self, tasks: List[int], sessionTime: int) -> int:
        n = len(tasks)
        ok = [False] * (1 << n)
        for i in range(1, 1 << n):
            t = sum(tasks[j] for j in range(n) if i >> j & 1)
            ok[i] = t <= sessionTime
        f = [inf] * (1 << n)
        f[0] = 0
        for i in range(1, 1 << n):
            j = i
            while j:
                if ok[j]:
                    f[i] = min(f[i], f[i ^ j] + 1)
                j = (j - 1) & i
        return f[-1]
```

2305. Fair Distribution of Cookies

Medium · Bit Manipulation, Array, Dynamic Programming, Backtracking, Bitmask

leetcode.com/problems/fair-distribution-of-cookies

★ **TOP 10 PROBLEM** in Bitmask DP: master this one first

PROBLEM

You are given an integer array `cookies`, where `cookies[i]` denotes the number of cookies in the i^{th} bag. You are also given an integer `k` that denotes the number of children to distribute **all** the bags of cookies to. All the cookies in the same bag must go to the same child and cannot be split up.

The **unfairness** of a distribution is defined as the **maximum total** cookies obtained by a single child in the distribution.

Return *the **minimum** unfairness of all distributions*.

Example 1:

```
Input: cookies = [8,15,10,20,8], k = 2
Output: 31
Explanation: One optimal distribution is [8,15,8] and [10,20]
- The 1st child receives [8,15,8] which has a total of 8 + 15 + 8 = 31 cookies.
- The 2nd child receives [10,20] which has a total of 10 + 20 = 30 cookies.
The unfairness of the distribution is max(31,30) = 31.
It can be shown that there is no distribution with an unfairness less than 31.
```

Example 2:

```
Input: cookies = [6,1,3,2,2,4,1,2], k = 3
Output: 7
Explanation: One optimal distribution is [6,1], [3,2,2], and [4,1,2]
- The 1st child receives [6,1] which has a total of 6 + 1 = 7 cookies.
- The 2nd child receives [3,2,2] which has a total of 3 + 2 + 2 = 7 cookies.
- The 3rd child receives [4,1,2] which has a total of 4 + 1 + 2 = 7 cookies.
The unfairness of the distribution is max(7,7,7) = 7.
It can be shown that there is no distribution with an unfairness less than 7.
```

Constraints:

- `2 <= cookies.length <= 8`
- `1 <= cookies[i] <= 10^5`
- `2 <= k <= cookies.length`

SOLUTION (PYTHON 3)

Solution 1: Backtracking + Pruning

How to think about it

We assign n ≤ 8 bags to k ≤ 8 children and minimize the maximum load. Unconstrained assignment has k^n states, which is too large near the limits. Unfairness does not depend on bag order, but placing large bags first triggers pruning sooner. Sort bags decreasingly, then backtrack: skip a child if adding the bag is already no better than the known answer; treat equal loads on adjacent children as symmetric. After every bag is placed, update the answer with the current maximum.

First, we sort the array cookies in descending order (to reduce the number of searches), and then create an array cnt of length k to store the number of cookies each child gets. Also, we use a variable ans to maintain the current minimum degree of unfairness, initialized to a very large value.

Next, we start from the first snack pack. For the current snack pack i, we enumerate each child j. If the cookies cookies[i] in the current snack pack are given to child j, making the degree of unfairness greater than or equal to ans, or the number of cookies the current child already has is the same as the previous child, then we don't need to consider giving the cookies in the current snack pack to child j, just skip it (pruning). Otherwise, we give the cookies cookies[i] in the current snack pack to child j, and then continue to consider the next snack pack. When we have considered all the snack packs, we update the value of ans, then backtrack to the previous snack pack, and continue to enumerate which child to give the cookies in the current snack pack to.

Finally, we return ans.

Python 3

```python
class Solution:
    def distributeCookies(self, cookies: List[int], k: int) -> int:
        def dfs(i):
            if i >= len(cookies):
                nonlocal ans
                ans = max(cnt)
                return
            for j in range(k):
                if cnt[j] + cookies[i] >= ans or (j and cnt[j] == cnt[j - 1]):
                    continue
                cnt[j] += cookies[i]
                dfs(i + 1)
                cnt[j] -= cookies[i]

        ans = inf
        cnt = [0] * k
        cookies.sort(reverse=True)
        dfs(0)
        return ans
```

Complexity. Time: O(k^n) in the worst case (pruned in practice). Space: O(n + k).

            loads[child] -= cookies[i]
```

```
    go(0)
    return best[0]
```

PART 2 · BITMASK DP · PROBLEM 4 OF 4

847. Shortest Path Visiting All Nodes

Hard · Bit Manipulation, Breadth-First Search, Graph, Dynamic Programming, Bitmask

leetcode.com/problems/shortest-path-visiting-all-nodes

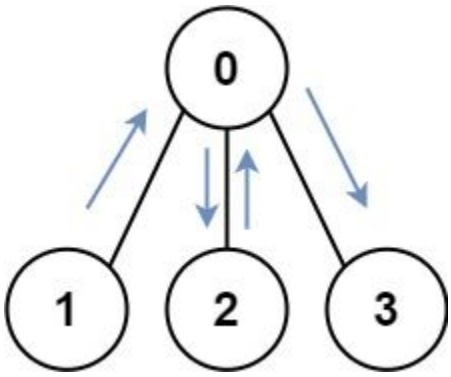
★ **TOP 10 PROBLEM** in Bitmask DP: master this one first

PROBLEM

You have an undirected, connected graph of `n` nodes labeled from `0` to `n - 1`. You are given an array `graph` where `graph[i]` is a list of all the nodes connected with node `i` by an edge.

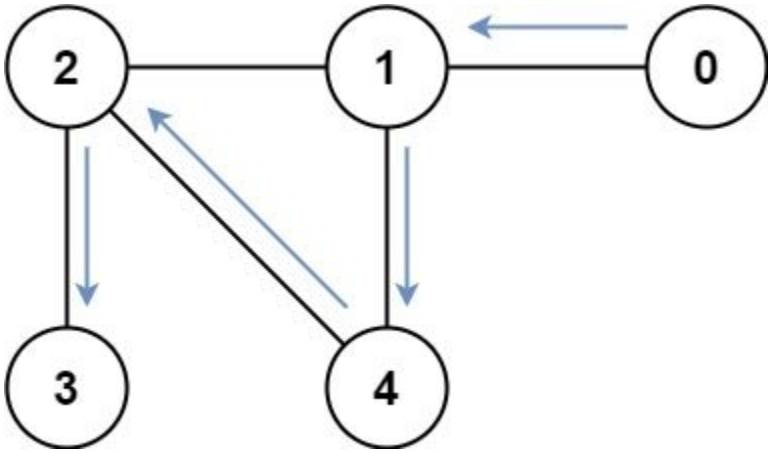
Return *the length of the shortest path that visits every node*. You may start and stop at any node, you may revisit nodes multiple times, and you may reuse edges.

Example 1:



```
Input: graph = [[1,2,3],[0],[0],[0]]
Output: 4
Explanation: One possible path is [1,0,2,0,3]
```

Example 2:



```
Input: graph = [[1],[0,2,4],[1,3,4],[2],[1,2]]
Output: 4
Explanation: One possible path is [0,1,4,2,3]
```

Constraints:

- `n == graph.length`
- `1 <= n <= 12`
- `0 <= graph[i].length < n`

- `graph[i]` does not contain `i`.
- If `graph[a]` contains `b`, then `graph[b]` contains `a`.
- The input graph is always connected.

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

We want a shortest walk that visits every node; edges may be reused. n≤ 12, so the walk itself is not the state, but (current node, visited mask) has only n· 2^n pairs. Multi-source BFS from every start on that state space: the first time the mask is full, the layer index is the answer.

Python 3

```
class Solution:
    def shortestPathLength(self, graph: List[List[int]]) -> int:
        n = len(graph)
        q = deque()
        vis = set()
        for i in range(n):
            q.append((i, 1 << i))
            vis.add((i, 1 << i))
        ans = 0
        while 1:
            for _ in range(len(q)):
                i, st = q.popleft()
                if st == (1 << n) - 1:
                    return ans
                for j in graph[i]:
                    nst = st | 1 << j
                    if (j, nst) not in vis:
                        vis.add((j, nst))
                        q.append((j, nst))
            ans += 1
```

Complexity. Time: O(2^n * E), at most O(2^n * n^2). Space: O(n * 2^n).

Solution 2

How to think about it

Plain BFS expands by layer. An admissible heuristic — the number of still-unvisited nodes — lets a priority queue pop dist+h first. Relaxation is still unit-weight shortest paths, so optimality is kept; full masks tend to appear earlier once most nodes are visited.

Python 3

```python
class Solution:
    def shortestPathLength(self, graph: List[List[int]]) -> int:
        n = len(graph)

        def f(state):
            return sum(((state >> i) & 1) == 0 for i in range(n))

        q = []
        dist = [[inf] * (1 << n) for _ in range(n)]
        for i in range(n):
            heappush(q, (f(1 << i), i, 1 << i))
            dist[i][1 << i] = 0
        while q:
            _, u, state = heappop(q)
            if state == (1 << n) - 1:
                return dist[u][state]
            for v in graph[u]:
                nxt = state | (1 << v)
                if dist[v][nxt] > dist[u][state] + 1:
                    dist[v][nxt] = dist[u][state] + 1
                    heappush(q, (dist[v][nxt] + f(nxt), v, nxt))
        return 0
```

Complexity. Time: O(2^n * E * log), at most O(2^n * n^2 * log); the heuristic only reorders the search. Space: O(n * 2^n).

★ **TOP 10 PROBLEM** in Digit DP: master this one first

PROBLEM

Given an integer `n`, return the count of all numbers with unique digits, `x`, where `0 <= x < 10^n`.

Example 1:

```
Input: n = 2
Output: 91
Explanation: The answer should be the total numbers in the range of 0 ≤ x < 100, excluding
11,22,33,44,55,66,77,88,99
```

Example 2:

```
Input: n = 0
Output: 1
```

Constraints:

- `0 <= n <= 8`

SOLUTION (PYTHON 3)

Solution 1: State Compression + Digit DP

How to think about it

Count integers with at most n digits and all distinct digits (including 0). Brute force still works for n=8, but digit DP handles leading zeros and used digits uniformly. dfs(i,mask,lead) is the remaining i+1 positions, the used-digit mask, and whether we are still leading zeros. A leading zero does not occupy a digit; otherwise j enters the mask. Start at i=n-1; the memoized state space is small.

This problem essentially asks for the number of numbers in the given range [l, ..r] that satisfy certain conditions. The conditions are related to the composition of the numbers rather than their size, so we can use the concept of Digit DP to solve it. In Digit DP, the size of the number has little impact on the complexity.

For the range [l, ..r] problem, we generally convert it to the problem of [1, ..r] and then subtract the result of [1, ..l - 1], i.e.:

$$ans = \sum_{i=1}^{r} ans_i - \sum_{i=1}^{l-1} ans_i$$

However, for this problem, we only need to find the value for the range $[1, ..10^n-1]$.

Here, we use memoized search to implement Digit DP. We search from the starting point downwards, and at the lowest level, we get the number of solutions. We then return the answers layer by layer upwards, and finally get the final answer from the starting point of the search.

Based on the problem information, we design a function dfs(i, mask, lead), where:

- The digit i represents the current position being searched, starting from the highest digit, i.e., i = 0 represents the highest digit.
- The digit mask represents the current state of the number, i.e., the j-th bit of mask being 1 indicates that the digit j has been used.
- The boolean lead indicates whether the current number only contains leading 0s.

The function executes as follows:

If i exceeds the length of the number n, i.e., i < 0, it means the search is over, directly return 1.

Otherwise, we enumerate the digits j from 0 to 9 for the position i. For each j:

- If the j-th bit of mask is 1, it means the digit j has been used, so we skip it.
- If lead is true and j = 0, it means the current number only contains leading 0s. When we recurse to the next level, lead remains true.
- Otherwise, we recurse to the next level, update the j-th bit of mask to 1, and set lead to false.

Finally, we sum all the results from the recursive calls to the next level, which is the answer.

The answer is dfs(n - 1, 0, True).

The time complexity is $O(n \times 2^D \times D)$, and the space complexity is $O(n \times 2^D)$. Here, n is the length of the number n, and D = 10.

★ **TOP 10 PROBLEM** in Digit DP: master this one first

PROBLEM

Given an integer `n`, count *the total number of digit* `1` *appearing in all non-negative integers less than or equal to* `n`.

Example 1:

```
Input: n = 13
Output: 6
```

Example 2:

```
Input: n = 0
Output: 0
```

Constraints:

- $0 <= n <= 10^9$

SOLUTION (PYTHON 3)

Solution 1: Digit DP

How to think about it

Scanning every integer in [1,n] is impossible for large n. The count of digit 1 depends only on the digits and the upper bound, which is a digit-DP setting. Treat n as a string and memoize dfs(i,cnt,limit): position i from the high end, cnt ones so far, and whether we still match the prefix of n. Enumerate the current digit and add the results.

This problem essentially asks for the number of times the digit 1 appears in the given range [l, ..r]. The count is related to the number of digits and the value of each digit. We can use the concept of Digit DP to solve this problem. In Digit DP, the size of the number has little impact on the complexity.

For the range [l, ..r] problem, we generally convert it to the problem of [1, ..r] and then subtract the result of [1, ..l - 1], i.e.:

$$ans = \sum_{i=1}^{r} ans_i - \sum_{i=1}^{l-1} ans_i$$

However, for this problem, we only need to find the value for the range [1, ..r].

Here, we use memoized search to implement Digit DP. We search from the starting point downwards, and at the lowest level, we get the number of solutions. We then return the answers layer by layer upwards, and finally get the final answer from the starting point of the search.

The basic steps are as follows:

First, we convert the number n to a string s. Then we design a function dfs(i, cnt, limit), where:

- The digit i represents the current position being searched, starting from the highest digit, i.e., i = 0 represents the highest digit.
- The digit cnt represents the current count of the digit 1 in the number.
- The boolean limit indicates whether the current number is restricted by the upper bound.

The function executes as follows:

If i exceeds the length of the number n, it means the search is over, directly return cnt. If limit is true, up is the i-th digit of the current number. Otherwise, up = 9. Next, we iterate j from 0 to up. For each j:

- If j equals 1, we increment cnt by one.

- Recursively call dfs(i + 1, cnt, limit ∧ j = up).

The answer is dfs(0, 0, True).

The time complexity is $O(m^2 \times D)$, and the space complexity is $O(m^2)$. Here, m is the length of the number n, and D = 10.

PART 2 · DIGIT DP · PROBLEM 3 OF 3

902. Numbers At Most N Given Digit Set

Hard · Array, Math, String, Binary Search, Dynamic Programming

leetcode.com/problems/numbers-at-most-n-given-digit-set

★ **TOP 10 PROBLEM** in Digit DP: master this one first

PROBLEM

Given an array of `digits` which is sorted in **non-decreasing** order. You can write numbers using each `digits[i]` as many times as we want. For example, if `digits = ['1','3','5']`, we may write numbers such as `'13'`, `'551'`, and `'1351315'`.

Return *the number of positive integers that can be generated* that are less than or equal to a given integer `n`.

Example 1:

```
Input: digits = ["1","3","5","7"], n = 100
Output: 20
Explanation:
The 20 numbers that can be written are:
1, 3, 5, 7, 11, 13, 15, 17, 31, 33, 35, 37, 51, 53, 55, 57, 71, 73, 75, 77.
```

Example 2:

```
Input: digits = ["1","4","9"], n = 1000000000
Output: 29523
Explanation:
We can write 3 one digit numbers, 9 two digit numbers, 27 three digit numbers,
81 four digit numbers, 243 five digit numbers, 729 six digit numbers,
2187 seven digit numbers, 6561 eight digit numbers, and 19683 nine digit numbers.
In total, this is 29523 integers that can be written using the digits array.
```

Example 3:

```
Input: digits = ["7"], n = 8
Output: 1
```

Constraints:

- `1 <= digits.length <= 9`
- `digits[i].length == 1`
- `digits[i]` is a digit from `'1'` to `'9'`.
- All the values in `digits` are **unique**.
- `digits` is sorted in **non-decreasing** order.
- `1 <= n <= 10^9`

SOLUTION (PYTHON 3)

Solution 1: Digit DP

How to think about it

Building every number from digits and testing x ≤ n re-expands the same prefixes near the decimal length of n. The count depends only on the position, whether we still have leading zeros, and whether we are tight against the upper bound. Write n as s and memoize dfs(i, lead, limit): a leading-zero state may still place 0, otherwise only digits from digits are allowed, clipped by limit. A finished number counts as 1 only if it is not all leading zeros.

This problem essentially asks for the number of positive integers that can be generated from the digits in digits within the given range [l, .., r]. The count depends on the number of digits and the value of each digit. We can solve this problem using

the Digit DP approach. In Digit DP, the size of the number has little impact on the complexity.

For the range [l, .., r] problem, we generally convert it to the problem of [1, .., r] and then subtract the result of [1, .., l - 1], i.e.,

$$ans = \sum_{i=1}^{r} ans_i - \sum_{i=1}^{l-1} ans_i$$

However, for this problem, we only need to find the value for the range [1, .., r].

Here, we use memoization to implement Digit DP. We start searching from the top, get the number of solutions at the bottom, and return the answers layer by layer until we get the final answer from the starting point.

The basic steps are as follows:

We convert the number n into a string s and denote the length of the string s as m.

Next, we design a function dfs(i, lead, limit) to represent the number of solutions from the current i-th digit to the last digit of the string. Here:

- The integer i represents the current position in the string s.
- The boolean lead indicates whether the current number contains only leading zeros.
- The boolean limit indicates whether the current position is restricted by the upper bound.

The function executes as follows:

If i is greater than or equal to m, it means we have processed all digits. If lead is true, it means the current number is a leading zero, and we should return 0. Otherwise, we should return 1.

Otherwise, we calculate the upper bound up. If limit is true, then up is the digit corresponding to s[i]. Otherwise, up is 9.

Then, we enumerate the current digit j in the range [0, up]. If j is 0 and lead is true, we recursively calculate dfs(i + 1, true, limit ∧ j = up). Otherwise, if j is in digits, we recursively calculate dfs(i + 1, false, limit ∧ j = up). We accumulate all the results as the answer.

Finally, we return dfs(0, true, true).

The time complexity is O(log n × D), and the space complexity is O(log n). Here, D = 10.

        def dfs(i: int, lead: int, limit: bool) -> int:
            if i >= len(s):
                return lead ^ 1

            up = int(s[i]) if limit else 9
            ans = 0
            for j in range(up + 1):
                if j == 0 and lead:
                    ans += dfs(i + 1, 1, limit and j == up)
                elif j in nums:
                    ans += dfs(i + 1, 0, limit and j == up)
            return ans

        s = str(n)
        nums = {int(x) for x in digits}
        return dfs(0, 1, True)

688. Knight Probability in Chessboard

Medium · Dynamic Programming

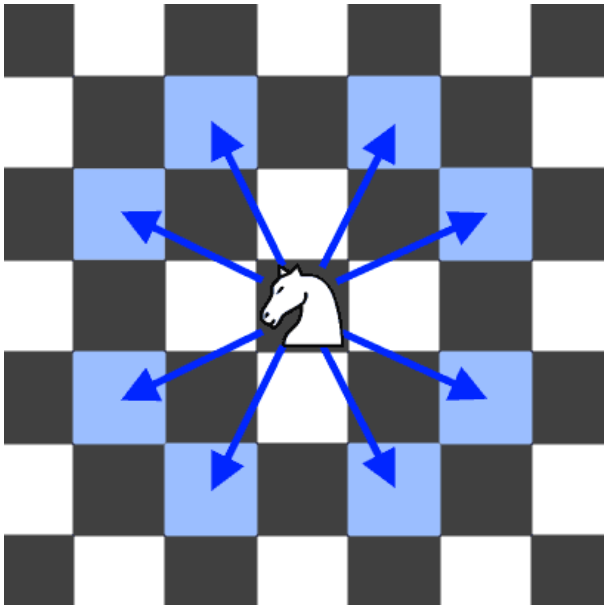
leetcode.com/problems/knight-probability-in-chessboard

★ **TOP 10 PROBLEM** in Probability DP: master this one first

PROBLEM

On an `n x n` chessboard, a knight starts at the cell `(row, column)` and attempts to make exactly `k` moves. The rows and columns are **0-indexed**, so the top-left cell is `(0, 0)`, and the bottom-right cell is `(n - 1, n - 1)`.

A chess knight has eight possible moves it can make, as illustrated below. Each move is two cells in a cardinal direction, then one cell in an orthogonal direction.



Each time the knight is to move, it chooses one of eight possible moves uniformly at random (even if the piece would go off the chessboard) and moves there.

The knight continues moving until it has made exactly `k` moves or has moved off the chessboard.

Return *the probability that the knight remains on the board after it has stopped moving*.

Example 1:

```
Input: n = 3, k = 2, row = 0, column = 0
Output: 0.06250
Explanation: There are two moves (to (1,2), (2,1)) that will keep the knight on the board.
From each of those positions, there are also two moves that will keep the knight on the board.
The total probability the knight stays on the board is 0.0625.
```

Example 2:

```
Input: n = 1, k = 0, row = 0, column = 0
Output: 1.00000
```

Constraints:

- `1 <= n <= 25`
- `0 <= k <= 100`
- `0 <= row, column <= n - 1`

SOLUTION (PYTHON 3)

Solution 1: Dynamic Programming

> **How to think about it**
>
> The probability a knight stays on an n× n board after k moves. An 8^k search is impossible for k≤ 100. f[h][i][j] is the chance of staying after h more moves from (i,j). Base h=0 is 1; otherwise average f[h-1] over the eight in-bound landings.

We define f[h][i][j] to represent the probability that the knight remains on the board after taking h steps starting from position (i, j). The final answer is f[k][row][column].

When h=0, the knight is definitely on the board, so the probability is 1, i.e., f[0][i][j]=1.

When h > 0, the probability that the knight is at position (i, j) can be derived from the probabilities of the 8 possible positions it could have come from in the previous step, i.e.,

$$f[h][i][j] = \sum_{x,\, y} f[h - 1][x][y] \times 1/8$$

where (x, y) is one of the 8 positions the knight can move to from (i, j).

The final answer is f[k][row][column].

The time complexity is $O(k \times n^2)$, and the space complexity is $O(k \times n^2)$. Here, k and n are the given number of steps and the size of the board, respectively.

Python 3

```python
class Solution:
    def knightProbability(self, n: int, k: int, row: int, column: int) -> float:
        f = [[[0] * n for _ in range(n)] for _ in range(k + 1)]
        for i in range(n):
            for j in range(n):
                f[0][i][j] = 1
        for h in range(1, k + 1):
            for i in range(n):
                for j in range(n):
                    for a, b in pairwise((-2, -1, 2, 1, -2, 1, 2, -1, -2)):
                        x, y = i + a, j + b
                        if 0 <= x < n and 0 <= y < n:
                            f[h][i][j] += f[h - 1][x][y] / 8
        return f[k][row][column]
```

    return 1 - sum(sum(r) for r in current)
```

808. Soup Servings

Medium · Math, Dynamic Programming, Probability and Statistics

leetcode.com/problems/soup-servings

★ **TOP 10 PROBLEM** in Probability DP: master this one first

PROBLEM

You have two soups, **A** and **B**, each starting with `n` mL. On every turn, one of the following four serving operations is chosen *at random*, each with probability `0.25` **independent** of all previous turns:

- pour 100 mL from type A and 0 mL from type B
- pour 75 mL from type A and 25 mL from type B
- pour 50 mL from type A and 50 mL from type B
- pour 25 mL from type A and 75 mL from type B

Note:

- There is no operation that pours 0 mL from A and 100 mL from B.
- The amounts from A and B are poured *simultaneously* during the turn.
- If an operation asks you to pour **more than** you have left of a soup, pour all that remains of that soup.

The process stops immediately after any turn in which *one of the soups* is used up.

Return the probability that A is used up *before* B, plus half the probability that both soups are used up in the **same turn**. Answers within 10^{-5} of the actual answer will be accepted.

Example 1:

```
Input: n = 50
Output: 0.62500
Explanation:
If we perform either of the first two serving operations, soup A will become empty first.
If we perform the third operation, A and B will become empty at the same time.
If we perform the fourth operation, B will become empty first.
So the total probability of A becoming empty first plus half the probability that A and B become empty
at the same time, is 0.25 * (1 + 1 + 0.5 + 0) = 0.625.
```

Example 2:

```
Input: n = 100
Output: 0.71875
Explanation:
If we perform the first serving operation, soup A will become empty first.
If we perform the second serving operations, A will become empty on performing operation [1, 2, 3],
and both A and B become empty on performing operation 4.
If we perform the third operation, A will become empty on performing operation [1, 2], and both A and B
become empty on performing operation 3.
If we perform the fourth operation, A will become empty on performing operation 1, and both A and B
become empty on performing operation 2.
So the total probability of A becoming empty first plus half the probability that A and B become empty
at the same time, is 0.71875.
```

Constraints:

- $0 <= n <= 10^9$

SOLUTION (PYTHON 3)

Solution 1: Memoization Search

How to think about it

Four operations deplete the soups with equal probability; we want the probability that A empties first (ties count as 1/2). n can be 10^9, so a millilitre-level simulation is impossible. Each pour removes at least 25 ml, so states shrink to ceil(n/25). dfs(i,j) is the probability with i and j remaining units, with base cases 1, 0, or 1/2. For large n, A almost surely finishes first, so the code returns 1 when n>4800.

In this problem, since each operation is a multiple of 25, we can consider every 25ml of soup as one unit. This reduces the data scale to ceil(n/25).

We design a function dfs(i, j), which represents the probability result when there are i units of soup A and j units of soup B remaining.

When i ≤ 0 and j ≤ 0, it means both soups are finished, and we should return 0.5. When i ≤ 0, it means soup A is finished first, and we should return 1. When j ≤ 0, it means soup B is finished first, and we should return 0.

Next, for each operation, we have four choices:

- Take 4 units from soup A and 0 units from soup B;
- Take 3 units from soup A and 1 unit from soup B;
- Take 2 units from soup A and 2 units from soup B;
- Take 1 unit from soup A and 3 units from soup B.

Each choice has a probability of 0.25, so we can derive:

$$dfs(i, j) = 0.25 \times (dfs(i - 4, j) + dfs(i - 3, j - 1) + dfs(i - 2, j - 2) + dfs(i - 1, j - 3))$$

We use memoization to store the results of the function.

Additionally, we find that when n=4800, the result is 0.999994994426, and the required precision is 10^{-5}. As n increases, the result gets closer to 1. Therefore, when n > 4800, we can directly return 1.

The time complexity is $O(C^2)$, and the space complexity is $O(C^2)$. In this problem, C=200.

Python 3

```python
class Solution:
    def soupServings(self, n: int) -> float:
        @cache
        def dfs(i: int, j: int) -> float:
            if i <= 0 and j <= 0:
                return 0.5
            if i <= 0:
                return 1
            if j <= 0:
                return 0
            return 0.25 * (
                dfs(i - 4, j)
                + dfs(i - 3, j - 1)
                + dfs(i - 2, j - 2)
                + dfs(i - 1, j - 3)
            )

        return 1 if n > 4800 else dfs((n + 24) // 25, (n + 24) // 25)
```

837. New 21 Game

Medium · Math, Dynamic Programming, Sliding Window, Probability and Statistics

leetcode.com/problems/new-21-game

★ **TOP 10 PROBLEM** in Probability DP: master this one first

PROBLEM

Alice plays the following game, loosely based on the card game **"21"**.

Alice starts with `0` points and draws numbers while she has less than `k` points. During each draw, she gains an integer number of points randomly from the range `[1, maxPts]`, where `maxPts` is an integer. Each draw is independent and the outcomes have equal probabilities.

Alice stops drawing numbers when she gets `k` **or more points**.

Return the probability that Alice has `n` or fewer points.

Answers within 10^{-5} of the actual answer are considered accepted.

Example 1:

```
Input: n = 10, k = 1, maxPts = 10
Output: 1.00000
Explanation: Alice gets a single card, then stops.
```

Example 2:

```
Input: n = 6, k = 1, maxPts = 10
Output: 0.60000
Explanation: Alice gets a single card, then stops.
In 6 out of 10 possibilities, she is at or below 6 points.
```

Example 3:

```
Input: n = 21, k = 17, maxPts = 10
Output: 0.73278
```

Constraints:

- `0 <= k <= n <=` 10^4
- `1 <= maxPts <=` 10^4

SOLUTIONS (PYTHON 3)

Solution 1: Memoized Search

How to think about it

We add a uniform integer in [1,maxPts] until the total reaches k, and want the probability it is still ≤ n. Expanding every draw is impossible for k,n≤ 10^4; memoize on the current total. dfs(i) is the success probability from total i. For i≥ k we stop and test i≤ n; i=k-1 has a closed form. Other states use a difference of neighbors so each transition is O(1) instead of O(maxPts).

We design a function dfs(i), which represents the probability that when the current score is i, the final score does not exceed n when we stop drawing numbers. The answer is dfs(0).

The calculation method of function dfs(i) is as follows:

- If i ≥ k, then we stop drawing numbers. If i ≤ n, return 1, otherwise return 0;
- Otherwise, we can draw the next number j in the range [1,..maxPts], then dfs(i) = 1/maxPts $\sum_{j=1}^{maxPts}$ dfs(i+j).

Here we can use memoized search to accelerate the calculation.

The time complexity of the above method is O(k × maxPts), which will exceed the time limit, so we need to optimize it.

When i < k, the following equation holds:

$$\text{dfs}(i) = (\text{dfs}(i+1) + \text{dfs}(i+2) + \ldots + \text{dfs}(i+\text{maxPts})) / \text{maxPts} \quad (1)$$

When i < k - 1, the following equation holds:

$$\text{dfs}(i+1) = (\text{dfs}(i+2) + \text{dfs}(i+3) + \ldots + \text{dfs}(i+\text{maxPts}+1)) / \text{maxPts} \quad (2)$$

Therefore, when i < k-1, we subtract equation (2) from equation (1) to get:

$$\text{dfs}(i) - \text{dfs}(i+1) = (\text{dfs}(i+1) - \text{dfs}(i+\text{maxPts}+1)) / \text{maxPts}$$

That is:

$$\text{dfs}(i) = \text{dfs}(i+1) + (\text{dfs}(i+1) - \text{dfs}(i+\text{maxPts}+1)) / \text{maxPts}$$

If i=k-1, we have:

$$\text{dfs}(i) = \text{dfs}(k-1) = (\text{dfs}(k) + \text{dfs}(k+1) + \ldots + \text{dfs}(k+\text{maxPts}-1)) / \text{maxPts} \quad (3)$$

We assume there are i numbers not exceeding n, then k+i-1 ≤ n, and since i≤ maxPts, we have i ≤ min(n-k+1, maxPts), so equation (3) can be written as:

$$\text{dfs}(k-1) = \min(n-k+1, \text{maxPts}) / \text{maxPts}$$

In summary, we have the following state transition equation:

$$\text{dfs}(i) = \begin{cases} 1, & i \geq k, i \leq n \\ 0, & i \geq k, i > n \\ \min(n-k+1, \text{maxPts}) / \text{maxPts}, & i = k-1 \\ \text{dfs}(i+1) + (\text{dfs}(i+1) - \text{dfs}(i+\text{maxPts}+1)) / \text{maxPts}, & i < k-1 \end{cases}$$

Time complexity O(k + maxPts), space complexity O(k + maxPts). Where k is the maximum score.

Python 3

```python
class Solution:
    def new21Game(self, n: int, k: int, maxPts: int) -> float:
        @cache
        def dfs(i: int) -> float:
            if i >= k:
                return int(i <= n)
            if i == k - 1:
                return min(n - k + 1, maxPts) / maxPts
            return dfs(i + 1) + (dfs(i + 1) - dfs(i + maxPts + 1)) / maxPts

        return dfs(0)
```

Solution 2: Dynamic Programming

> **How to think about it**
>
> Solution 1 already fills the probabilities from the high scores downward. Each f[i] comes from f[i+1] and the window end f[i+maxPts+1]. Terminals in [k,min(n,k+maxPts)) are 1. The answer is f[0]. Time stays linear.

Solution 1 already fills this table from the high scores downward. The transitions below are the same ones.

Define f[i] to represent the probability that when the current score is i, the final score does not exceed n when we stop drawing numbers. The answer is f[0].

When k ≤ i ≤ min(n, k + maxPts - 1), we have f[i] = 1.

When i = k - 1, we have f[i] = min(n-k+1, maxPts) / maxPts.

When i < k - 1, we have f[i] = f[i + 1] + (f[i + 1] - f[i + maxPts + 1]) / maxPts.

Time complexity O(k + maxPts), space complexity O(k + maxPts). Where k is the maximum score.

Python 3

```python
class Solution:
    def new21Game(self, n: int, k: int, maxPts: int) -> float:
        f = [0] * (k + maxPts)
        for i in range(k, min(n + 1, k + maxPts)):
            f[i] = 1
        f[k - 1] = min(n - k + 1, maxPts) / maxPts
        for i in range(k - 2, -1, -1):
            f[i] = f[i + 1] + (f[i + 1] - f[i + maxPts + 1]) / maxPts
        return f[0]
```

Solution 3: Dynamic Programming

> **How to think about it**
>
> We add a uniform integer in [1,maxPts] until the total reaches k, and want the probability it is still ≤ n. k can be 10^4, so expanding every draw is impossible. After the one-step difference, every state except the closed form at k-1 reads a larger score first. The chain from 0 to k has length k and overflows the stack. Larger scores are known if we walk downward. Let f[i] be the success probability from total i, write the terminal window as 1, and fill from k-2 down to 0.

Let f[i] be the probability that a current score of i ends at most n. The answer is f[0].

The value of f[i] is as follows:

- If i ≥ k, drawing stops. The value is 1 when i ≤ n, and 0 otherwise;
- Otherwise the next draw j lies in [1,..maxPts], so f[i] = 1/maxPts $\sum_{j=1}^{maxPts}$ f[i+j].

Every state depends only on a larger score, so fill from k - 2 down to 0. When k = 0 no draw has started, and the answer is 1.

The time complexity of the above method is O(k × maxPts), which will exceed the time limit, so we need to optimize it.

When i < k, the following equation holds:

$$\begin{aligned} f[i] &= (f[i + 1] + f[i + 2] + \ldots + f[i + maxPts]) / maxPts \quad (1) \end{aligned}$$

When i < k - 1, the following equation holds:

$$\begin{aligned} f[i+1] &= (f[i + 2] + f[i + 3] + \ldots + f[i + maxPts + 1]) / maxPts \quad (2) \end{aligned}$$

Therefore, when i < k-1, we subtract equation (2) from equation (1) to get:

$$\begin{aligned} f[i] - f[i+1] &= (f[i + 1] - f[i + maxPts + 1]) / maxPts \end{aligned}$$

That is:

$$\begin{aligned} f[i] &= f[i + 1] + (f[i + 1] - f[i + maxPts + 1]) / maxPts \end{aligned}$$

If i=k-1, we have:

$$\begin{aligned} f[i] &= f[k - 1] = (f[k] + f[k + 1] + \ldots + f[k + maxPts - 1]) / maxPts \quad (3) \end{aligned}$$

We assume there are i numbers not exceeding n, then k+i-1 ≤ n, and since i≤ maxPts, we have i ≤ min(n-k+1, maxPts), so equation (3) can be written as:

$$\begin{aligned} f[k-1] &= min(n-k+1, maxPts) / maxPts \end{aligned}$$

In summary, we have the following state transition equation:

$$\begin{aligned} f[i] &= \begin{cases} 1, & i \geq k, i \leq n \\ 0, & i \geq k, i > n \\ min(n-k+1, maxPts) / maxPts, & i = k - 1 \\ f[i + 1] + (f[i + 1] - f[i + maxPts + 1]) / maxPts, & i < k - 1 \end{cases} \end{aligned}$$

Time complexity O(k + maxPts), space complexity O(k + maxPts). Where k is the maximum score.

Python 3

```python
class Solution:
    def new21Game(self, n: int, k: int, maxPts: int) -> float:
        f = [0] * (k + maxPts)
        for i in range(k, min(n + 1, k + maxPts)):
            f[i] = 1
        f[k - 1] = min(n - k + 1, maxPts) / maxPts
        for i in range(k - 2, -1, -1):
            f[i] = f[i + 1] + (f[i + 1] - f[i + maxPts + 1]) / maxPts
        return f[0]
```

714. Best Time to Buy and Sell Stock with Transaction Fee

Medium · Greedy, Array, Dynamic Programming

leetcode.com/problems/best-time-to-buy-and-sell-stock-with-transaction-fee

★ **TOP 10 PROBLEM** in State Machine DP: master this one first

PROBLEM

You are given an array `prices` where `prices[i]` is the price of a given stock on the i^{th} day, and an integer `fee` representing a transaction fee.

Find the maximum profit you can achieve. You may complete as many transactions as you like, but you need to pay the transaction fee for each transaction.

Note:

- You may not engage in multiple transactions simultaneously (i.e., you must sell the stock before you buy again).
- The transaction fee is only charged once for each stock purchase and sale.

Example 1:

```
Input: prices = [1,3,2,8,4,9], fee = 2
Output: 8
Explanation: The maximum profit can be achieved by:
- Buying at prices[0] = 1
- Selling at prices[3] = 8
- Buying at prices[4] = 4
- Selling at prices[5] = 9
The total profit is ((8 - 1) - 2) + ((9 - 4) - 2) = 8.
```

Example 2:

```
Input: prices = [1,3,7,5,10,3], fee = 3
Output: 6
```

Constraints:

- `1 <= prices.length <= 5 * 10^4`
- `1 <= prices[i] < 5 * 10^4`
- `0 <= fee < 5 * 10^4`

SOLUTIONS (PYTHON 3)

Solution 1: Memoization

How to think about it

We may trade many times and pay fee on each completed sale. n ≤ 5× 10^4, so an unmemoized search over days repeats states. A day has two modes: flat or holding. From flat we buy or skip; from holding we sell (minus fee) or hold. The optimum from day i in mode j depends only on those two successors. Memoize dfs(i,j); past the last day the profit is 0. The answer is dfs(0,0). There are O(n) states.

We design a function dfs(i, j), which represents the maximum profit that can be obtained starting from day i with state j. Here, j can take the values 0 and 1, representing not holding and holding a stock, respectively. The answer is dfs(0, 0).

The execution logic of the function dfs(i, j) is as follows:

If i ≥ n, there are no more stocks to trade, so we return 0.

Otherwise, we can choose not to trade, in which case dfs(i, j) = dfs(i + 1, j). We can also choose to trade stocks. If j > 0, it means that we currently hold a stock and can sell it. In this case, dfs(i, j) = prices[i] + dfs(i + 1, 0) - fee. If j = 0, it means that

we currently do not hold a stock and can buy one. In this case, dfs(i, j) = -prices[i] + dfs(i + 1, 1). We take the maximum value as the return value of the function dfs(i, j).

The answer is dfs(0, 0).

To avoid redundant calculations, we use memoization to record the return value of dfs(i, j) in an array f. If f[i][j] is not equal to -1, it means that we have already calculated it, so we can directly return f[i][j].

The time complexity is O(n), and the space complexity is O(n). Here, n is the length of the array prices.

Python 3

```python
class Solution:
    def maxProfit(self, prices: List[int], fee: int) -> int:
        @cache
        def dfs(i: int, j: int) -> int:
            if i >= len(prices):
                return 0
            ans = dfs(i + 1, j)
            if j:
                ans = max(ans, prices[i] + dfs(i + 1, 0) - fee)
            else:
                ans = max(ans, -prices[i] + dfs(i + 1, 1))
            return ans

        return dfs(0, 0)
```

Solution 2: Dynamic Programming

> **How to think about it**
>
> Solution 1 fills a suffix table from the end. The same choices can be written forward: f[i][0/1] is the best profit after day i, flat or holding. Flat comes from staying flat or selling today and paying fee; holding comes from staying put or buying today. Fill left to right; the answer is flat on the last day. Time stays O(n).

We define f[i][j] as the maximum profit that can be obtained up to day i with state j. Here, j can take the values 0 and 1, representing not holding and holding a stock, respectively. We initialize f[0][0] = 0 and f[0][1] = -prices[0].

When i ≥ 1, if we do not hold a stock at the current day, then f[i][0] can be obtained by transitioning from f[i - 1][0] and f[i - 1][1] + prices[i] - fee, i.e., f[i][0] = max(f[i - 1][0], f[i - 1][1] + prices[i] - fee). If we hold a stock at the current day, then f[i][1] can be obtained by transitioning from f[i - 1][1] and f[i - 1][0] - prices[i], i.e., f[i][1] = max(f[i - 1][1], f[i - 1][0] - prices[i]). The final answer is f[n - 1][0].

The time complexity is O(n), and the space complexity is O(n). Here, n is the length of the array prices.

Python 3

```python
class Solution:
    def maxProfit(self, prices: List[int], fee: int) -> int:
        n = len(prices)
        f = [[0] * 2 for _ in range(n)]
        f[0][1] = -prices[0]
        for i in range(1, n):
            f[i][0] = max(f[i - 1][0], f[i - 1][1] + prices[i] - fee)
            f[i][1] = max(f[i - 1][1], f[i - 1][0] - prices[i])
        return f[n - 1][0]
```

Solution 3: Dynamic Programming (Space Optimization)

> **How to think about it**
>
> Day i in Solution 2 reads only day i-1, so the full table is unnecessary. Roll two scalars f_0,f_1. Parallel assignment keeps the previous pair while both updates run, so the new holding state still sees the old flat profit. Space is O(1).

The transition only needs the previous day, so two variables are enough and the space complexity is O(1).

Python 3

```python
class Solution:
    def maxProfit(self, prices: List[int], fee: int) -> int:
        f0, f1 = 0, -prices[0]
        for x in prices[1:]:
            f0, f1 = max(f0, f1 + x - fee), max(f1, f0 - x)
        return f0
```

Solution 4: Dynamic Programming

> **How to think about it**
>
> We may trade many times and pay fee on each completed sale. n ≤ 5× 10^4, so a raw decision tree over days is far too large. The state is the day and whether we hold. Skipping always calls the next day before it returns, so the chain has length n and overflows the stack. Later days are known if we walk backward. Let f[i][j] be the best profit from day i with holding flag j, and fill i from n-1 down to 0. Selling subtracts fee; buying enters the holding state.

Let f[i][j] be the maximum profit starting from day i in state j. The values of j are 0 and 1, meaning we do not hold a stock and we hold a stock. The answer is f[0][0]. Days past the end contribute 0, so f[n][j] = 0.

Fill i from n - 1 down to 0. Doing nothing keeps f[i + 1][j]. If j > 0, we hold a stock and may sell it, earning prices[i] + f[i + 1][0] - fee. If j = 0, we may buy, earning -prices[i] + f[i + 1][1]. Take the larger value:

$$f[i][j] = \max(f[i + 1][j], prices[i] + f[i + 1][0] - fee)$$

when j > 0, and

$$f[i][j] = \max(f[i + 1][j], -prices[i] + f[i + 1][1])$$

when j = 0.

The time complexity is O(n), and the space complexity is O(n), where n is the length of the array prices.

Python 3

```python
class Solution:
    def maxProfit(self, prices: List[int], fee: int) -> int:
        n = len(prices)
        f = [[0] * 2 for _ in range(n + 1)]
        for i in range(n - 1, -1, -1):
            for j in range(2):
                ans = f[i + 1][j]
                if j:
                    ans = max(ans, prices[i] + f[i + 1][0] - fee)
                else:
                    ans = max(ans, -prices[i] + f[i + 1][1])
                f[i][j] = ans
        return f[0][0]
```

PART 2 · STATE MACHINE DP · PROBLEM 2 OF 3

123. Best Time to Buy and Sell Stock III

Hard · Array, Dynamic Programming

leetcode.com/problems/best-time-to-buy-and-sell-stock-iii

★ **TOP 10 PROBLEM** in State Machine DP: master this one first

PROBLEM

You are given an array `prices` where `prices[i]` is the price of a given stock on the i^{th} day.

Find the maximum profit you can achieve. You may complete **at most two transactions**.

Note: You may not engage in multiple transactions simultaneously (i.e., you must sell the stock before you buy again).

Example 1:

```
Input: prices = [3,3,5,0,0,3,1,4]
Output: 6
Explanation: Buy on day 4 (price = 0) and sell on day 6 (price = 3), profit = 3-0 = 3.
Then buy on day 7 (price = 1) and sell on day 8 (price = 4), profit = 4-1 = 3.
```

Example 2:

```
Input: prices = [1,2,3,4,5]
Output: 4
Explanation: Buy on day 1 (price = 1) and sell on day 5 (price = 5), profit = 5-1 = 4.
Note that you cannot buy on day 1, buy on day 2 and sell them later, as you are engaging multiple
transactions at the same time. You must sell before buying again.
```

Example 3:

```
Input: prices = [7,6,4,3,1]
Output: 0
Explanation: In this case, no transaction is done, i.e. max profit = 0.
```

Constraints:

- `1 <= prices.length <=` 10^5
- `0 <= prices[i] <=` 10^5

SOLUTION (PYTHON 3)

Solution 1: Dynamic Programming

How to think about it

At most two transactions, so the unlimited-trade state of the previous problem is not enough. A 3D DP over day, trades finished, and hold is heavier than we need. The legal order is buy1, sell1, buy2, sell2. Four variables update in that order, each day using the previous stage. Buying and selling on the same day yields 0 and does not hurt the optimum.

We define the following variables:

- `f1` represents the maximum profit after the first purchase of the stock;
- `f2` represents the maximum profit after the first sale of the stock;
- `f3` represents the maximum profit after the second purchase of the stock;
- `f4` represents the maximum profit after the second sale of the stock.

During the traversal, we directly calculate `f1`, `f2`, `f3`, `f4`. We consider that buying and selling on the same day will result in a profit of 0, which will not affect the answer.

Finally, return `f4`.

The time complexity is O(n), where n is the length of the `prices` array. The space complexity is O(1).

Python 3

```python
class Solution:
    def maxProfit(self, prices: List[int]) -> int:
        # 第一次买入，第一次卖出，第二次买入，第二次卖出
        f1, f2, f3, f4 = -prices[0], 0, -prices[0], 0
        for price in prices[1:]:
            f1 = max(f1, -price)
            f2 = max(f2, f1 + price)
            f3 = max(f3, f2 - price)
            f4 = max(f4, f3 + price)
        return f4
```

            sell[j] = max(sell[j], buy[j] + p)
    return sell[k]
```

188. Best Time to Buy and Sell Stock IV

Hard · Array, Dynamic Programming

leetcode.com/problems/best-time-to-buy-and-sell-stock-iv

★ **TOP 10 PROBLEM** in State Machine DP: master this one first

PROBLEM

You are given an integer array `prices` where `prices[i]` is the price of a given stock on the i^{th} day, and an integer `k`.

Find the maximum profit you can achieve. You may complete at most `k` transactions: i.e. you may buy at most `k` times and sell at most `k` times.

Note: You may not engage in multiple transactions simultaneously (i.e., you must sell the stock before you buy again).

Example 1:

```
Input: k = 2, prices = [2,4,1]
Output: 2
Explanation: Buy on day 1 (price = 2) and sell on day 2 (price = 4), profit = 4-2 = 2.
```

Example 2:

```
Input: k = 2, prices = [3,2,6,5,0,3]
Output: 7
Explanation: Buy on day 2 (price = 2) and sell on day 3 (price = 6), profit = 6-2 = 4. Then buy on day
5 (price = 0) and sell on day 6 (price = 3), profit = 3-0 = 3.
```

Constraints:

- `1 <= k <= 100`
- `1 <= prices.length <= 1000`
- `0 <= prices[i] <= 1000`

SOLUTIONS (PYTHON 3)

Solution 1: Memoization Search

How to think about it

At most k transactions generalizes the two-trade problem. n≤ 1000, k≤ 100, so a 3D state is fine. dfs(i,j,hold) starts on day i with j buys left. Skipping is always legal; holding may sell (buy count unchanged); a flat position with remaining buys may buy and consume one. Memoize (i,j,hold).

We design a function dfs(i, j, k) to represent the maximum profit that can be obtained when starting from day i, completing at most j transactions, and holding the stock with the current state k (not holding the stock is represented by 0, and holding the stock is represented by 1). The answer is dfs(0, k, 0).

The execution logic of the function dfs(i, j, k) is as follows:

- If i is greater than or equal to n, return 0 directly.
- The i-th day can choose not to do anything, then dfs(i, j, k) = dfs(i + 1, j, k).
- If k > 0, the i-th day can choose to sell the stock, then dfs(i, j, k) = max(dfs(i + 1, j - 1, 0) + prices[i], dfs(i + 1, j, k)).
- Otherwise, if j > 0, the i-th day can choose to buy the stock, then dfs(i, j, k) = max(dfs(i + 1, j - 1, 1) - prices[i], dfs(i + 1, j, k)).

The value of dfs(i, j, k) is the maximum value of the above three cases.

During the process, we can use memoization search to save the results of each calculation to avoid repeated calculations.

The time complexity is O(n × k), and the space complexity is O(n × k), where n and k are the length of the prices array and the value of k, respectively.

Python 3

```python
class Solution:
    def maxProfit(self, k: int, prices: List[int]) -> int:
        @cache
        def dfs(i: int, j: int, k: int) -> int:
            if i >= len(prices):
                return 0
            ans = dfs(i + 1, j, k)
            if k:
                ans = max(ans, prices[i] + dfs(i + 1, j, 0))
            elif j:
                ans = max(ans, -prices[i] + dfs(i + 1, j - 1, 1))
            return ans

        return dfs(0, k, 0)
```

Solution 2: Dynamic Programming

> **How to think about it**
>
> Solution 1 is memoized recursion. Bottom-up, f[i][j][0/1] is the best profit after day i with j buys used. Day 0 buy is -prices[0]; later transitions are sell, stay flat, buy, or keep holding — the same state space.

We can also use dynamic programming to define f[i][j][k] as the maximum profit that can be obtained when completing at most j transactions (here we define the number of transactions as the number of purchases), and holding the stock with the current state k on the i-th day. The initial value of f[i][j][k] is 0. The answer is f[n - 1][k][0].

When i = 0, the stock price is prices[0]. For any j \in [1, k], we havef[0][j][1] = -prices[0], which means buying the stock on the 0-th day with a profit of-prices[0]$.

When i > 0:

- If the i-th day does not hold the stock, it may be that the stock was held on the i-1-th day and sold on the i-th day, or the stock was not held on the i-1-th day and no operation was performed on the i-th day. Therefore, f[i][j][0] = max(f[i - 1][j][1] + prices[i], f[i - 1][j][0]).
- If the i-th day holds the stock, it may be that the stock was not held on the i-1-th day and bought on the i-th day, or the stock was held on the i-1-th day and no operation was performed on the i-th day. Therefore, f[i][j][1] = max(f[i - 1][j - 1][0] - prices[i], f[i - 1][j][1]).

Therefore, when i > 0, we can get the state transition equation:

aligned f[i][j][0] &= max(f[i - 1][j][1] + prices[i], f[i - 1][j][0]) \ f[i][j][1] &= max(f[i - 1][j - 1][0] - prices[i], f[i - 1][j][1]) aligned

The final answer is f[n - 1][k][0].

The time complexity is O(n × k), and the space complexity is O(n × k), where n and k are the length of the prices array and the value of k, respectively.

Python 3

```python
class Solution:
    def maxProfit(self, k: int, prices: List[int]) -> int:
        n = len(prices)
        f = [[[0] * 2 for _ in range(k + 1)] for _ in range(n)]
        for j in range(1, k + 1):
            f[0][j][1] = -prices[0]
        for i, x in enumerate(prices[1:], 1):
            for j in range(1, k + 1):
                f[i][j][0] = max(f[i - 1][j][1] + x, f[i - 1][j][0])
                f[i][j][1] = max(f[i - 1][j - 1][0] - x, f[i - 1][j][1])
        return f[n - 1][k][0]
```

Solution 3: Dynamic Programming (Space Optimization)

> **How to think about it**
>
> Day i in Solution 2 depends only on day i-1. Drop the day dimension and roll f[j][2] in O(k) space.

f[i][j][k] depends only on the previous day, so a table of size (k+1) × 2 is enough. The space complexity is O(k).

Python 3

```python
class Solution:
    def maxProfit(self, k: int, prices: List[int]) -> int:
        f = [[0] * 2 for _ in range(k + 1)]
        for j in range(1, k + 1):
            f[j][1] = -prices[0]
        for x in prices[1:]:
            for j in range(k, 0, -1):
                f[j][0] = max(f[j][1] + x, f[j][0])
                f[j][1] = max(f[j - 1][0] - x, f[j][1])
        return f[k][0]
```

593. Valid Square

Medium · Geometry, Math

leetcode.com/problems/valid-square

★ **TOP 10 PROBLEM** in Maths / Geometry: master this one first

PROBLEM

Given the coordinates of four points in 2D space `p1`, `p2`, `p3` and `p4`, return `true` *if the four points construct a square*.

The coordinate of a point p_i is represented as $[x_i, y_i]$. The input is **not** given in any order.

A **valid square** has four equal sides with positive length and four equal angles (90-degree angles).

Example 1:

```
Input: p1 = [0,0], p2 = [1,1], p3 = [1,0], p4 = [0,1]
Output: true
```

Example 2:

```
Input: p1 = [0,0], p2 = [1,1], p3 = [1,0], p4 = [0,12]
Output: false
```

Example 3:

```
Input: p1 = [1,0], p2 = [-1,0], p3 = [0,1], p4 = [0,-1]
Output: true
```

Constraints:

- `p1.length == p2.length == p3.length == p4.length == 2`
- $-10^4 <= x_i, y_i <= 10^4$

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Four points form a square if the sides are equal and adjacent sides are perpendicular — equivalently, every triple is an isosceles right triangle. Testing permutations of a quadrilateral is messy. For each triple, check that two squared sides are equal and the Pythagorean identity holds, rejecting zero length. If all four triples pass, the points form a square.

Python 3

```
class Solution:
    def validSquare(
        self, p1: List[int], p2: List[int], p3: List[int], p4: List[int]
    ) -> bool:
        def check(a, b, c):
            (x1, y1), (x2, y2), (x3, y3) = a, b, c
            d1 = (x1 - x2) * (x1 - x2) + (y1 - y2) * (y1 - y2)
            d2 = (x1 - x3) * (x1 - x3) + (y1 - y3) * (y1 - y3)
            d3 = (x2 - x3) * (x2 - x3) + (y2 - y3) * (y2 - y3)
            return any(
                [
                    d1 == d2 and d1 + d2 == d3 and d1,
                    d2 == d3 and d2 + d3 == d1 and d2,
                    d1 == d3 and d1 + d3 == d2 and d1,
                ]
            )

        return (
            check(p1, p2, p3)
            and check(p2, p3, p4)
            and check(p1, p3, p4)
            and check(p1, p2, p4)
        )
```

Complexity. Time: O(1). Space: O(1).

611. Valid Triangle Number

Medium · Greedy, Array, Two Pointers, Binary Search, Sorting

leetcode.com/problems/valid-triangle-number

★ **TOP 10 PROBLEM** in Maths / Geometry: master this one first

PROBLEM

Given an integer array `nums`, return *the number of triplets chosen from the array that can make triangles if we take them as side lengths of a triangle*.

Example 1:

```
Input: nums = [2,2,3,4]
Output: 3
Explanation: Valid combinations are:
2,3,4 (using the first 2)
2,3,4 (using the second 2)
2,2,3
```

Example 2:

```
Input: nums = [4,2,3,4]
Output: 4
```

Constraints:

- `1 <= nums.length <= 1000`
- `0 <= nums[i] <= 1000`

SOLUTION (PYTHON 3)

Solution 1: Sorting + Binary Search

How to think about it

A triple loop is acceptable for $n \le 10^3$ but sorting reduces the check: after $a \le b \le c$ only $a+b>c$ remains. Fix the two smaller sides i,j and binary-search the first index ≥ nums[i]+nums[j]; every k in between is a valid third side.

A valid triangle must satisfy: **the sum of any two sides is greater than the third side**. That is:

$$a + b > c \text{ tag1}$$

$$a + c > b \text{ tag2}$$

$$b + c > a \text{ tag3}$$

If we arrange the sides in ascending order, i.e., $a \le b \le c$, then obviously conditions (2) and (3) are satisfied. We only need to ensure that condition (1) is also satisfied to form a valid triangle.

We enumerate i in the range [0, n - 3], enumerate j in the range [i + 1, n - 2], and perform binary search in the range [j + 1, n - 1] to find the first index left that is greater than or equal to nums[i] + nums[j]. Then, the values of k in the range [j + 1, left - 1] satisfy the condition, and we add them to the result ans.

The time complexity is $O(n^2 \log n)$, and the space complexity is $O(\log n)$, where n is the length of the array.

Python 3

```
class Solution:
    def triangleNumber(self, nums: List[int]) -> int:
        nums.sort()
        ans, n = 0, len(nums)
        for i in range(n - 2):
            for j in range(i + 1, n - 1):
                k = bisect_left(nums, nums[i] + nums[j], lo=j + 1) - 1
                ans += k - j
        return ans
```

```

939. Minimum Area Rectangle

Medium · Geometry, Array, Hash Table, Math, Sorting

leetcode.com/problems/minimum-area-rectangle

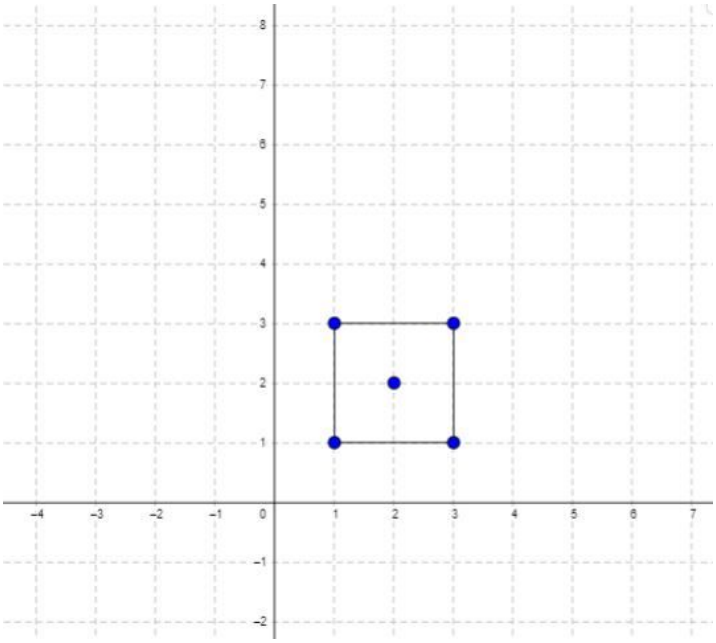
★ **TOP 10 PROBLEM** in Maths / Geometry: master this one first

PROBLEM

You are given an array of points in the **X-Y** plane `points` where `points[i] = [x_i, y_i]`.

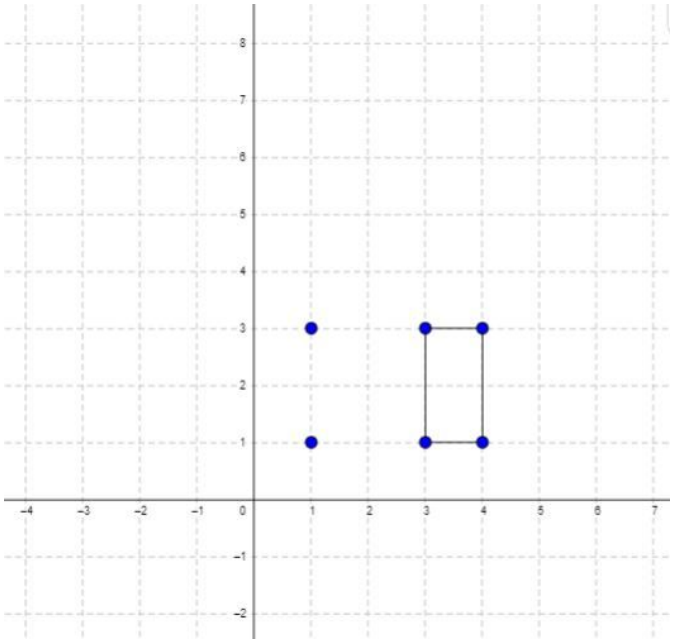
Return *the minimum area of a rectangle formed from these points, with sides parallel to the X and Y axes*. If there is not any such rectangle, return `0`.

Example 1:



```
Input: points = [[1,1],[1,3],[3,1],[3,3],[2,2]]
Output: 4
```

Example 2:



Input: points = [[1,1],[1,3],[3,1],[3,3],[4,1],[4,3]]
Output: 2

Constraints:

- 1 <= points.length <= 500
- points[i].length == 2
- 0 <= x_i, y_i <= 4 * 10^4
- All the given points are **unique**.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

An axis-aligned rectangle is spanned by two pairs of matching y-coordinates. n≤ 500, so four-nested loops are too slow, but pairs on the same vertical line are manageable. Group by x and scan left to right. For each pair (y_1,y_2) on the current line, a previous occurrence of that pair yields a rectangle. A map stores the latest x of every y-pair.

Python 3

```
class Solution:
    def minAreaRect(self, points: List[List[int]]) -> int:
        d = defaultdict(list)
        for x, y in points:
            d[x].append(y)
        pos = {}
        ans = inf
        for x in sorted(d):
            ys = d[x]
            ys.sort()
            n = len(ys)
            for i, y1 in enumerate(ys):
                for y2 in ys[i + 1 :]:
                    if (y1, y2) in pos:
                        ans = min(ans, (x - pos[(y1, y2)]) * (y2 - y1))
                    pos[(y1, y2)] = x
        return 0 if ans == inf else ans
```

Complexity. Time: O(n^2). Space: O(n^2).

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

```

963. Minimum Area Rectangle II

Medium · Geometry, Array, Hash Table, Math

leetcode.com/problems/minimum-area-rectangle-ii

★ **TOP 10 PROBLEM** in Maths / Geometry: master this one first

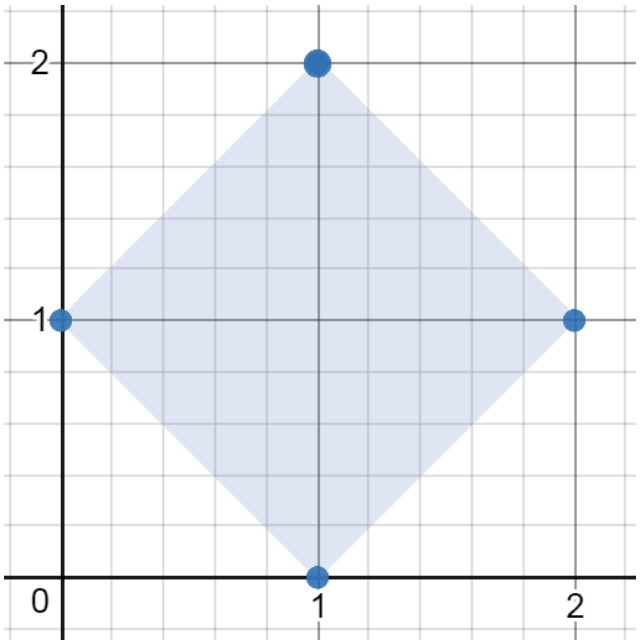
PROBLEM

You are given an array of points in the **X-Y** plane `points` where `points[i] = [x_i, y_i]`.

Return *the minimum area of any rectangle formed from these points, with sides **not necessarily parallel** to the X and Y axes*. If there is not any such rectangle, return `0`.

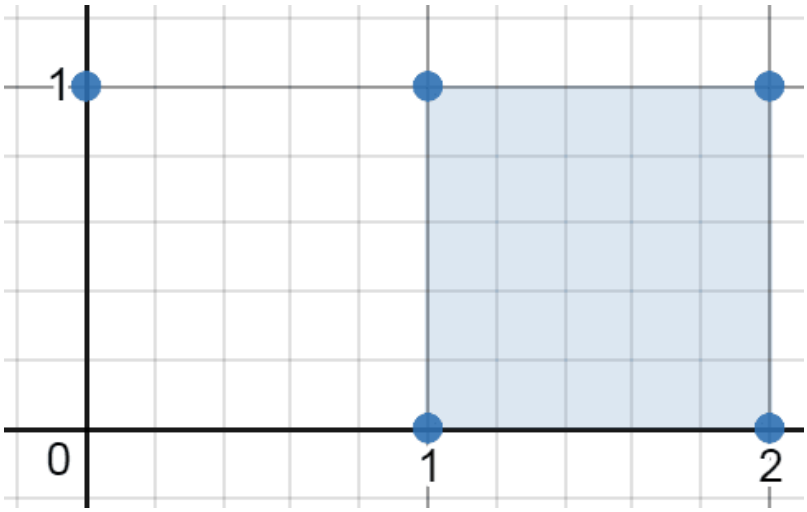
Answers within 10^{-5} of the actual answer will be accepted.

Example 1:



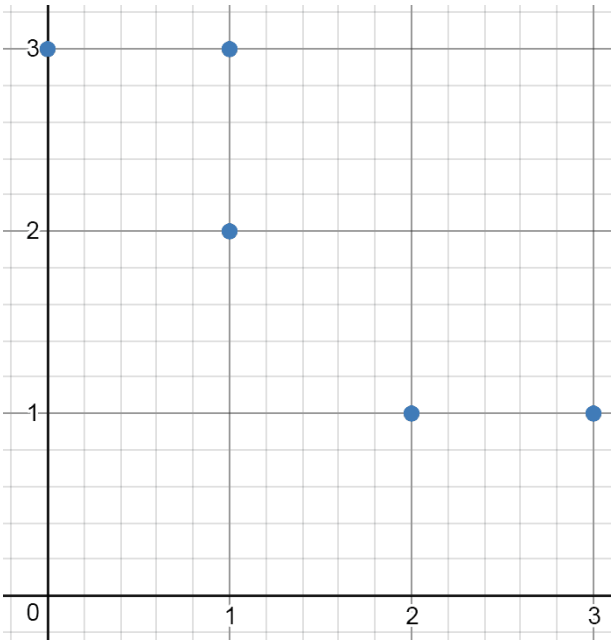
```
Input: points = [[1,2],[2,1],[1,0],[0,1]]
Output: 2.00000
Explanation: The minimum area rectangle occurs at [1,2],[2,1],[1,0],[0,1], with an area of 2.
```

Example 2:



```
Input: points = [[0,1],[2,1],[1,1],[1,0],[2,0]]
Output: 1.00000
Explanation: The minimum area rectangle occurs at [1,0],[1,1],[2,1],[2,0], with an area of 1.
```

Example 3:



```
Input: points = [[0,3],[1,2],[3,1],[1,3],[2,1]]
Output: 0
Explanation: There is no possible rectangle to form from these points.
```

Constraints:

- `1 <= points.length <= 50`
- `points[i].length == 2`
- `0 <= x_i, y_i <= 4 * 10^4`
- All the given points are **unique**.

SOLUTION (PYTHON 3)

Solution 1: Hash Table + Enumeration

How to think about it

The smallest area of a (possibly rotated) rectangle, n≤ 50, allows enumerating three vertices. With a right angle at p_1, the fourth corner is the vector sum of the two edges. The packed key x × 40001 + y repeats once a coordinate leaves [0, 4 × 10^4], and the sum of two squared edges exceeds 2^{31}-1. Inside that square the key is unique, and those squares fit in a 64-bit integer. The fourth corner is accepted only when both coordinates lie in range and the key is present. Squared edge lengths are accumulated in 64 bits before the square root.

We use a hash table to store all the points, then enumerate three points $p_1 = (x_1, y_1)$, $p_2 = (x_2, y_2)$, $p_3 = (x_3, y_3)$. If overrightarrowp_1p_2 and overrightarrowp_1p_3 are perpendicular, the fourth corner is $(x_4, y_4)=(x_2 - x_1 + x_3, y_2 - y_1 + y_3)$. Coordinates lie in [0, 4 × 10^4], and the packed key x × 40001 + y is unique only inside that square, so this corner counts only when both coordinates fall in range and the key is present. The squared edge lengths are summed in 64-bit integers, since each sum can exceed 2^{31}-1, and the area is the square root of their product.

Finally, if a rectangle that satisfies the conditions is found, return the minimum area among them. Otherwise, return 0.

The time complexity is $O(n^3)$ and the space complexity is O(n), where n is the length of the array points.

Python 3

```python
class Solution:
    def minAreaFreeRect(self, points: List[List[int]]) -> float:
        s = {(x, y) for x, y in points}
        n = len(points)
        ans = inf
        for i in range(n):
            x1, y1 = points[i]
            for j in range(n):
                if j != i:

1922. Count Good Numbers

Medium · Recursion, Math

leetcode.com/problems/count-good-numbers

★ **TOP 10 PROBLEM** in Maths / Geometry: master this one first

PROBLEM

A digit string is **good** if the digits **(0-indexed)** at **even** indices are **even** and the digits at **odd** indices are **prime** (`2`, `3`, `5`, or `7`).

- For example, `"2582"` is good because the digits (`2` and `8`) at even positions are even and the digits (`5` and `2`) at odd positions are prime. However, `"3245"` is **not** good because `3` is at an even index but is not even.

Given an integer `n`, return *the **total** number of good digit strings of length* `n`. Since the answer may be large, **return it modulo** $10^9 + 7$.

A **digit string** is a string consisting of digits `0` through `9` that may contain leading zeros.

Example 1:

```
Input: n = 1
Output: 5
Explanation: The good numbers of length 1 are "0", "2", "4", "6", "8".
```

Example 2:

```
Input: n = 4
Output: 400
```

Example 3:

```
Input: n = 50
Output: 564908303
```

Constraints:

- $1 <= n <= 10^{15}$

SOLUTION (PYTHON 3)

Solution 1: Fast Exponentiation

How to think about it

Even indices have 5 choices and odd indices have 4, independently. Looping $n \le 10^{15}$ times is impossible. The count is $5^{\text{ceil}(n/2)} \cdot 4^{\text{floor}(n/2)}$, evaluated with modular fast exponentiation in O(log n).

For a "good number" of length n, the even-indexed positions have ceil(n/2) = floor((n + 1)/2) digits, and these positions can be filled with 5 different digits (0, 2, 4, 6, 8). The odd-indexed positions have floor(n/2) digits, and these positions can be filled with 4 different digits (2, 3, 5, 7). Therefore, the total number of "good numbers" of length n is:

$$\text{ans} = 5^{\text{ceil}(n/2)} \times 4^{\text{floor}(n/2)}$$

We can use fast exponentiation to compute $5^{\text{ceil}(n/2)}$ and $4^{\text{floor}(n/2)}$. The time complexity is O(log n), and the space complexity is O(1).

Python 3

```python
class Solution:
    def countGoodNumbers(self, n: int) -> int:
        mod = 10**9 + 7
        return pow(5, (n + 1) >> 1, mod) * pow(4, n >> 1, mod) % mod
```

```

149. Max Points on a Line

Hard · Geometry, Array, Hash Table, Math, Greatest Common Divisor, Euclidean Algorithm

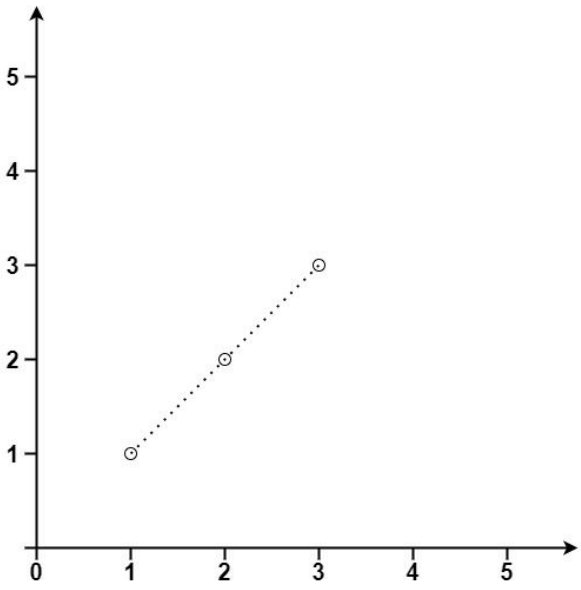
leetcode.com/problems/max-points-on-a-line

★ **TOP 10 PROBLEM** in Maths / Geometry: master this one first

PROBLEM

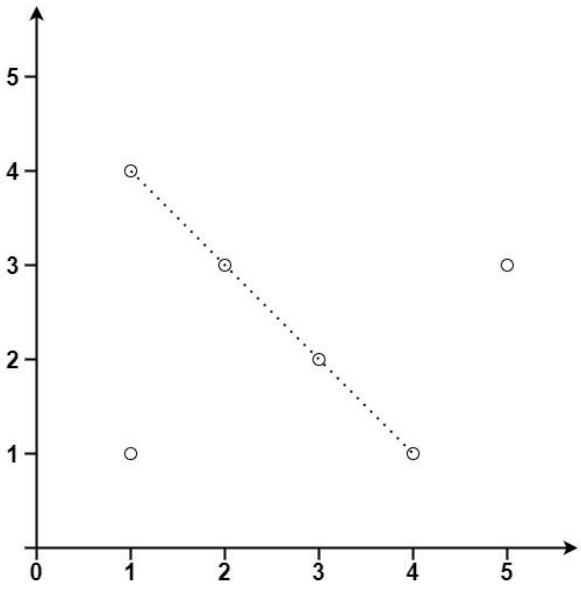
Given an array of `points` where `points[i] = [x_i, y_i]` represents a point on the **X-Y** plane, return *the maximum number of points that lie on the same straight line*.

Example 1:



```
Input: points = [[1,1],[2,2],[3,3]]
Output: 3
```

Example 2:



```
Input: points = [[1,1],[3,2],[5,3],[4,1],[2,3],[1,4]]
Output: 4
```

Constraints:

- `1 <= points.length <= 300`
- `points[i].length == 2`
- -10^4 `<=` x_i, y_i `<=` 10^4
- All the `points` are **unique**.

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

Maximum number of collinear points. Points are distinct and n is small. Enumerate two points to fix a line, then test the rest with a cross product so we never divide. $O(n^3)$ is acceptable.

Python 3

```python
class Solution:
    def maxPoints(self, points: List[List[int]]) -> int:
        n = len(points)
        ans = 1
        for i in range(n):
            x1, y1 = points[i]
            for j in range(i + 1, n):
                x2, y2 = points[j]
                cnt = 2
                for k in range(j + 1, n):
                    x3, y3 = points[k]
                    a = (y2 - y1) * (x3 - x1)
                    b = (y3 - y1) * (x2 - x1)
                    cnt += a == b
                ans = max(ans, cnt)
        return ans
```

Solution 2

How to think about it

Solution 1 is $O(n^3)$. Fix one point and group the others by slope; equal slopes are collinear. Store a reduced (Δ y,Δ x) pair as the key to avoid floats. O(n) work per point, $O(n^2)$ overall.

Python 3

```python
class Solution:
    def maxPoints(self, points: List[List[int]]) -> int:
        def gcd(a, b):
            return a if b == 0 else gcd(b, a % b)

        n = len(points)
        ans = 1
        for i in range(n):
            x1, y1 = points[i]
            cnt = Counter()
            for j in range(i + 1, n):
                x2, y2 = points[j]
                dx, dy = x2 - x1, y2 - y1
                g = gcd(dx, dy)
                k = (dx // g, dy // g)
                cnt[k] += 1
                ans = max(ans, cnt[k] + 1)
        return ans
```

PART 2 · STRING MATCHING · PROBLEM 1 OF 3

686. Repeated String Match

Medium · String, String Matching, KMP, Boyer–Moore, Extended KMP

leetcode.com/problems/repeated-string-match

★ **TOP 10 PROBLEM** in String Matching: master this one first

PROBLEM

Given two strings `a` and `b`, return *the minimum number of times you should repeat string* `a` *so that string* `b` *is a substring of it*. If it is impossible for `b` to be a substring of `a` after repeating it, return `-1`.

Notice: string `"abc"` repeated 0 times is `""`, repeated 1 time is `"abc"` and repeated 2 times is `"abcabc"`.

Example 1:

```
Input: a = "abcd", b = "cdabcdab"
Output: 3
Explanation: We return 3 because by repeating a three times "abcdabcdabcd", b is a substring of it.
```

Example 2:

```
Input: a = "a", b = "aa"
Output: 2
```

Constraints:

- `1 <= a.length, b.length <= 10^4`
- `a` and `b` consist of lowercase English letters.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

b must appear inside some repetition of a. At least ceil(|b|/|a|) copies are required, and a few extra copies cover a wrap-around match. Start from that lower bound and append a at most three more times. If `b` is a substring, return the count; otherwise -1.

Python 3

```python
class Solution:
    def repeatedStringMatch(self, a: str, b: str) -> int:
        m, n = len(a), len(b)
        ans = ceil(n / m)
        t = [a] * ans
        for _ in range(3):
            if b in ''.join(t):
                return ans
            ans += 1
            t.append(a)
        return -1
```

Complexity. Time: O(m + n). Space: O(m + n).

FOLLOW-UPS AN INTERVIEWER MAY ASK NEXT (CODE ONLY)

1698. Number of Distinct Substrings in a String

Medium · Trie, String, Suffix Array, Hash Function, Rolling Hash

leetcode.com/problems/number-of-distinct-substrings-in-a-string

★ **TOP 10 PROBLEM** in String Matching: master this one first

PROBLEM

Given a string `s`, return *the number of **distinct** substrings of* `s`.

A **substring** of a string is obtained by deleting any number of characters (possibly zero) from the front of the string and any number (possibly zero) from the back of the string.

Example 1:

```
Input: s = "aabbaba"
Output: 21
Explanation: The set of distinct strings is ["a","b","aa","bb","ab","ba","aab","abb","bab","bba","aba"
,"aabb","abba","bbab","baba","aabba","abbab","bbaba","aabbab","abbaba","aabbaba"]
```

Example 2:

```
Input: s = "abcdefg"
Output: 28
```

Constraints:

- `1 <= s.length <= 500`
- `s` consists of lowercase English letters.

Follow up:

Can you solve this problem in

`O(n)`

time complexity?

SOLUTIONS (PYTHON 3)

Solution 1: Brute Force Enumeration

How to think about it

Count distinct substrings. n is small, so put all $O(n^2)$ slices into a set. Slicing makes the time about $O(n^3)$, which is acceptable here.

Enumerate all substrings and use a hash table to record the count of different substrings.

The time complexity is $O(n^3)$, and the space complexity is $O(n^2)$. Here, n is the length of the string.

Python 3

```python
class Solution:
    def countDistinct(self, s: str) -> int:
        n = len(s)
        return len({s[i:j] for i in range(n) for j in range(i + 1, n + 1)})
```

Solution 2: String Hashing

> **How to think about it**
>
> Solution 1 compares whole slices. Polynomial hashes give any substring fingerprint in O(1); enumerating endpoints and storing hashes compares integers in $O(n^2)$.

String hashing is a method to map a string of any length to a non-negative integer, and the probability of collision is almost zero. String hashing is used to calculate the hash value of a string, which can quickly determine whether two strings are equal.

We take a fixed value BASE, treat the string as a number in BASE radix, and assign a value greater than 0 to represent each character. Generally, the values we assign are much smaller than BASE. For example, for a string composed of lowercase letters, we can set a=1, b=2, ..., z=26. We take a fixed value MOD, calculate the remainder of the BASE radix number to MOD, and use it as the hash value of the string.

Generally, we take BASE=131 or BASE=13331, at which point the probability of collision of the hash value is extremely low. As long as the hash values of two strings are the same, we consider the two strings to be equal. Usually, MOD is taken as 2^64. In C++, we can directly use the unsigned long long type to store this hash value. When calculating, we do not handle arithmetic overflow. When overflow occurs, it is equivalent to automatically taking the modulus of 2^64, which can avoid inefficient modulus operations.

Except for extremely specially constructed data, the above hash algorithm is unlikely to cause collisions. In general, the above hash algorithm can appear in the standard answer of the problem. We can also take some appropriate BASE and MOD values (such as large prime numbers), perform several groups of hash operations, and only consider the original strings equal when the results are all the same, making it even more difficult to construct data that causes this hash to produce errors.

The time complexity is $O(n^2)$, and the space complexity is $O(n^2)$. Here, n is the length of the string.

Python 3

```python
class Solution:
    def countDistinct(self, s: str) -> int:
        base = 131
        n = len(s)
        p = [0] * (n + 10)
        h = [0] * (n + 10)
        p[0] = 1
        for i, c in enumerate(s):
            p[i + 1] = p[i] * base
            h[i + 1] = h[i] * base + ord(c)
        ss = set()
        for i in range(1, n + 1):
            for j in range(i, n + 1):
                t = h[j] - h[i - 1] * p[j - i + 1]
                ss.add(t)
        return len(ss)
```

PART 2 · STRING MATCHING · PROBLEM 3 OF 3

1044. Longest Duplicate Substring

Hard · String, Binary Search, Suffix Array, Suffix Tree, Sliding Window, Hash Function, Rolling Hash, Boyer–Moore, Extended KMP, Suffix Automato

leetcode.com/problems/longest-duplicate-substring

★ **TOP 10 PROBLEM** in String Matching: master this one first

PROBLEM

Given a string `s`, consider all *duplicated substrings*: (contiguous) substrings of s that occur 2 or more times. The occurrences may overlap.

Return **any** duplicated substring that has the longest possible length. If `s` does not have a duplicated substring, the answer is `""`.

Example 1:

```
Input: s = "banana"
Output: "ana"
```

Example 2:

```
Input: s = "abcd"
Output: ""
```

Constraints:

- `2 <= s.length <= 3 * 10^4`
- `s` consists of lowercase English letters.

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Inserting every substring into a set is quadratic and fails for $n \leq 3 \times 10^4$. If a duplicate of length L exists, shorter duplicates exist as well, so length is monotonic. Binary search the length. The check inserts every slice of length mid into a set and returns on the first collision. A hit tries a longer length; a miss shortens it. The implementation uses ordinary Python slices and a hash set, remembering the last hit as the answer.

Python 3

```python
class Solution:
    def longestDupSubstring(self, s: str) -> str:
        def check(l: int) -> str:
            vis = set()
            for i in range(1, n - l + 2):
                j = i + l - 1
                t = h[j] - h[i - 1] * p[j - i + 1]
                if t in vis:
                    return s[i - 1 : j]
                vis.add(t)
            return ''

        base, n = 131, len(s)
        p = [0] * (n + 10)
        h = [0] * (n + 10)
        p[0] = 1
        for i, c in enumerate(s):
            p[i + 1] = p[i] * base
            h[i + 1] = h[i] * base + ord(c)
        left, right = 0, n
        ans = ''
        while left < right:
            mid = (left + right + 1) >> 1
            t = check(mid)
            if t:
                left = mid
                ans = t
            else:
                right = mid - 1
        return ans
```

Complexity. Time: O(n log n). Space: O(n).

leetcode.com/problems/range-sum-query-2d-mutable

★ **TOP 10 PROBLEM** in Binary Indexed Tree / Segment Tree: master this one first

PROBLEM

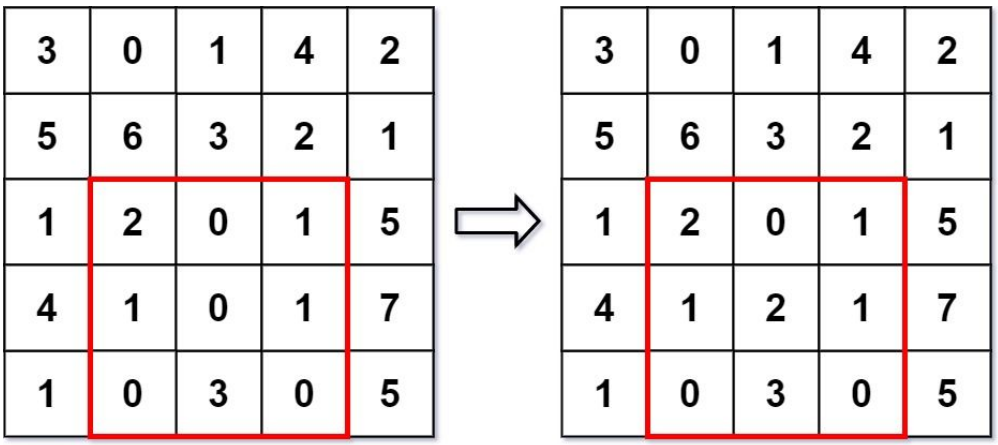
Given a 2D matrix `matrix`, handle multiple queries of the following types:

1. **Update** the value of a cell in `matrix`.
2. Calculate the **sum** of the elements of `matrix` inside the rectangle defined by its **upper left corner** `(row1, col1)` and **lower right corner** `(row2, col2)`.

Implement the NumMatrix class:

- `NumMatrix(int[][] matrix)` Initializes the object with the integer matrix `matrix`.
- `void update(int row, int col, int val)` **Updates** the value of `matrix[row][col]` to be `val`.
- `int sumRegion(int row1, int col1, int row2, int col2)` Returns the **sum** of the elements of `matrix` inside the rectangle defined by its **upper left corner** `(row1, col1)` and **lower right corner** `(row2, col2)`.

Example 1:



```
Input
["NumMatrix", "sumRegion", "update", "sumRegion"]
[[[[3, 0, 1, 4, 2], [5, 6, 3, 2, 1], [1, 2, 0, 1, 5], [4, 1, 0, 1, 7], [1, 0, 3, 0, 5]]], [2, 1, 4, 3],
[3, 2, 2], [2, 1, 4, 3]]
Output
[null, 8, null, 10]

Explanation
NumMatrix numMatrix = new NumMatrix([[3, 0, 1, 4, 2], [5, 6, 3, 2, 1], [1, 2, 0, 1, 5], [4, 1, 0, 1,
7], [1, 0, 3, 0, 5]]);
numMatrix.sumRegion(2, 1, 4, 3); // return 8 (i.e. sum of the left red rectangle)
numMatrix.update(3, 2, 2); // matrix changes from left image to right image
numMatrix.sumRegion(2, 1, 4, 3); // return 10 (i.e. sum of the right red rectangle)
```

Constraints:

- `m == matrix.length`
- `n == matrix[i].length`
- `1 <= m, n <= 200`
- `-1000 <= matrix[i][j] <= 1000`
- `0 <= row < m`

- `0 <= col < n`
- `-1000 <= val <= 1000`
- `0 <= row1 <= row2 < m`
- `0 <= col1 <= col2 < n`
- At most `5000` calls will be made to `sumRegion` and `update`.

SOLUTIONS (PYTHON 3)

Solution 1

How to think about it

The matrix needs both point updates and sub-rectangle sums. Scanning a rectangle per query, or rebuilding a 2D prefix after every write, cannot keep both cheap. The code builds one Fenwick tree per row: a row range is a prefix difference, then those rows in [row1,row2] are added. An update touches only that row. With a modest number of rows this is simpler than a true 2D Fenwick tree.

Python 3

```python
class BinaryIndexedTree:
    def __init__(self, n):
        self.n = n
        self.c = [0] * (n + 1)

    @staticmethod
    def lowbit(x):
        return x & -x

    def update(self, x, delta):
        while x <= self.n:
            self.c[x] += delta
            x += BinaryIndexedTree.lowbit(x)

    def query(self, x):
        s = 0
        while x > 0:
            s += self.c[x]
            x -= BinaryIndexedTree.lowbit(x)
        return s

class NumMatrix:
    def __init__(self, matrix: List[List[int]]):
        self.trees = []
        n = len(matrix[0])
        for row in matrix:
            tree = BinaryIndexedTree(n)
            for j, v in enumerate(row):
                tree.update(j + 1, v)
            self.trees.append(tree)

    def update(self, row: int, col: int, val: int) -> None:
        tree = self.trees[row]
        prev = tree.query(col + 1) - tree.query(col)
        tree.update(col + 1, val - prev)

    def sumRegion(self, row1: int, col1: int, row2: int, col2: int) -> int:
        return sum(
            tree.query(col2 + 1) - tree.query(col1)
            for tree in self.trees[row1 : row2 + 1]
        )

# Your NumMatrix object will be instantiated and called as such:
# obj = NumMatrix(matrix)
# obj.update(row,col,val)
# param_2 = obj.sumRegion(row1,col1,row2,col2)
```

Complexity. Time: build O(m * n log n), update O(log n), sumRegion O(m log n). Space: O(m * n).

Solution 2

> **How to think about it**
>
> Method 1 still walks every involved row. Replacing each Fenwick tree with a segment tree keeps point updates and in-row ranges at O(log n) with the same meaning. A sub-rectangle is still the sum of per-row interval sums. Explicit interval nodes make the column-range aggregation easier to read.

Python 3

```
class Node:
    def __init__(self):
        self.l = 0
        self.r = 0
        self.v = 0

class SegmentTree:
    def __init__(self, nums):
        n = len(nums)
        self.nums = nums
        self.tr = [Node() for _ in range(4 * n)]
        self.build(1, 1, n)

    def build(self, u, l, r):
        self.tr[u].l = l
        self.tr[u].r = r
        if l == r:
            self.tr[u].v = self.nums[l - 1]
            return
        mid = (l + r) >> 1
        self.build(u << 1, l, mid)
        self.build(u << 1 | 1, mid + 1, r)
        self.pushup(u)

    def modify(self, u, x, v):
        if self.tr[u].l == x and self.tr[u].r == x:
            self.tr[u].v = v
            return
        mid = (self.tr[u].l + self.tr[u].r) >> 1
        if x <= mid:
            self.modify(u << 1, x, v)
        else:
            self.modify(u << 1 | 1, x, v)
        self.pushup(u)

    def query(self, u, l, r):
        if self.tr[u].l >= l and self.tr[u].r <= r:
            return self.tr[u].v
        mid = (self.tr[u].l + self.tr[u].r) >> 1
        v = 0
        if l <= mid:
            v += self.query(u << 1, l, r)
        if r > mid:
            v += self.query(u << 1 | 1, l, r)
        return v

    def pushup(self, u):
        self.tr[u].v = self.tr[u << 1].v + self.tr[u << 1 | 1].v

class NumMatrix:
    def __init__(self, matrix: List[List[int]]):
        self.trees = [SegmentTree(row) for row in matrix]

    def update(self, row: int, col: int, val: int) -> None:
        tree = self.trees[row]

3161. Block Placement Queries

Hard · Binary Indexed Tree, Segment Tree, Array, Binary Search, Ordered Set

leetcode.com/problems/block-placement-queries

★ **TOP 10 PROBLEM** in Binary Indexed Tree / Segment Tree: master this one first

PROBLEM

There exists an infinite number line, with its origin at 0 and extending towards the **positive** x-axis.

You are given a 2D array `queries`, which contains two types of queries:

1. For a query of type 1, `queries[i] = [1, x]`. Build an obstacle at distance `x` from the origin. It is guaranteed that there is **no** obstacle at distance `x` when the query is asked.
2. For a query of type 2, `queries[i] = [2, x, sz]`. Check if it is possible to place a block of size `sz` *anywhere* in the range `[0, x]` on the line, such that the block **entirely** lies in the range `[0, x]`. A block **cannot** be placed if it intersects with any obstacle, but it may touch it. Note that you do **not** actually place the block. Queries are separate.

Return a boolean array `results`, where `results[i]` is `true` if you can place the block specified in the i^{th} query of type 2, and `false` otherwise.

Example 1:

Input: queries = [[1,2],[2,3,3],[2,3,1],[2,2,2]]

Output: [false,true,true]

Explanation:

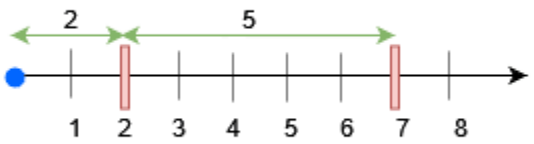
For query 0, place an obstacle at `x = 2`. A block of size at most 2 can be placed before `x = 3`.

Example 2:

Input: queries = [[1,7],[2,7,6],[1,2],[2,7,5],[2,7,6]] notionvc: 4a471445-5af1-4d72-b11b-94d351a2c8e9

Output: [true,true,false]

Explanation:



- Place an obstacle at `x = 7` for query 0. A block of size at most 7 can be placed before `x = 7`.
- Place an obstacle at `x = 2` for query 2. Now, a block of size at most 5 can be placed before `x = 7`, and a block of size at most 2 before `x = 2`.

Constraints:

- `1 <= queries.length <= 15 * 10^4`

- `2 <= queries[i].length <= 3`
- `1 <= queries[i][0] <= 2`
- `1 <= x, sz <= min(5 * 10^4, 3 * queries.length)`
- The input is generated such that for queries of type 1, no obstacle exists at distance `x` when the query is asked.
- The input is generated such that there is at least one query of type 2.

SOLUTION (PYTHON 3)

Solution 1: Binary Indexed Tree + Ordered Set

> **How to think about it**
>
> Obstacles are inserted only, and a query asks whether a block of size sz fits in [0,x]. Scanning gaps online is $O(q^2)$. Reversed time turns insertions into deletions, which only enlarge gaps. A Fenwick tree can store prefix maxima of gap lengths keyed by the right endpoint. Load every obstacle plus sentinels, write gaps, then go backward: a query checks the prefix maximum up to pre and the tail x-pre; a deletion updates the successor gap to nxt-pre. Reverse the collected answers.

Obstacles are only inserted, so we can process the queries offline in reverse and turn "insert an obstacle" into "delete an obstacle". After a deletion the adjacent gap only grows, and a Fenwick tree can maintain prefix maxima.

Put all obstacles into an ordered set, and add sentinels 0 and m+1, where m is the maximum coordinate. For every pair of neighboring obstacles x_1, x_2, update index x_2 in the Fenwick tree with the gap $x_2 - x_1$.

Then scan the queries from back to front:

- Type 2: find the last obstacle pre ≤ x. The block can be placed if the maximum gap in [0, pre] or the tail gap (pre, x] is at least sz.
- Type 1: delete obstacle x, and update the gap at its successor nxt to nxt - pre.

The time complexity is O(q × log m), and the space complexity is O(m), where q is the number of queries and m is the maximum coordinate.

Python 3

```
class BinaryIndexedTree:
    def __init__(self, n: int):
        self.n = n
        self.c = [0] * (n + 1)

    def update(self, x: int, v: int):
        while x <= self.n:
            self.c[x] = max(self.c[x], v)
            x += x & -x

    def query(self, x: int) -> int:
        mx = 0
        while x:
            mx = max(mx, self.c[x])
            x -= x & -x
        return mx

class Solution:
    def getResults(self, queries: List[List[int]]) -> List[bool]:
        m = max(q[1] for q in queries)
        sl = SortedList([0, m + 1])
        for q in queries:
            if q[0] == 1:
                sl.add(q[1])
        tree = BinaryIndexedTree(m + 1)
        for x1, x2 in pairwise(sl):
            tree.update(x2, x2 - x1)
        ans = []
        for q in reversed(queries):
            x = q[1]
            if q[0] == 1:
                i = sl.index(x)
                tree.update(sl[i + 1], sl[i + 1] - sl[i - 1])
                sl.remove(x)
            else:
                i = sl.bisect_right(x)
                pre = sl[i - 1]
                ans.append(tree.query(pre) >= q[2] or x - pre >= q[2])
        return ans[::-1]
```

3721. Longest Balanced Subarray II

Hard · Segment Tree, Array, Hash Table, Divide and Conquer, Prefix Sum

leetcode.com/problems/longest-balanced-subarray-ii

★ **TOP 10 PROBLEM** in Binary Indexed Tree / Segment Tree: master this one first

PROBLEM

You are given an integer array `nums`.

A **subarray** is called **balanced** if the number of **distinct even** numbers in the subarray is equal to the number of **distinct odd** numbers.

Return the length of the **longest** balanced subarray.

Example 1:

Input: nums = [2,5,4,3]

Output: 4

Explanation:

- The longest balanced subarray is `[2, 5, 4, 3]`.
- It has 2 distinct even numbers `[2, 4]` and 2 distinct odd numbers `[5, 3]`. Thus, the answer is 4.

Example 2:

Input: nums = [3,2,2,5,4]

Output: 5

Explanation:

- The longest balanced subarray is `[3, 2, 2, 5, 4]`.
- It has 2 distinct even numbers `[2, 4]` and 2 distinct odd numbers `[3, 5]`. Thus, the answer is 5.

Example 3:

Input: nums = [1,2,3,2]

Output: 3

Explanation:

- The longest balanced subarray is `[2, 3, 2]`.
- It has 1 distinct even number `[2]` and 1 distinct odd number `[3]`. Thus, the answer is 3.

Constraints:

- `1 <= nums.length <= 10^5`
- `1 <= nums[i] <= 10^5`

SOLUTION (PYTHON 3)

Solution 1: Segment Tree + Prefix Sum + Hash Table

How to think about it

The quadratic scan of the previous problem does not scale. Mapping odds to +1 and evens to -1, balance becomes a zero-sum segment; a repeated value must undo its earlier contribution. Those updates are range adds, and we query the earliest prefix equal to the current sum, which a segment tree with min/max and lazy tags supports.

We can transform the problem into a prefix sum problem. Define a prefix sum variable now, representing the difference between odd and even numbers in the current subarray:

now = distinct odd numbers - distinct even numbers

For odd elements, record as +1, and for even elements, record as -1. Use a hash table last to record the last occurrence position of each number. If a number appears repeatedly, we need to revoke its previous contribution.

To efficiently calculate the subarray length each time a right endpoint element is added, we use a segment tree to maintain the minimum and maximum values of the interval prefix sum, while supporting interval addition operations and binary search queries on the segment tree. When iterating to right endpoint i, first update the contribution of the current element, then use the segment tree to query the earliest position pos where the current prefix sum now appears. The current subarray length is i - pos, and we update the answer:

$$\text{ans} = \max(\text{ans}, i - \text{pos})$$

The time complexity is O(n log n), where n is the length of the array. Each segment tree modification and query operation takes O(log n), and enumerating the right endpoint n times gives a total time complexity of O(n log n). The space complexity is O(n), where segment tree nodes and the hash table each occupy O(n) space.

Python 3

```python
class Solution:
    def longestBalanced(self, nums: List[int]) -> int:
        n = len(nums)

        class Node:
            __slots__ = ("l", "r", "mn", "mx", "lazy")
            def __init__(self):
                self.l = self.r = 0
                self.mn = self.mx = 0
                self.lazy = 0

        tr = [Node() for _ in range((n + 1) * 4)]

        def build(u: int, l: int, r: int):
            tr[u].l, tr[u].r = l, r
            tr[u].mn = tr[u].mx = tr[u].lazy = 0
            if l == r:
                return
            mid = (l + r) >> 1
            build(u << 1, l, mid)
            build(u << 1 | 1, mid + 1, r)

        def apply(u: int, v: int):
            tr[u].mn += v
            tr[u].mx += v
            tr[u].lazy += v

        def pushdown(u: int):
            if tr[u].lazy:
                apply(u << 1, tr[u].lazy)
                apply(u << 1 | 1, tr[u].lazy)
                tr[u].lazy = 0

        def pushup(u: int):
            tr[u].mn = min(tr[u << 1].mn, tr[u << 1 | 1].mn)
            tr[u].mx = max(tr[u << 1].mx, tr[u << 1 | 1].mx)

        def modify(u: int, l: int, r: int, v: int):
            if tr[u].l >= l and tr[u].r <= r:
                apply(u, v)
                return
            pushdown(u)
            mid = (tr[u].l + tr[u].r) >> 1
            if l <= mid:
                modify(u << 1, l, r, v)
            if r > mid:
                modify(u << 1 | 1, l, r, v)
            pushup(u)

        def query(u: int, target: int) -> int:
            if tr[u].l == tr[u].r:
                return tr[u].l
            pushdown(u)
            if tr[u << 1].mn <= target <= tr[u << 1].mx:
                return query(u << 1, target)
            return query(u << 1 | 1, target)

        build(1, 0, n)

        last = {}
        now = ans = 0

        for i, x in enumerate(nums, start=1):
            det = 1 if (x & 1) else -1
            if x in last:
                modify(1, last[x], n, -det)
```

```
                now -= det
            last[x] = i
            modify(1, i, n, det)
            now += det
            pos = query(1, now)
            ans = max(ans, i - pos)

        return ans
```

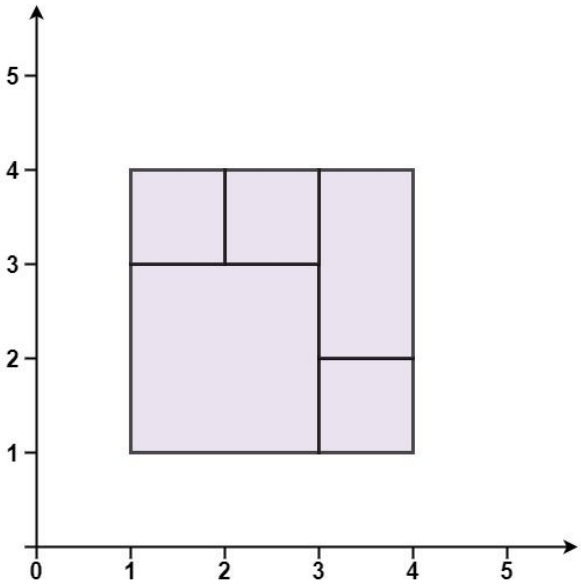
★ **TOP 10 PROBLEM** in Line Sweep: master this one first

PROBLEM

Given an array `rectangles` where `rectangles[i] = [x_i, y_i, a_i, b_i]` represents an axis-aligned rectangle. The bottom-left point of the rectangle is `(x_i, y_i)` and the top-right point of it is `(a_i, b_i)`.

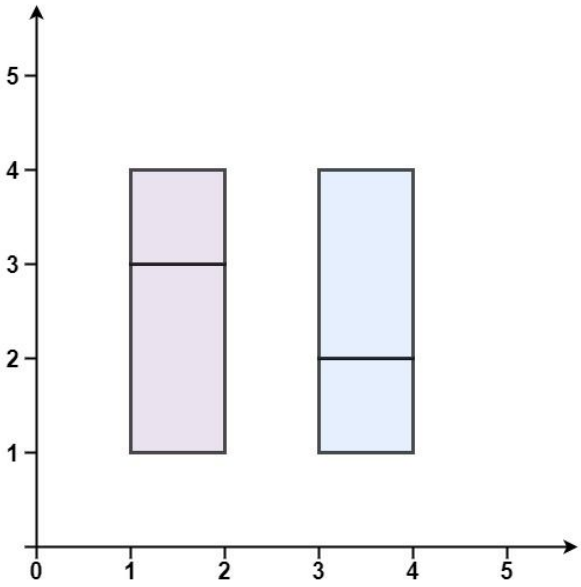
Return `true` *if all the rectangles together form an exact cover of a rectangular region*.

Example 1:



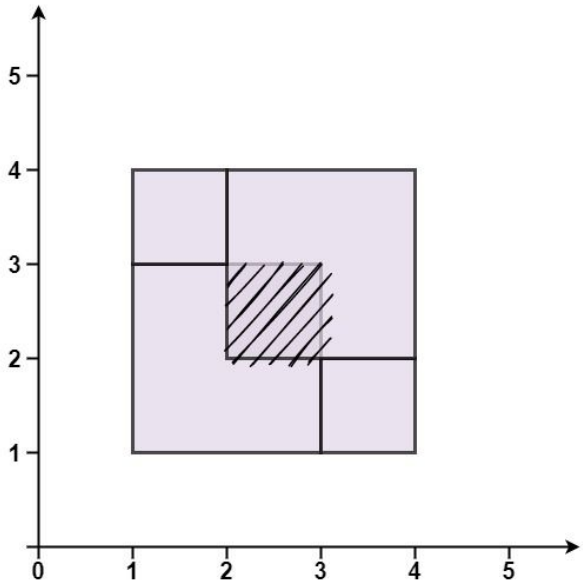
```
Input: rectangles = [[1,1,3,3],[3,1,4,2],[3,2,4,4],[1,3,2,4],[2,3,3,4]]
Output: true
Explanation: All 5 rectangles together form an exact cover of a rectangular region.
```

Example 2:



```
Input: rectangles = [[1,1,2,3],[1,3,2,4],[3,1,4,2],[3,2,4,4]]
Output: false
Explanation: Because there is a gap between the two rectangular regions.
```

Example 3:



```
Input: rectangles = [[1,1,3,3],[3,1,4,2],[1,3,2,4],[2,2,4,4]]
Output: false
Explanation: Because two of the rectangles overlap with each other.
```

Constraints:

- $1 <= rectangles.length <= 2 * 10^4$
- $rectangles[i].length == 4$
- $-10^5 <= x_i < a_i <= 10^5$
- $-10^5 <= y_i < b_i <= 10^5$

SOLUTION (PYTHON 3)

Solution 1

How to think about it

Can the small rectangles tile a large one without gaps or overlaps? Sweep lines are heavy. A perfect cover has equal area, and every vertex except the four outer corners appears an even number of times (2 or 4). Sum areas and count vertices. The bounding-box corners must appear once; every other vertex 2 or 4 times; area equals the bounding box.

Python 3

```python
class Solution:
    def isRectangleCover(self, rectangles: List[List[int]]) -> bool:
        area = 0
        minX, minY = rectangles[0][0], rectangles[0][1]
        maxX, maxY = rectangles[0][2], rectangles[0][3]
        cnt = defaultdict(int)

        for r in rectangles:
            area += (r[2] - r[0]) * (r[3] - r[1])

            minX = min(minX, r[0])
            minY = min(minY, r[1])
            maxX = max(maxX, r[2])
            maxY = max(maxY, r[3])

            cnt[(r[0], r[1])] += 1
            cnt[(r[0], r[3])] += 1
            cnt[(r[2], r[3])] += 1
            cnt[(r[2], r[1])] += 1

        if (
            area != (maxX - minX) * (maxY - minY)
            or cnt[(minX, minY)] != 1
            or cnt[(minX, maxY)] != 1
            or cnt[(maxX, maxY)] != 1
            or cnt[(maxX, minY)] != 1
        ):
            return False

        del cnt[(minX, minY)], cnt[(minX, maxY)], cnt[(maxX, maxY)], cnt[(maxX, minY)]

        return all(c == 2 or c == 4 for c in cnt.values())
```

Complexity. Time: O(n). Space: O(n).
